FIG. 4. (a) X-ray absorption spectra for Ti *K* edge in two TiO$_2$-containing silicate glasses, together with that for crystalline rutile for comparison (Greegor *et al.*, 1983). (b) Schematic illustration of the process leading to EXAFS. An atom (solid circle) absorbing an x-ray photon creates an outgoing photoelectron wave which backscatters off neighboring atoms (hatched circles). Interference between outgoing and backscattered electron waves results in the fine-structure oscillations in the x-ray absorption coefficient.

The physical origin of the postedge fine structure is illustrated in Fig. 4(b). The photoelectron created upon the absorption of an x-ray photon by a particular atom propagates outwards and is backscattered from the surrounding atoms; interference between outgoing and backscattered electron waves causes a modulation of the x-ray absorption coefficient with increasing photon energy and hence increasing photoelectron kinetic energy. The periodicity of the EXAFS oscillations is therefore clearly determined by the interatomic spacing. The origin of the XANES oscillations (up to ~50 eV from the edge) differs somewhat from that for EXAFS; multiple-scattering events characterize XANES, whereas only single-scattering processes are involved in EXAFS (in this regard EXAFS and diffraction are similar, yielding only information concerning *pair-correlation* functions. The origin of the pre-edge structure is rather different: core-level electrons are photoexcited into low-lying bound states of the atom (e.g., *d* levels in transition metals). XAS is clearly an atom-specific structural probe since each element has x-ray absorption edges at different energies.

XAS measurements may be performed in a number of ways. The x-ray absorption coefficient $\mu(E)$ may be measured directly by monitoring the transmission of the x-ray beam through the sample. Alternatively, $\mu(E)$ may be measured *indirectly* by monitoring the recombination processes of the photocreated core hole, either radiatively (via x-ray fluorescence) for heavy atoms, or nonradiatively (via Auger electron emission) for lighter atoms. The XANES or EXAFS amplitude is obtained from the measured x-ray absorption coefficient by subtracting the background absorption μ_0 and normalizing to it, viz.,

$$\chi(E)=\frac{\mu(E)-\mu_0(E)}{\mu_0(E)}. \tag{19}$$

The multiple scattering inherent in XANES precludes a simple theoretical treatment and an analytic expression for the XANES amplitude (Durham *et al.*, 1981). On the other hand, the single-scattering processes characteristic of EXAFS, together with the fact that the plane-wave approximation can be invoked for photon energies $\geqslant 100$ eV from the edge, means that an analytic expression for the EXAFS amplitude $\chi(k)$ can be obtained (Sayers *et al.*, 1971), namely,

$$\begin{aligned}\chi(k)=\sum_j &\frac{|f_j(\pi)|}{k}\exp(-2R_j/\lambda)\\ &\times\exp(-2\sigma_j^2 k^2)\\ &\times\sin[2kR_j+2\delta(k)+\eta(k)],\end{aligned} \tag{20}$$

where the photoelectron wave vector k is defined as

$$k=\frac{2\pi}{\lambda}=[2m_e(E-E_0)/\hbar^2]^{1/2}, \tag{21}$$

and where m_e is the electron mass and E_0 the photoelectron threshold (absorption edge). [Note that k for EXAFS is *half* that for diffraction; cf. Eq. (5).] In Eq. (20), the summation is taken over all shells of atoms j surrounding the absorbing atom, with N_j being the coordination number, R_j the interatomic distance, and σ_j its rms fluctuation characterizing each shell. The EXAFS amplitude is also determined by the backscattering amplitude $f_j(\pi)$ of atoms j, and is damped by two terms, one a Debye–Waller factor involving σ_j, and the other a term accounting for inelastic losses of the photoelectron where λ is the electronic mean free path. Finally, the EXAFS oscillations arise from the sine term in Eq. (20) reflecting the interference processes, the argument of which depends on the phase shift associated with the passage of the photoelectron to the backscattering atom and back, as well as the phase shifts suffered by the photoelectron traversing the emitter potential and scattering off the backscatterer potential.

The advantages of XAS as a structural tool for amorphous solids lie in its atom specificity, the sensitivity to dilute components (if fluorescence detection is used), the accuracy with which bond lengths can be measured, the sensitivity to symmetrical environments (particularly in the case of pre-edge structure), the ability to investigate the surface structure by means of glancing-angle techniques, and the possibility to undertake time-resolved studies by utilizing the pulsed nature of synchrotron radiation and using energy-dispersed detection. There are considerable disadvantages as well, however. Foremost amongst these is the fact that EXAFS is only sensitive to the very local structural order in an amorphous solid, principally the first coordination shell; higher-lying shells in noncrystalline materials have increasingly large amounts of static disorder and correspondingly their contribution to the EXAFS amplitude becomes increasingly damped [cf. Eq. (20)] and confined to values of k for which the single-scattering EXAFS formalism is invalid. Furthermore, the uncertainties in the value of coordination numbers resulting from fitting EXAFS data are rather large.

2.3 Nuclear Resonance Techniques

Two nuclear resonance techniques can be used to provide structural information on amorphous solids—these are nuclear magnetic resonance and Mössbauer spectroscopies, which by their very nature are atom specific. However, they both suffer the disadvantage that not all nuclei are amenable to investigation in this way. Moreover, since NMR is far more widely used and is applicable to a wider range of nuclei than is the case for Mössbauer spectroscopy, only NMR will be discussed further.

2.3.1 Nuclear Magnetic Resonance. NMR is the resonant excitation by rf photons of the magnetic-field-split Zeeman levels of the nucleus (see MAGNETIC RESONANCE, NUCLEAR). Early work used cw spectrometers, in which the rf frequency was fixed and the magnetic field was varied to establish the resonance condition (see, e.g., Bray, 1978). The field has been rejuvenated following the introduction of modern Fourier-transform NMR spectrometers, in which the magnetic field is kept fixed, and the frequency effectively swept by the use of pulses of rf power containing many Fourier components. This approach has the advantage that the signal-to-noise ratio can be greatly improved by the repeated application of pulses and the use of signal averaging; moreover, particular pulse sequences can be used to eliminate the effect of certain interactions involving the nuclear spins which serve to broaden the resonance lines.

Further significant progress in the use of NMR to study solids, particularly amorphous materials, has come through the use of the "magic-angle spinning" (MAS) technique combined with Fourier-transform spectrometers (Andrew, 1981). In nonmetallic systems, it is the chemical-shift interaction, in which the external magnetic field is partially shielded from the nuclear spins by the electronic charge distribution in the atoms, that mainly carries the structural information. However, other interactions involving the nuclear spins, e.g., dipolar and quadrupolar, can broaden the resonance lines of solids so much that their position and shape are no longer discernible; the same effect can also arise from the chemical-shift interaction itself in the case when the resonant nucleus is at a very nonsymmetrical structural site. All these broadening effects can be reduced to a greater or lesser extent by the use of the MAS technique, in which the sample is rotated at a high frequency (usually 1–10 kHz), comparable to the strength of the interaction which it is desired to remove, at an angle θ to the external magnetic field. In this case, it is found that the Hamiltonian for all interactions (but only to first order for the quadrupolar interaction) is multiplied by the factor (Andrew, 1981):

$$\beta=(3\cos^2\theta-1). \tag{22}$$

Thus, spinning the sample at the "magic angle" $\theta=54°44'$ ($=\cos^{-1}1/\surd 3$) means that the factor β vanishes, with the result that the line-broadening interactions are removed, and a previously broad line collapses to a single narrow line situated at the isotropic value of the chemical shift tensor, viz., $\sigma_i=\frac{1}{3}\operatorname{Tr}(\sigma)$, exactly as in liquid-state NMR where the improved resolution arises from the isotropic thermal rotational motion of the molecules in the liquid.

NMR is a powerful atom-specific structural probe, being particularly sensitive to the symmetry of sites and the coordination thereof, and often also sensitive to dilute components. However, it does have a number of disadvantages, principal among which is the fact that relatively few nuclei are NMR-active, and of these the natural abundance or sensitivity may be very low. Furthermore, *direct* structural information is mostly not obtainable from NMR spectra, although coordination-number information can sometimes be deduced by a "fingerprinting" process, namely, by comparison of the unknown (amorphous) NMR spectrum with that for a (crystalline) standard whose structure is known. In some cases, direct structural information can be obtained, e.g., in the case of glassy silicates. The ^{29}Si MASNMR spectra of various crystalline polymorphs of SiO_2 exhibit a systematic variation of chemical shift with oxygen bond angle θ, obeying the empirical relation (Smith and Blackwell, 1983)

$$\sigma=a+b\sec\theta. \tag{23}$$

Assuming that the same relation holds for the *continuous* distribution of oxygen bond angles in vitreous SiO_2 resulting from the static disorder which is present, Eq. (23) can be used to convert the observed ^{29}Si NMR line shape into a bond-angle distribution (Dupree and Pettifor, 1984; Gladden *et al.*, 1986).

An additional limitation to the applicability of the MASNMR technique to (amorphous) solids is in the case of *quadrupolar* nuclei (those for which the nuclear spin is $\geqslant 1$), where magic-angle spinning only removes the first-order broadening effects of the interaction; if the nuclear quadrupolar moment is very large, little resolution enhancement of lines is achievable using MAS, and the existence of a multiplicity of structural sites with different chemical shifts can therefore be obscured. In this regard, the very recent advance of double sample rotation (Samoson *et al.*, 1988) holds out considerable promise. In this, the sample is rotated about *two* axes simultaneously, one being at the magic angle, and in this way second-order quadrupolar broadening effects can be removed as well. Although significant increases in the resolution of NMR spectra of quadrupolar nuclei in crystalline materials have been achieved (Chmelka *et al.*, 1989), as yet the technique has not been applied to the study of amorphous materials.

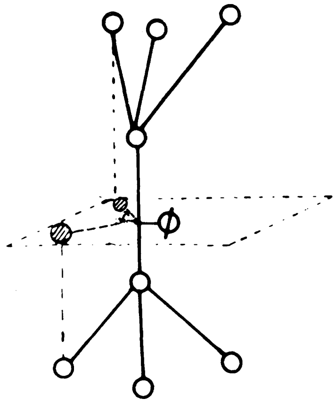

FIG. 5. Definition of dihedral (or torsion) angle ϕ for a covalently bonded material.

3. STRUCTURAL MODELING

It should be apparent from the above discussion that in the determination of the structure of amorphous solids, the use of experimental probes alone is insufficient, since only a rather limited amount of structural information can be obtained unambiguously in this way. An essential complementary activity, therefore, is to undertake modeling studies in which the structure of an amorphous material is simulated theoretically, using as input the limited amount of structural information (usually concerning SRO) available from experiment.

The cause of nonperiodicity in solids can be different depending on whether directional (covalent) or spherically symmetric (e.g., metallic) bonding is involved. For the case of *covalent* materials, it seems to be the case that amorphous structures arise as a result of a plethora of bonding configurations being available, which therefore allow crystallization to be bypassed. In other words, topological disorder results from the presence of a (quasi-)random distribution of dihedral (or torsion) angles, viz., the relative angles of rotation about a common bond to bring two neighboring structural units into coincidence (see Fig. 5). In addition, some static disorder in the bond-angle distribution $P(\theta)$ is also necessary to ensure complete connectivity (i.e., no dangling bonds) within the interior of such a disordered covalent structure. The ideal amorphous structure conforming to this picture is the "continuous random network" (CRN), first proposed by Zachariasen (1932).

In the case of amorphous metallic, molecular, or ionic systems, where central forces (metallic, van der Waals, or electrostatic, respectively) are predominant, other factors may influence glass formation, principal among which is that of "frustration." Small clusters of equally sized atoms tend to have noncrystallographic configurations as the lowest-energy structures, e.g., containing fivefold symmetry elements such as in the dodecagonal icosahedron, and aggregates of such clusters (for example, present in the liquid state) cannot form three-dimensional translationally periodic structures (i.e., crystals) on cooling. The ideal amorphous structure pertaining to this situation is thus the "dense random packing" (DRP) of spheres, first advanced by Bernal (1959, 1964).

A considerable number of modeling studies of the structure of amorphous materials have been performed for systems containing variously covalent, van der Waals, ionic, and metallic interactions. Furthermore, a variety of modeling techniques have been employed in such studies, the most important of which will be summarized below.

3.1 Serial-Addition Models

One of the conceptually most simple methods of constructing noncrystalline models is by the method of serial addition of atoms to an aperiodic seed. This approach has been followed in numerous studies involving the construction of hand-built models, following the pioneering work on covalent materials by Polk (1971) for the case of *a*-Ge and Bell and Dean (1972) for the case of *v*-SiO_2, and in the case of metallic (or other central-force systems) by Bernal (1959, 1964) and Finney

(1970). [For a review of such models, see Elliott (1984).] This adatom-by-adatom construction technique can also be achieved using computer algorithms, as in the work by Bennett (1972) on amorphous metallic systems, or that by Gladden and Elliott (1987, 1989) for covalent systems (for *v*-$SiSe_2$) and Gladden (1989) for *v*-SiO_2. The difficulty with the use of computers in constructing structural models in this way is to ensure that the resulting model has a sufficiently large density (and in the case of covalent systems a low concentration of dangling-bond defects).

3.2 Monte Carlo Methods

At the other extreme from the serial-addition method is the Monte Carlo technique, in which an existing structure (usually a crystalline polymorph of the material in question) is progressively disordered by a series of suitable randomization steps, involving, say, bond-switching for covalent structures. An example of this procedure is that used to generate the "sillium" model for *a*-Si starting from the diamondlike crystalline silicon lattice (Wooten and Weaire, 1984), and that employed in the simulation studies of the same system by Beeman and Bobbs (1975) in which the starting structure used was the even-ring tetrahedrally coordinated CRN model of Connell and Temkin (1974), and varying proportions of odd-membered rings were introduced by Monte Carlo means.

3.3 Molecular Dynamics

Potentially, the most physically realistic method of simulating the structure of amorphous solids is by using the molecular dynamics (MD) technique. In this, the time evolution of the classical motion of a collection of atoms (or molecules), interacting by means of a given interatomic potential, is calculated as a function of a change in temperature (or some other thermodynamic variable). A computer "liquid" is first generated by raising the temperature of a starting configuration of atoms, usually having a crystalline structure, confined within a box having periodic boundary conditions. A "glassy" structure can then be created by rapidly decreasing the temperature of the system. Attractive though this approach is in principle, in practice it suffers from a number of disadvantages insofar as the study of the properties and structure of amorphous solids (rather than of liquids) is concerned. One major limitation is the unavoidably very high rate of cooling ($>10^{10}$ K s^{-1}) characteristic of MD simulations; these values are essentially dictated by the minimum duration of the time step for a given configuration for which the simulation must be run ($\sim 10^{-15}$ s) and economic constraints on the total amount of computer time available. It is relatively easy to perform MD simulations using nondirectional (e.g., ionic or van der Waals) interactions, and a number of appropriate glass-forming systems have been simulated in this way (see, e.g., Angell *et al.*, 1977). However, such spherically symmetric (ionic) potentials are inappropriate for use in simulating the structure of network glasses in which covalency effects play a significant role. It is only very recently that three-body bond-bending terms have been included in the interatomic potential in an attempt to account for covalent interactions, as, for example, in *v*-SiO_2 (Feuston and Garofalini, 1988).

4. EXAMPLES OF THE STRUCTURE OF AMORPHOUS MATERIALS

In this section we will discuss the salient features of the structure of some important representative families of amorphous materials in the light of the preceding discussion of experimental and theoretical techniques for structure determination.

4.1 Amorphous Hydrogenated Silicon

By far the most important member of the family of amorphous tetrahedrally coordinated materials is hydrogenated silicon, *a*-Si:H, deposited in thin-film form by various chemical-vapor-deposition techniques from silane. The importance of *a*-Si:H lies in its various technological applications, arising from the fact that it can be doped electrically *p*- or *n*-type. Problems relating to the atomic structure of this material may be divided into three categories: those relating to the structure of the Si framework, those concerned with the H sublattice, and those relating to the structural environment of other alloying elements (e.g., C, Ge, or N) and dopants (e.g., P, B). An extensive review of recent structural investigations of *a*-Si:H has been given by Elliott (1989), and earlier work has been reviewed by Knights (1984).

Structural information concerning the Si framework of *a*-Si:H alloys can be obtained most straightforwardly from diffraction experiments. X-ray diffraction of *a*-Si:H is sensitive only to Si–Si correlations, i.e., the Si framework, since the light H atoms do not scatter x rays. The same information can be obtained from neutron scattering experiments utilizing isotopic substitution for the hydrogen. Since H and D isotopes have *oppositely* signed values of neutron scattering length, the appropriate null-element mixture of H and D results in scattering from Si–Si correlations only. Neutron diffraction for other isotopic mixtures will contain contributions from H–H and Si–H correlations as well; the use of three such isotopic substitution experiments therefore allows the individual partial distribution functions (PDFs) to be extracted, as shown in Fig. 6 (Bellisent *et al.*, 1985 a,b). The position of the first peak in the Si–Si PDF yields a value for the Si–Si bond length, namely, 2.34 Å. The area under the peak gives an estimate for the coordination number for Si atoms surrounding a given Si atom of $N_1 \approx 3.8$; the discrepancy between this value and the value of 4 expected for ideal tetrahedral coordination reflects, of course, the bonding of hydrogen to some Si atoms as well as, to a lesser extent, the influence of coordination defects (e.g., dangling bonds). EXAFS measurements, taken at the Si *K* edge (Menelle *et al.*, 1986; Filipponi *et al.*, 1986a) also confirm these findings for the first coordination shell of the Si framework structure.

A well-defined second peak lying at 3.85–3.9 Å also occurs in the Si–Si PDFs obtained from diffraction data (see Fig. 6); from the values of the first- and second-neighbor distances, a value for the Si bond angle of $\theta = 110°$ can be inferred. However, the width of the second peak is considerably greater than that of the first peak in the Si–Si PDF; the extra width is due to the *static* disorder in the structure associated with a finite width of the Si–Si–Si bond-angle distribution, in addition to the broadening factors due to experimental resolution (finite value of $k_{\max}$) and thermal vibrational disorder of the bonds. Typically, rms fluctuations of the Si bond angle of $\Delta\theta \approx 7°–10°$ are inferred from diffraction data.

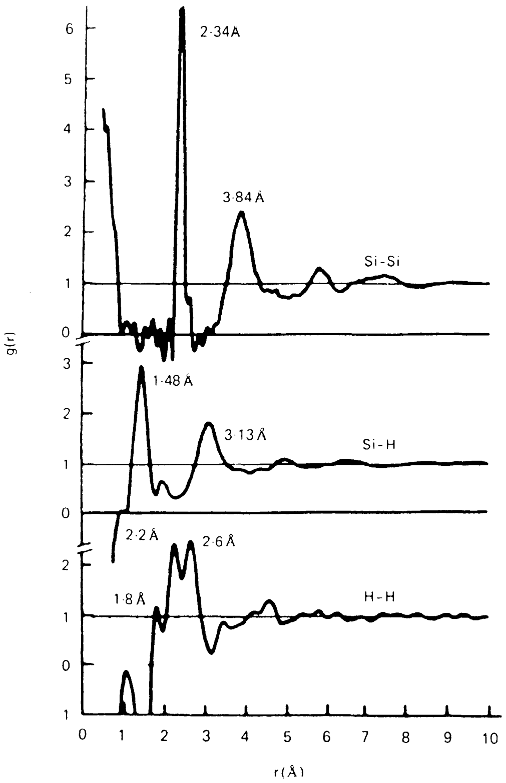

FIG. 6. Partial pair distribution functions for sputtered a-Si$_{84}$(H,D)$_{16}$ obtained from isotopic-substitution neutron-scattering experiments (Bellisent *et al.*, 1985 a,b).

Estimates for the magnitude of Si bond-angle fluctuations in *a*-Si:H can also be obtained from vibrational spectroscopy, notably Raman scattering. The quantities of interest are the width (FWHM) Γ and position ω_{TO} of the TO-like Raman peak at ~500 cm^{-1} [see Fig. 7(a)], which experimentally are observed to depend on the amount of (bond-angle) strain in the films (Maley *et al.*, 1983; Tsu, 1987). The relationship between Γ and $\Delta\theta$ has been investigated theoretically for a number of CRN models of *a*-Si containing varying amounts of bond-angle strain by Beeman *et al.* (1985) [see Fig. 7(b)] and the behavior of the calculated Raman peak widths can be accounted for by two empirical relations, namely,

$$\Gamma = a + b\Delta\theta, \qquad (24a)$$

proposed by Beeman *et al.* (1985), and the similar expression proposed by Tsu *et al.* (1984),

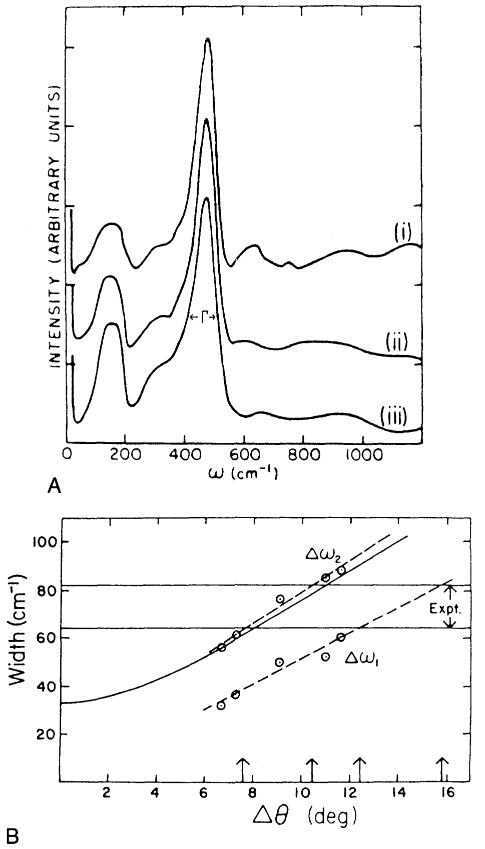

FIG. 7. (a) Experimental VH-polarized Raman spectra of a-$Si_{1-x}H_x$ (Maley *et al.*, 1983): (i) $x=0$; (ii) $x=0.4$ at. %; (iii) $x=32$ at. %. (b) Theoretical TO-like peak widths $\Delta\omega_1$ and $\Delta\omega_2$ (calculated for two different models of the Raman mechanisms), plotted against the rms bond-angle fluctuation $\Delta\theta$ for a number of models of a-Si (Beeman *et al.*, 1985). The curved solid line is given by Eq. (24b) and the dashed straight lines are fits according to Eq. (24a), where $\Gamma=\Delta\omega$ in both cases.

$$\Gamma^2=c+d(\Delta\theta)^2, \tag{24b}$$

where a, b, c, and d are appropriate constants. The intersections of the experimental TO-like peak widths with the theoretical predictions shown in Fig. 7(b) provide estimates for the rms bond-angle fluctuations in the range $\Delta\theta\sim8°$–$16°$, depending on the exact Raman mechanism assumed to be operative. Tsu (1987) has shown that there is also a correlation between the experimental values of the position of the TO peak and its width (and hence $\Delta\theta$), obeying the relation

$$\omega_{\mathrm{TO}}=\omega_0-k\Gamma_\theta^2, \tag{25}$$

where ω_0 is the unshifted (strain-free) frequency of the TO peak, k is a constant, and Γ_θ is the peak-width contribution associated *directly* with the bond-angle strain, namely, $\Gamma_\theta^2 = d(\Delta\theta)^2$ [cf. Eq. (24b)]. The form of Eq. (25) can be understood theoretically in terms of the vibrational characteristics of anharmonic potentials (Tsu, 1987).

Although information on the SRO of the Si-related structure of a-Si:H can be obtained fairly unambiguously from diffraction or EXAFS data (and to a limited extent, Raman spectra), the same is *not* true for the case of MRO. Although tetrahedrally coordinated amorphous materials exhibit considerably less MRO than other amorphous systems, e.g., chalcogenide glasses, nevertheless a small feature in the Si–Si PDF at ~4.8 Å has been regarded as being a signature of MRO. For instance, Dixmier *et al.* (1985) have suggested that the incorporation of two Si–H monohydride groups into the structure, such that the two Si atoms involved are members of the same ring, invariably leads to the creation of an ovoid-shaped void around the hydride units formed by rings characterized by intermediate values of dihedral angle, viz., $\phi=35°$–$45°$. However, detailed modeling studies to confirm this prediction are wanting.

Of interest also is the structural environment of the hydrogen in a-Si:H, the presence of which (up to ~10 at. %) is necessary to suppress the Si dangling-bond density in order to reduce concomitantly the electronic density of states in the band gap of the material so as to achieve the optimum electronic performance. Three distinct H-related configurations can exist in principle in a-Si:H, namely, monohydride (Si–H), dihydride (Si–H_2), and trihydride (Si–H_3) groups. In addition, there is evidence that material containing a large amount of H should be regarded as being a "polysilane," denoted $(SiH_2)_n$.

One technique which can distinguish between the various H configurations is infrared (IR) vibrational spectroscopy, and it is useful in this regard since the phonon modes associated with the Si framework are restricted to the range of frequencies $0<\omega<550$ cm^{-1} (or energies $0<E<70$ meV), the maximum phonon frequency being given by the expression

$$\omega_{\max}=(8\alpha/m)^{1/2}, \tag{26}$$

where a is the bond-stretching force constant and m is the atomic mass, whereas the vibrational modes involving H in a-Si:H occur at considerably higher frequencies ($600 < \omega < 2100$ cm^{-1}) due to the light mass of H. Therefore, H-related vibrational modes can be identified unambiguously from IR absorption spectra. For reviews of this topic, see Lucovsky and Pollard (1984) and Lucovsky (1985).

Figure 8(a) shows a schematic representation of the assignment of features in the IR absorption spectrum of a-Si:H in terms of the various H-related configurations, the local and resonance modes of which are indicated in Fig. 8(b). It can be seen from Fig. 8(a) that the different H-related configurations can be distinguished in this way. Although it was originally thought that trihydride groups existed in H-rich material, it is now generally accepted that in such cases polysilane groupings are predominant (Lucovsky, 1985). Thus, IR spectroscopy can readily be used as a diagnostic tool in order to check the quality of a-Si:H films: the best electronic-grade material, containing essentially only monohydride species, is easily distinguished by the lack of features in the IR spectrum at ~900 cm^{-1} due to scissor-bending modes of SiH$_2$ groups.

Although IR spectroscopy can give quantitative information concerning the concentration of H-related configurations present in a sample of a-Si:H, it can provide no other direct structural information. For this purpose, isotopic-substitution neutron scattering can beemployed, using isotopic mixtures of hydrogen and deuterium, as in the work of Bellisent *et al.* (1985a,b), the results of which are shown in Fig. 6. From the Si–H partial PDF shown in Fig. 6, the Si–H bond length is found to be ~1.48 Å, and the Si–Si–H bond angle (averaged over all the Si–H and Si–H$_2$ configurations in the samples) is ~107.9°, appreciably less than the tetrahedral angle of 109.5°. The first peak in the H–H partial PDF at 2.2–2.6 Å can be interpreted as being due to H–H correlations within dihydride Si–H$_2$ units; if this interpretation is correct, a value for the average H–Si–H bond angle of 109.5° can be inferred (Elliott, 1989). However, neutron experiments are complicated in the case of H-containing materials in view of the large corrections necessary to account for the substantial incoherent scattering of H.

FIG. 8. (a) Schematic representation of the assignment of features in the IR absorption spectrum of a-Si:H in terms of various H-related structural groupings (Lucovsky and Pollard, 1984). (b) Local and resonance modes for various H-related configurations in a-Si:H (Lucovsky *et al.*, 1979).

Proton NMR can also be used to provide some structural information, particularly concerning the H-related structure (see Reimer, 1981, for a review). This is in contrast to the case for ^{29}Si NMR, where the static disorder (in the Si bond-angle distribution) results in broad, featureless resonance lines which

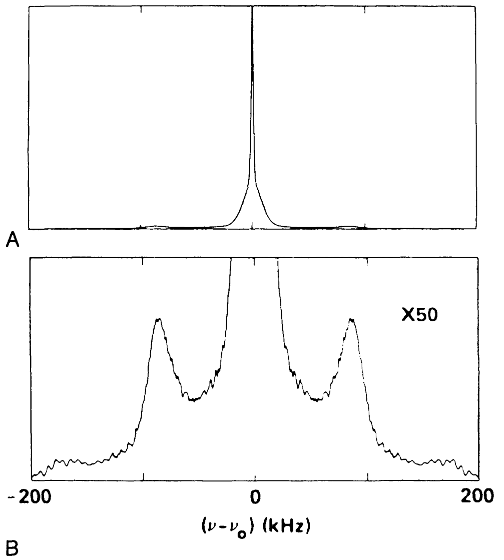

FIG. 9. (a) ^{1}H NMR spectrum of *a*-Si:H taken at 1.43 K showing the narrow and broad components of the central line, and the satellite lines due to the Pake doublet characteristic of solid H_2 (Boyce and Stutzmann, 1985). (b) An enlargement of (a), showing the Pake doublet more clearly.

are devoid of any discernible structural features, although the *width* of the ^{29}Si NMR lines appears to be governed by the fluctuations in the Si bond angle and consequently may be used to obtain an estimate for $\Delta\theta$ (Jeffrey *et al.*, 1981). The ^{1}H NMR spectrum is much more informative (see Fig. 9). At all but the very lowest temperatures, the NMR line is characterized by a combination of both a broad and a narrow component, the relative proportion of which depends both on the total concentration of H in the material and on the relative abundance of H-related configurations. Since the width of the NMR line in this case is determined by the homonuclear dipolar interaction between the nuclear spins of neighboring protons ($I=1/2$), which depends on the internuclear distance r as r^{-6}, clustered protons will experience a large dipolar interaction and hence lead to a broadening of the ^{1}H NMR line, whereas isolated (monohydride) groups will experience essentially no dipolar interactions and hence these H-related configurations are the origin of the narrow component of the line (Carlos and Taylor, 1982a,b).

At temperatures below $\sim$10 K, another component to the ^{1}H NMR line emerges [see Fig. 9(b)]: this has been identified as the Pake powder-pattern signature of solid *molecular* ortho-H_2 trapped in microvoids of size 10–20 Å in the amorphous silicon framework (Boyce and Stutzmann, 1985). This finding has been confirmed by a number of other techniques, including calorimetric measurements and IR spectroscopy (see Elliott, 1989, for a review).

Finally, we consider the structure of those alloying components (e.g., C, Ge, or N substituting for Si, or F substituting for H) and dopants (e.g., P or B) introduced deliberately into the material so as to alter, say, its optical or electrical properties. In such cases, where at least ternary materials are involved, atom-specific structural probes are essential in order to obtain structural information. In this regard, EXAFS and NMR have proved to be useful.

In the case of Si-substitutional alloy systems, EXAFS measurements have provided a great deal of information (see Mobilio and Filipponi, 1987, for a recent review). In Fig. 10(a), Fourier-transformed Si *K*-edge EXAFS data are shown for *a*-$Si_{1-x}N_x$:H thin-film alloys; the emergence of a Si–N peak as the N content increases is clearly apparent. From these results, the compositional dependence of the Si–Si and Si–substituent bond lengths and coordination numbers may be deduced. Figure 10(b) shows the compositional dependence of the average relative first-shell Si coordination numbers, $C = N_A/(N_{\mathrm{Si}} + N_A)$, so obtained for Si–Ge and Si–N alloys, from which it can be seen that Ge randomly substitutes for the Si whereas the N prefers a chemically ordered environment, both as in the corresponding crystals.

In the case of dopant impurities (e.g., P or B), knowledge of the SRO structural environment around the dopant can provide important information concerning the mechanism of doping in *a*-Si:H. For instance, As *K*-edge EXAFS studies of As-doped *a*-Si:H by Knights *et al.* (1977) have indicated that the average coordination of As is nearer to three than to four, implying that most As atoms occupy electrically inactive, normally bonded threefold coordinated sites rather than tetrahedrally coordinated, substitutional doping sites, in agreement with the experimental finding that the doping efficiency of *a*-Si:H is very low. NMR studies of, say, ^{31}P in P-doped *a*-Si:H also provide evidence for the finding that the majority of impurity atoms reside in

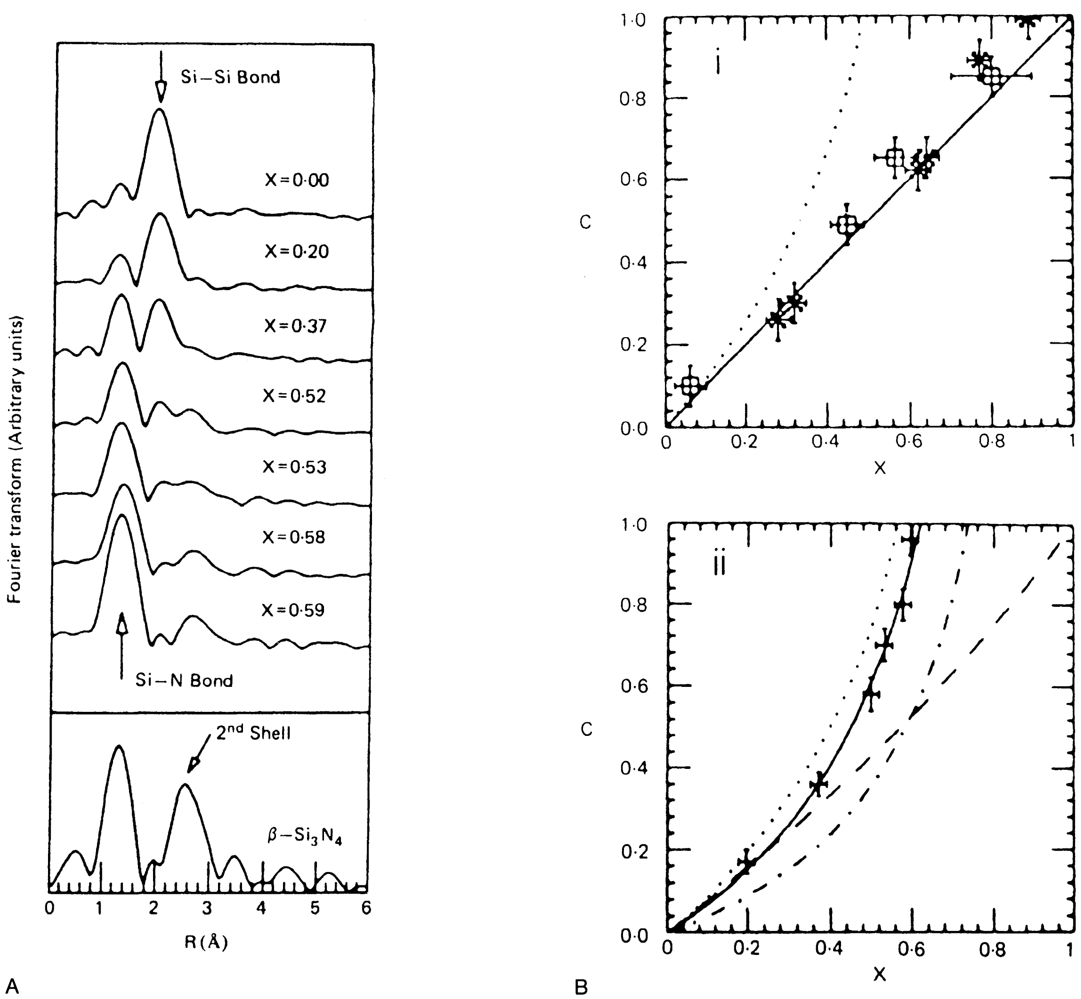

FIG. 10. (a) Fourier-transformed Si *K*-edge EXAFS data for *a*-$Si_{1-x}N_x$:H films and crystalline β-Si_3N_4 (Mobilio and Filippone, 1987). The Fourier transforms have been performed not taking into account phase-shift factors. (b) Average relative first-shell Si coordination numbers, $C = N_A/(N_{Si} + N_A)$, obtained from EXAFS data as a function of composition for amorphous silicon alloys (Mobilio and Filipponi, 1987): (i) *a*-$Si_{1-x}Ge_x$:H (solid line, random alloy model; dotted line, chemically ordered model); (ii) *a*-$Si_{1-x}N_x$:H [chemically ordered model incorporating H (–); chemically ordered model (···); random-alloy model (---) chemically ordered model with wrong bonds (-··-)].

sites satisfying their normal valence (Reimer and Duncan, 1983).

4.2 Oxide Glasses

Oxide materials, particularly silicates, are perhaps the canonical type of glass-forming systems. In view of this fact, and since these materials also have very many technological applications in a wide range of fields, it is important to understand their atomic structure and its relation to other physical properties.

At the outset it is useful to distinguish between two types of oxide materials: "network formers" are those materials which by themselves are glass formers (e.g., SiO_2, GeO_2, B_2O_3, P_2O_5, etc.), whereas "network modifiers" cannot by themselves form glasses, but do so when combined with a network former, and in so doing modify in some way the structure of the glass. There are other oxide materials which fall into neither of these categories. Such material, e.g., Al_2O_3, TiO_2, PbO_2, etc., are not, by themselves, glass formers, but they can be made into glasses if mixed with a network-forming material. Hence, they may be termed "conditional" glass formers, since the cations involved play a network-forming rather than -modifying role. It is important, therefore, to investigate the structure of both unmodified and modified oxide glasses.

For stoichiometric compositions of unmodified network-forming glassy systems, heteropolar bonds are dominant, and thus the principal factor determining the SRO is the number N_{co} of oxygen ligands surrounding each glass-forming cation or, in other words, the shape of the cation-centered coordination polyhedron characterizing the structure. For simple (binary) oxide glasses, the use of diffraction techniques is sufficient in order to ascertain N_{co} from the measured average coordination number (i.e., the area under the first peak in the *total* RDF), since it is safe to assume that the oxygen atoms will always be in "bridging sites," i.e., be twofold coordinated by cationic species (viz., $N_{oc}=2$). Thus, it is well established, for example, that Si in SiO_2 and Ge in GeO_2 are tetrahedrally coordinated and B in B_2O_3 is (planar) trigonally coordinated by bridging oxygen atoms, whereas P in P_2O_5 is tetrahedrally coordinated by three bridging oxygens and one double-bonded nonbridging oxygen atom. The tetrahedral coordination of Si by O, for example, is not only indicated by diffraction data (e.g., x-ray by Mozzi and Warren, 1969, and neutron by Wright and Sinclair, 1985), but also corroborated by ^{29}Si MASNMR experiments, where the chemical shift of the peak of the NMR line in vitreous SiO_2 (~ -111.5 ppm referenced to tetramethyl silane; see Gladden *et al.*, 1986) is practically identical to that characteristic of various crystalline polymorphs of silica in each of which Si is tetrahedrally coordinated (Smith and Blackwell, 1983).

Another SRO parameter of great interest is the oxygen bond-angle distribution $P(\theta_o)$. (The average cation-centered bond angle θ_c is constrained by symmetry to take only certain values in the case of very symmetrical coordination polyhedra, such as tetrahedra or planar triangles.) In the absence of isotopic-substitution neutron scattering data (or other diffraction results similarly yielding partial PDF information), extraction of $P(\theta_o)$ is very difficult to achieve using *total* diffraction data because of the problems of coordination-shell overlap in the region of the second peak in the RDF. However, Mozzi and Warren (1969) managed to obtain an estimate for $P(\theta_o)$ in the case of v-SiO_2 from their x-ray diffraction results after making a number of simplifying assumptions. This distribution, shown in Fig. 11, peaks at an angle $\theta_o \approx 145°$, and it can be seen that $P(\theta_o)$ is both broad and markedly asymmetric, being skewed to the high-angle side.

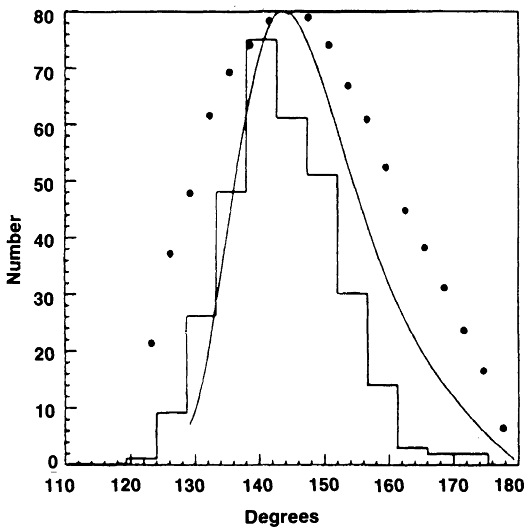

FIG. 11. Si–O–Si bond-angle distribution for v-SiO_2 obtained from x-ray diffraction data (·) (Mozzi and Warren, 1969), ^{29}Si MASNMR (–) (Gladden *et al.*, 1986), and the histogram distribution of a computer-generated CRN model (Gladden 1989).

For the case of v-SiO_2, MASNMR can also be used to obtain quantitative information concerning $P(\theta_o)$ by using the fact that the bond angle θ_o subtended at the oxygen ligands surrounding the resonant ^{29}Si nucleus subtly affects the ^{29}Si isotropic chemical shift σ. The empirical relation between σ and θ_o [Eq. (23)], deduced for the case of *crystalline* polymorphs of SiO_2 (Smith and Blackwell, 1983), can be assumed also to hold in the case of the inhomogeneously broadened oxygen bond-angle distribution, and hence NMR line, characteristic of v-SiO_2 (Dupree and Pettifor, 1984). Use of Eq. (23) therefore allows an estimate of $P(\theta_o)$ to be obtained from an analysis of the line shape of the ^{29}Si NMR signal, as shown in Fig. 11 (Gladden *et al.*, 1986). It can be seen that $P(\theta_o)$ obtained in this way is as similarly asymmetric as, but somewhat narrower than, that obtained from x-ray diffraction (Mozzi and Warren, 1969).

The fact that there is a wide distribution of oxygen bond angles in v-SiO_2 (see Fig. 11) implies that few constraints exist in the interconnection of neighboring SiO_4 tetrahedra other than those imposed by the steric constraints arising from the avoidance of a nonbonded oxygen atomic overlap (Galeener, 1985). This is consistent with *corner*-sharing connections between SiO_4 tetrahedra. This relative freedom of connection of structural units implies the existence of a minimal degree of MRO in the structure of v-SiO_2, and this is confirmed by the extensive structural modeling studies of Gladden (1989), in which a good fit to the experimental RDF obtained from neutron diffraction is achieved for models having a range of ring sizes, with a preference for 8- and 12-atom rings.

The situation in v-B_2O_3 is rather different, since here pronounced IRMRO in the form of superstructural units (see Sec. 1.4.2) seems to exist. The particular type of superstructural unit involved is the so-called "boroxol" ring, namely, a planar six-atom regular ring, which can be regarded as being constructed from three corner-sharing planar BO_3 triangles connected together in a triangular arrangement (see Fig. 12). The experimental evidence for the existence of boroxol rings in v-B_2O_3 comes from Raman scattering: the Raman spectrum is dominated by a very narrow, intense, strongly polarized line at $\sim 808\ cm^{-1}$ [Fig. 12(a)]. Isotopic substitution experiments by Windisch and Risen (1982) indicate that there is no change in the 808-cm^{-1} line on changing the B isotope, but that there *is* a pronounced shift in frequency when the O isotope is changed [Fig. 12(b)]. These results imply that only oxygen motion is involved in the vibrational mode responsible for the 808-cm^{-1} Raman peak, and the 1:3:3:1 intensity ratio for the resolved quadruplet line when a 50:50 mixture of ^{16}O and ^{18}O isotopes is used is consistent with a random isotopic substitution in a structural unit containing just three oxygen atoms. The strongly polarized nature and narrowness of the 808-cm^{-1} peak [see Fig. 12(a)] are also indicative of a highly symmetric, vibrational mode which is decoupled from the rest of the network.

The case of *modified* oxide glasses is considerably more complicated. Here, information on the structural influences of the modifying cation (often an alkali atom) on both the network-forming cation-centered coordination polyhedra and also on their interconnections is sought, together with that concerning the SRO structural environment of the network-modifier cations themselves. Thus, modifier-induced coordination changes of network-forming cations can occur, as can a depolymerization of the network by the transformation of bridging oxygen (BO) twofold-coordinated sites to "nonbridging" oxygen (NBO) singly coordinated (and negatively charged) anionic configurations. Atom-specific structural probes are obviously more useful in the structure determination of such ternary or more complicated systems than are conventional diffraction techniques.

In the case of alkali silicate glasses, addition of the alkali modifier ions causes a depolymerization of the silicate framework with the formation of NBO sites but with no change in the coordination of the Si. This observation is supported by the results of ^{29}Si MASNMR experiments (see, e.g., Dupree *et al.*, 1984), where the value of the isotropic chemical shift is approximately the same as that for pure v-SiO_2, indicating that the Si coordination remains unaltered. However, there *are* subtle changes to the ^{29}Si NMR line shape, as seen in Fig. 13(a), indicating changes in the oxygen coordination shell. There are *five* possible configurations involving the incorporation of NBO atoms in the tetrahedrally coordinated Si polyhedra, conventionally denoted Q_n species where $n=0$–4 is the number of BO atoms around a given Si atom. It might be thought that the incorporation of network-modifying cations in the glassy network, and concomitantly the distribution of NBO and Q_n species, would occur in a purely statistically random way; in such a case, for a given modifier content, it would be expected that *all* five Q_n species would occur, the relative proportion of each being determined by the composition. The MASNMR results [Fig. 13(a)] indicate otherwise; at stoichiometric compositions, essentially only *one* type of Q_n species exists, with the two species Q_n and Q_{n+1} (corresponding to the endpoint compositions) predominating at intermediate compositions [Fig. 13(b)]. Nevertheless, *static* ^{29}Si NMR experiments have indicated some discrepancies with this simple ordered picture (Stebbins, 1987). For the case of binary $(Na_2O)_x(SiO_2)_{1-x}$ glasses, it was found from static NMR spectra that Q_4 species existed for compositions close to stoichiometry ($x=0.33$) where the simple picture would predict the presence of only Q_3 units. Figure 14 clearly shows the emergence of a

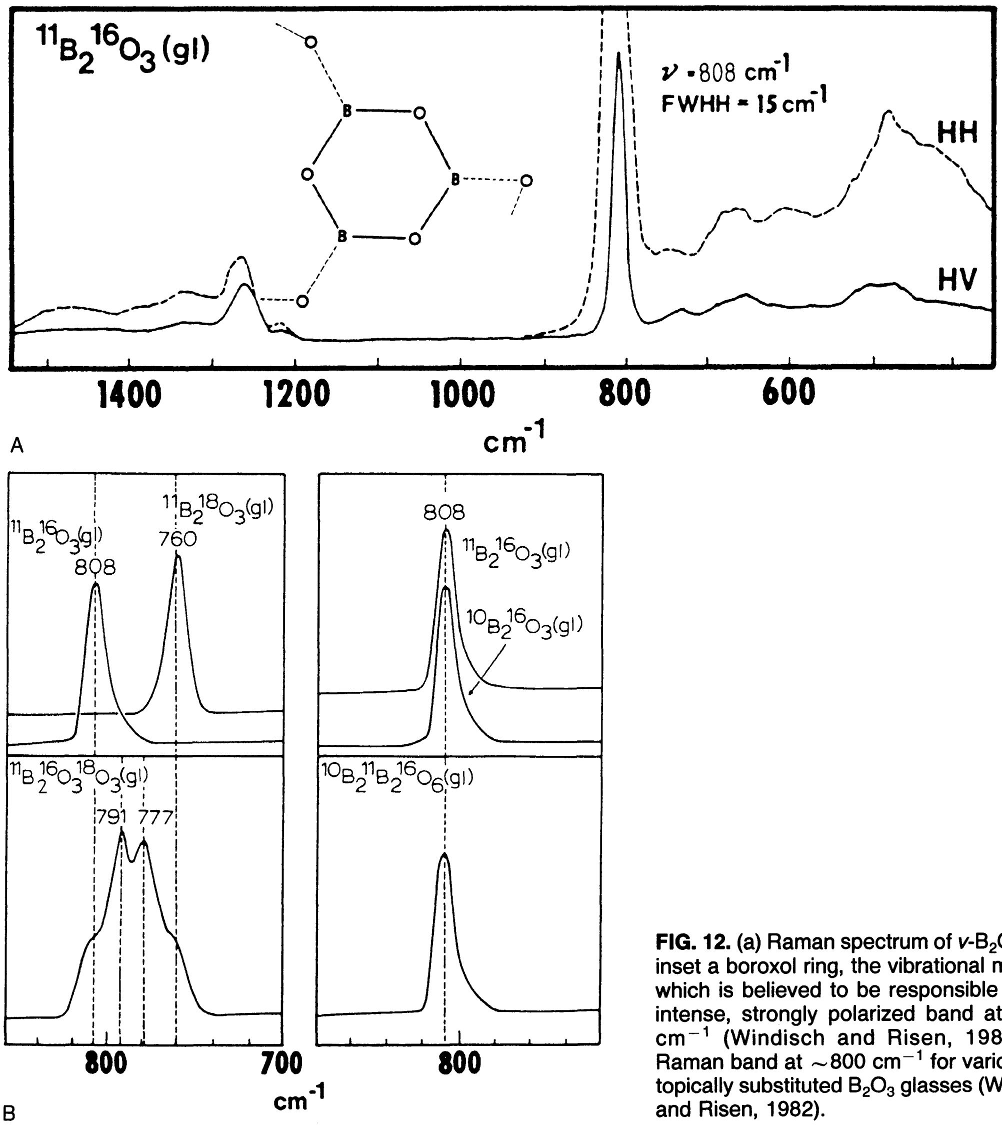

FIG. 12. (a) Raman spectrum of v-B_2O_3, with inset a boroxol ring, the vibrational mode of which is believed to be responsible for the intense, strongly polarized band at ~808 cm^{-1} (Windisch and Risen, 1982). (b) Raman band at ~800 cm^{-1} for various isotopically substituted B_2O_3 glasses (Windisch and Risen, 1982).

peak, identified as being due to Q_4 units, superimposed upon the axially symmetric powder pattern characteristic of Q_3 units (with C_{3v} symmetry, the axis of symmetry being along the bond connecting a Si atom and a neighboring NBO).

In certain exceptional cases, a change in the coordination of the Si can be effected with the addition of other network formers and modifiers, the coordination becoming octahedral as in the high-pressure polymorph of silica, stishovite, and in the crystal $Si_2P_2O_7$. For example, it has been found from ^{29}Si MASNMR studies (Dupree *et al.*, 1987) that $Na_2Si_2O_5$ glasses containing in excess of ~30 mol % of P_2O_5 contain an increasingly large proportion of octahedrally coordinated Si sites (see Fig. 15). The strongly polarizing P(V) atoms can stabilize electrostatically the change in coordination.

In other oxide glass-forming systems, where the radius ratio of the network-forming cation is more favorable, compositionally induced coordination changes occur more easily. Thus, for example, a transformation to octahedral coordination of Ge occurs in alkali germanate glasses with increasing alkali content (up to ~35 at. % alkali), as evidenced by Ge *K*-edge EXAFS studies (Sakka and Kamiya, 1982); at higher alkali contents,

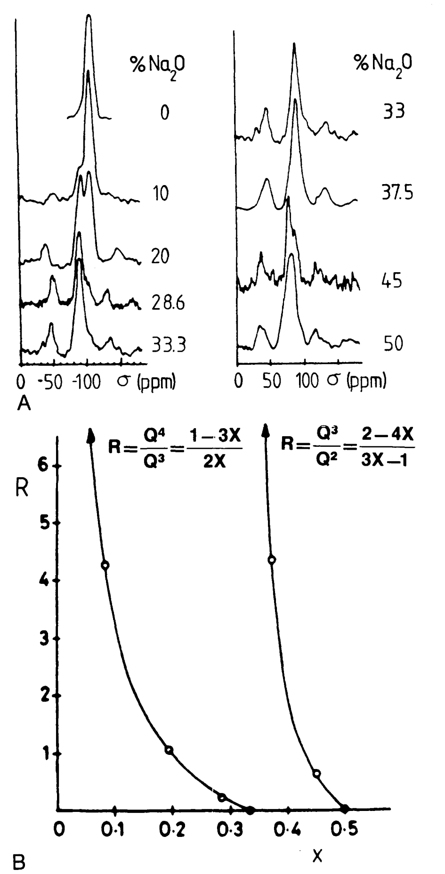

FIG. 13. (a) ^{29}Si MASNMR spectra for binary $(Na_2O)_x(SiO_2)_{1-x}$ glasses (Dupree *et al.*, 1984). (b) Calculated (curves) and experimental (circles) intensity ratios for Q_n species contributing to the ^{29}Si MASNMR line shape for different compositions (Dupree *et al.*, 1984).

NBO sites are created at the expense of octahedral Ge sites. The case of borate glasses is very similar. As discussed previously, B is planar threefold coordinated in pure v-B_2O_3, but the addition of alkali oxides causes a change from trigonal to tetrahedral coordination of B up to a limiting content of ~35 at. % alkali; thereafter the B coordination reverts to being trigonal and NBOs are created as charge-compensating centers for the alkali ions. ^{11}B NMR experiments, even static ones, are very sensitive to such coordination changes because of the concomitant changes in the quadrupolar interaction between the electric field gradient (EFG) at the nucleus caused by the electronic charge distribution in the atom and the nuclear quadrupolar moment, and the broadening effect this has on the NMR line. Trigonally coordinated B atoms will have large EFG values (and hence very broad lines), whereas the symmetry associated with tetrahedral coordination significantly reduces the value of the EFG, leading to characteristically narrow NMR lines. A review of this topic has been given by Bray (1978).

Thus far, we have concentrated mainly on aspects of the SRO of (modified) oxide glasses without discussing MRO in any detail. With the exception of v-B_2O_3, short-range and intermediate-range MRO (Secs. 1.4.1 and 1.4.2) is not particularly pronounced in oxide glasses, principally because of the inherent flexibility imparted to the structure by the corner-sharing connections of coordination polyhedra characteristic of most oxide glasses. However, the network depolymerization in, say, silicates caused by the modifier-induced creation of NBO centers can lead to the formation of long-range MRO (see Sec. 1.4.3). In particular, for, say, the composition $(Na_2O)_{0.33}(SiO_2)_{0.67}$, where Q_3 units predominate, the structure locally is forced to be *two dimensional* on topological grounds, as in the corresponding layerlike crystal. This type of reduced dimensionality, delineated by chan-

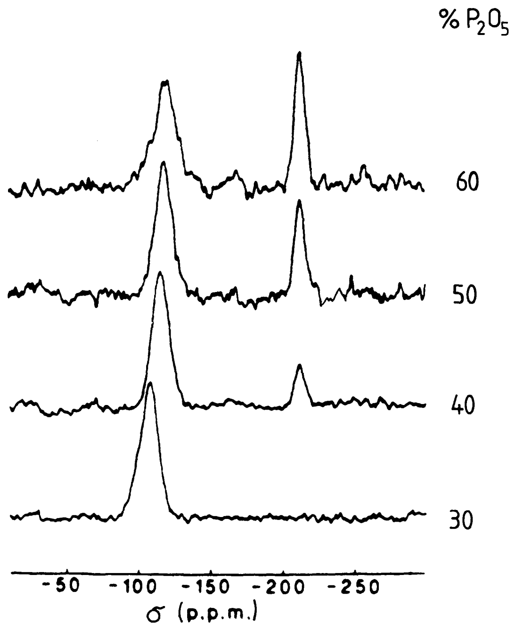

FIG. 15. ^{29}Si MASNMR spectra of $Na_2Si_2O_5$ glasses containing varying amounts of P_2O_5 (Dupree *et al.*, 1987). At low P_2O_5 contents, only tetrahedrally coordinated Si is present (with a chemical shift of ~ -110 ppm), whereas at higher concentrations, a peak at ~ -210 ppm appears, characteristic of octahedral coordination.

nels containing the modifier cations surrounded by NBOs, is the basis of the concept of the "modified" CRN proposed by Greaves (1985) (see Fig. 16).

4.3 Chalcogenide Glasses

Chalcogenide glasses are those inorganic compounds of chalcogen (group VI) elements (viz., S, Se, and Te) with elements such as P, As, Si, or Ge. Although oxygen is also a group VI element, and so technically a chalcogen, nevertheless it is conventional to discuss separately oxide and other chalcogenide materials, partly for historical reasons, and also because oxide materials are much more ionic than the more covalentlike chalcogenide materials. Furthermore, because the Si- and Ge-containing chalcogenide analogs of silica can have edge-sharing as well as corner-sharing connections between neighboring tetrahedra, the MRO of these glasses can be much richer than that found in the corresponding oxide glasses; the local two dimensionality imparted to the structure by the inclusion of pnictogen atoms (P, As, Sb), resulting from the appreciable "bond-free solid angle" associated with their threefold coordination, has much the same effect. Finally, since chalcogenide materials have predominantly covalent bonding, the degree of chemical ordering (heteropolar bonding) can be much less pronounced than is found in oxide systems, particularly when the elements involved have similar electronegativity values.

Diffraction experiments on chalcogenide glasses, particularly for stoichiometric compositions, confirm that in general the basic coordination polyhedra in these materials conform to the expected values of the network-forming cations, viz., tetrahedral for Si- and Ge-containing materials, and trigonal pyramidal for pnictogen-containing glasses. The larger sizes of the chalcogen atoms compared with oxygen, however, mean that increases in coordination of the network-forming cations caused by the addition of network-modifying atoms, which are found in oxide systems (Sec. 4.2), are not observed in chalcogenide glasses.

However, it is much more difficult to ascertain the extent of chemical ordering in chalcogenide glasses using diffraction methods alone. In the case of Ge chalcogenide glasses, Mössbauer spectroscopy has been used to investigate the breakdown of chemical order (see Boolchand, 1985, for a review), using ^{119}Sn and ^{129}I as probes for Ge and chalcogens, respectively. In the former, Sn is assumed to substitute isomorphously for Ge at

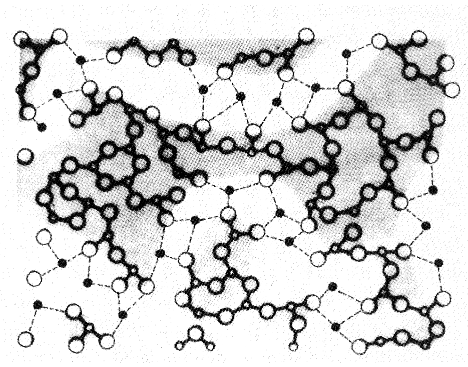

FIG. 16. Modified CRN model for alkali oxide glasses, proposed by Greaves (1985). The unmodified regions of the network are shown shaded, and the bonds between the modifier cations (solid circles) lying in the channels and nonbridging oxygen anions are shown as dashed lines.

the 1% level, and ^{119}Sn absorption Mössbauer spectra indicate the presence of two Ge sites even at the stoichiometric composition (e.g., $GeSe_2$) (Boolchand, 1985): the so-called A site is characterized by a single Mössbauer line and is ascribed to a symmetrical tetrahedral $Ge(Se_{1/2})_4$ unit; the other, B site is characterized by a weaker quadrupolar doublet Mössbauer line, and has been ascribed to an "ethanelike" structural configuration, viz., $Ge_2(Se_{1/2})_6$, i.e., containing *homopolar* Ge–Ge bonds. The Mössbauer experiments involving ^{129}I are somewhat complicated but yield similar complementary results. In these, radioactive $^{129}Te^m$ atoms, incorporated into, say, a $GeSe_2$ glass in an assumed isomorphous manner, decay by β emission into $^{129}I^*$ atoms which subsequently emit recoilless γ rays, the spectrum of which is detected by a monoenergetic ^{129}I absorbing detector (e.g., NaI). Such Mössbauer results provide evidence for two types of site originally occupied by the Te (and hence Se) atoms before their transmutation to I atoms even at the stoichiometric composition (Boolchand, 1985): the A sites correspond originally to chemically ordered $Te(Ge_{1/4})_2$ sites, and the B sites correspond to sites in which the chemical order is broken, viz., Ge–Se–Se configurations, with Te substituting for one or other of the Se atoms.

As usual, although the SRO in chalcogenide glasses is more or less well understood, the type and extent of MRO remains controversial. Diffraction evidence for MRO remains scanty and difficult to interpret, although one almost universal feature observed in the diffraction pattern has been ascribed to the existence of MRO: this is the so-called "first sharp diffraction peak" (FSDP) or "prepeak," observed at $k \sim 1$ Å^{-1} in the structure factor of chalcogenide glasses. The term prepeak is used because removal of this first peak in the structure factor causes no discernible difference in the real-space RDF obtained by Fourier transformation of $S(Q)$; the FSDP therefore seems to be a signature of structural ordering (i.e., MRO) beyond that which is registered in the RDF. In fact, oxide glasses such as v-SiO_2 and B_2O_3 also exhibit FSDPs in their structure factors but at somewhat larger values of scattering vector than is the case for chalcogenide glasses. However, when plotted on a common reduced scale, viz., with the scattering vector multiplied by the nearest-neighbor bond length r_1, scattering data for both chalcogenide and oxide glasses are very similar (see Fig. 17), indicating perhaps a common cause for the FSDP. It is noteworthy also that the tetrahedrally coordinated materials, a-Si and Ge, as well as the pure chalcogen glass, a-Se, do *not* exhibit FSDPs in their diffraction patterns.

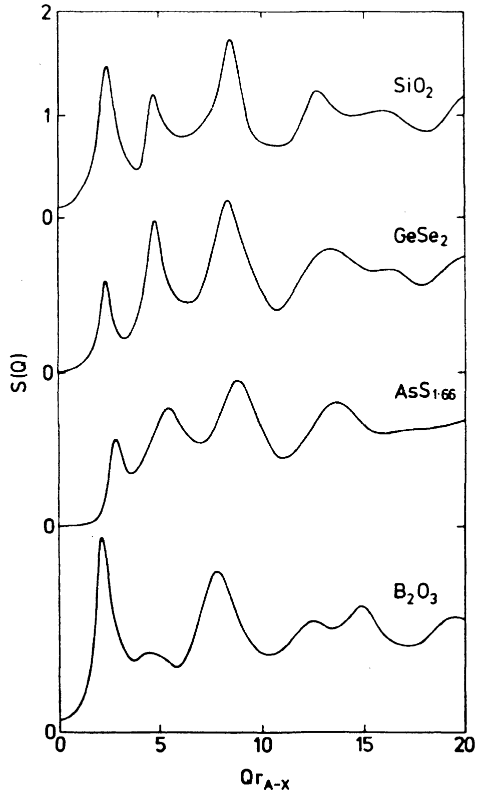

FIG. 17. Structure factors for chalcogenide and oxide glasses, plotted on a common reduced scale involving the nearest-neighbor bond length r_1, showing similar first sharp diffraction peaks (Wright *et al.*, 1985).

The structural origin of the FSDP remains obscure, however. One explanation treats the FSDP in reciprocal space as a single Bragg-like peak resulting from a quasiperiodic structural repeat in real space as, for example, in a layerlike structure. Busse (1984) has proposed this model for the case of As-chalcogenide glasses, and more recently Cervinka (1988) has extended this approach to the case of Ge-chalcogenide glasses where it is suggested that parallel arrangements of clusters of between two and five tetrahedral coordination polyhedra are responsible for the FSDP. However, the fact that the FSDP is observed even in the *liquid* state of chalcogenide materials (Uemura *et al.*, 1978) makes it unlikely that well-defined interlayer correlations over an appreciable correlation length of ~20 Å (necessary to account for the narrowness of the FSDP) are in fact responsible. Another explanation for the FSDP is based on intercluster correlations, as used in the case of molecular liquids. Here, the measured structure factor is regarded as arising from two terms:

$$S(Q)=f_m(Q)+D_m(Q), \qquad (27)$$

where $f_m(Q)$ is the "molecular" form factor describing the *intra*cluster scattering, and $D_m(Q)$ is the molecular-packing structure factor describing the *inter*cluster interference involving scattering from clusters separated by an average distance r_m. In this picture, therefore, the FSDP is simply the first (and largest) of a series of strongly damped peaks in $D_m(Q)$, the Fourier transform of a single broad peak at r_m in real space. [At high values of Q, the oscillations of $f_m(Q)$ dominate.] Moss and Price (1985) have proposed, in accord with this picture, that the FSDP in oxide and chalcogenide glasses arises from correlations involving the packing of coordination polyhedra.

The MRO in chalcogenide glasses is richer than that found in the corresponding oxide glasses due to the reduced local dimensionality associated with the trigonal pyramidal coordination of pnictogens and with the edge-sharing connections of tetrahedral coordination polyhedra believed to be present in Si and Ge chalcogenides. In the Si chalcogenides, SiS_2 and $SiSe_2$, edge sharing is predominant, leading to a locally *one-dimensional* structure as in the corresponding crystalline structures. A comprehensive theoretical modeling study of these systems, using computer-generated "ball-and-stick" models, has allowed those parameters to be identified which are essential for a model to match experimental (diffraction) results (Gladden and Elliott, 1989a,b). The results of this study are shown in Fig. 18, where the fit of the model to the experimental real-space correlation function derived from neutron diffraction is shown, together with the structural configurations believed to contribute particularly to certain regions of the RDF. It can be seen that the structure of v-SiS_2 or $SiSe_2$ appears to be well described in terms of amodel containing clusters of cross-linked parallel chain (edge-sharing) configurations.

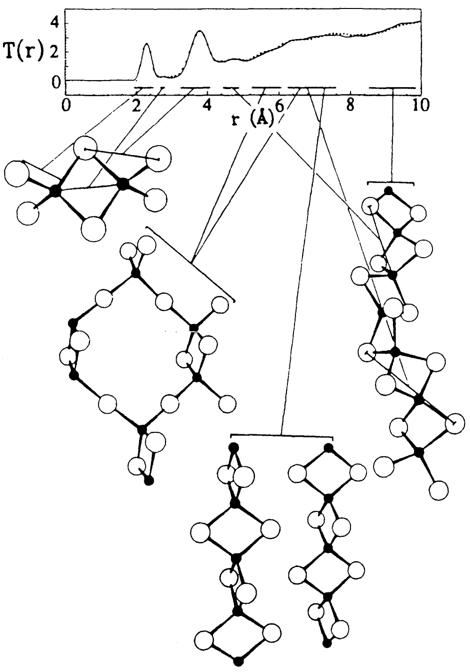

FIG. 18. Comparison of the experimental correlation function $T(r)[=J(r)/r]$ for v-$SiSe_2$ with that of a computer-generated model containing the structural configurations also shown (Gladden and Elliott, 1987).

Edge-sharing connections of tetrahedra are also believed to be present in Ge chalcogenide glasses, but to a lesser extent than in Si chalcogenide materials. The structure of one crystalline polymorph of GeS_2 or $GeSe_2$ is essentially layerlike, with the layers formed by edge-sharing tetrahedra cross-linking ribbons of corner-sharing units. It has been claimed (Phillips, 1981) that similar structural arrangements also exist in the corresponding glassy materials, termed "rafts," bordered by homopolar Se–Se bonds (with the conjugate ethanelike groupings involving Ge–Ge bonds occupying unspecified positions elsewhere in the structure).

Glassy Ge chalcogenides exhibit particular features in their Raman spectra which have been ascribed to the existence of MRO in the structure, namely, a sharp "companion" line accompanying the main A_1 stretching mode of the GeX_4 tetrahedra (X=S, Se); for the case of v-$GeSe_2$, for example, the A_1 line occurs at ~200 cm^{-1} and the companion line is at ~220 cm^{-1}. The companion line is distin-

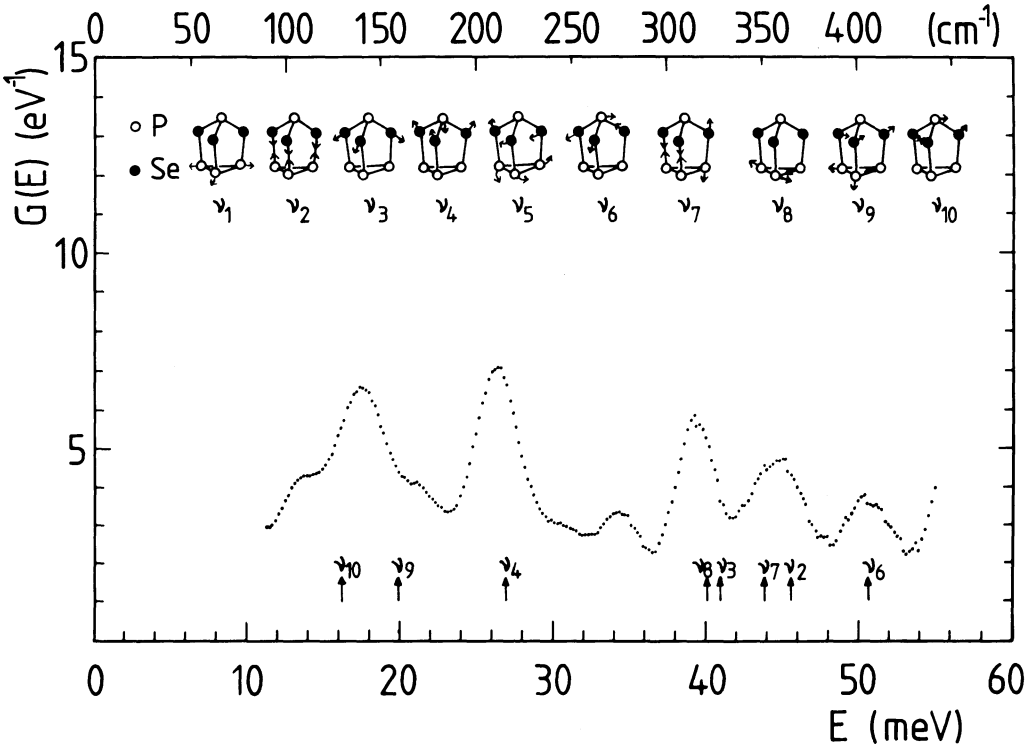

FIG. 19. Vibrational density of states for v-P_2Se obtained from inelastic neutron scattering (Verrall and Elliott, 1988). The assignment of the peaks in terms of various vibrational modes of P_4Se_3 molecules is indicated.

guished by its very strong compositional dependence as the composition departs from stoichiometry, indicating perhaps that the MRO configurations responsible for the companion line are particularly susceptible to breakup upon change of composition. In the Phillips raft model, the companion line was ascribed to modes involving the Se–Se bonds bordering the rafts. However, it is more likely that the companion line in Ge and Si chalcogenides arises from vibrations of the four-membered rings associated with edge-sharing connections of tetrahedra (Sugai, 1987). However, matrix-element enhancement of Raman lines, resulting from symmetric vibrational modes such as that associated with four-membered (edge-sharing) rings, can occur; unfortunately, the energy resolution of current inelastic neutron spectrometers is insufficient to be able to resolve the companion peak in v-$GeSe_2$ (Gladden *et al.*, 1988) in order to ascertain whether the anomalous composition dependence of the companion Raman line is in fact a result of matrix-element enhancement.

The final example of MRO in a chalcogenide glass to be discussed here concerns the phosphorus chalcogenide glass, P_2Se. This material is of interest since it appears to be a rare example of an inorganic molecular glass, i.e., a *zero-dimensional* solid. Inelastic neutron scattering results for v-P_2Se (Fig. 19) reveal a vibrational density of states (VDOS) which is highly structured and where the individual peaks are particularly narrow insofar as a glass is concerned (Verrall and Elliott, 1988). In fact, all but one of the peaks in the VDOS can be assigned to cagelike molecular vibrations of P_4Se_3 molecules (Fig. 19), in which the vibrational modes of the molecules are essentially decoupled from the overall network; the remaining vibrational mode at $\sim 250\ \mathrm{cm}^{-1}$ is ascribed to the vibrations of the excess phosphorus. Raman spectra support this picture of molecular modes (Elliott and Verrall, 1989), and allow some overlapping peaks in the neutron VDOS to be resolved. Conventional neutron diffraction experiments on v-P_2Se yield a structure factor which can be fitted perfectly at large values of

Q in terms of a P_4Se_3 molecule (Verrall and Elliott, 1989); features at smaller values of Q reflect intermolecular correlations [cf. Eq. (27)], and contain information on the IRMRO, viz., the packing of the P_4Se_3 molecular clusters.

4.4 Amorphous Metals

Amorphous metals are invariably alloys, and these glass-forming systems can be divided broadly into two categories: all-metal compositions include alloys of "simple" metals (e.g., $Ca_{67}Mg_{33}$) or of early and late transition metals(e.g., $Nb_{60}Ni_{40}$) or rare earths; in addition, alloys of transition metals with "metalloids" (e.g., C, B, Si, P) can also be glass formers (e.g., $Ni_{80}B_{20}$). Thus, since amorphous metallic systems are always at least binary alloys, atom-specific structural probes or diffraction methods yielding partial PDF data are necessary in order to obtain the maximum amount of interpretable structural information. In general, the structural information of interest in the case of amorphous metals concerns mainly the SRO around each constituent, although obviously this is not well defined as in the covalent materials discussed previously; in the case of the least ordered metal-metal alloy systems, only a statistical definition of SRO is possible, as given by Eqs. (3) and (4). A review of structural aspects of metallic glasses has been given by Sadoc and Wagner (1983), Gaskell (1983, 1987), and in the book edited by Luborsky (1983).

The transition metal-metalloid (T–M) glassy alloy systems have been investigated perhaps the most extensively due to their ease of fabrication and their technological applications, e.g., as transformer cores (Fe–B) and as record/playback heads in magnetic tape recording systems (Co-based alloys). An example of such a study is shown in Fig. 20, where the results of an isotopic-substitution neutron diffraction investigation of $Ni_{81}B_{19}$ are shown (Lamparter *et al.*, 1982). Use of the "null element" isotopic mixture $^{\phi}$Ni allows the B–B partial structure factor to be obtained directly [see Figs. 20(a) and 20(b)]. It can be seen from Fig. 20(c) that the nearest-neighbor coordination shell around the metal consists of metalloid atoms, and vice versa. In particular, it should be noted that there are *no* metalloid-metalloid near neighbors, a finding confirmed for another T–M glassy system, namely, $Co_{80}P_{20}$, using polarized neutron magnetic scattering (Sadoc and Dixmier, 1976).

The experimental observation of metalloid-metalloid avoidance in T–M glassy alloys rules out one possible model for their structure. In the case of the dense random packed (DRP) model, first proposed by Bernal (1959) for liquid structures and later extended to the case of amorphous metals, it was suggested by Polk (1970) that the structure of binary alloys such as T–M glasses could be represented by a DRP model consisting of two sizes of atom, the smaller (metalloid) atoms occupying the interstices between the larger (metal) atoms in a DRP arrangement. However, this model would predict that the metalloid atoms would be distributed in a statistical fashion, with at least some close metalloid-metalloid contacts, in contradiction with experimental results.

An alternative, stereochemical structural model for T–M glasses has been proposed by Gaskell (1979) in terms of local trigonal prismatic coordination. In *crystalline* T–M systems, e.g., cementite (Fe_3C), the dominant structural motif consists of trigonal prismatic coordination by metal atoms of the metalloid atoms, with the possibility of capping of three faces of the trigonal prism by further metal atoms (see Fig. 21). The occurrence of MT_6 trigonal prismatic units as the dominant structural motifs in glassy T–M alloys naturally explains, therefore, the absence of M–M nearest-neighbor bonds. This model gives reasonable agreement with experimental metal-metal partial PDFs, but rather poor agreement with metal-metalloid partial PDFs (Gaskell, 1981).

However, although in the case of covalent glasses, the directionality of the covalent bonding dictates the local SRO, i.e., the shape of the coordination polyhedra, in the absence of strong covalent interactions, as in the T–M alloy glasses, it is not clear precisely what determines such orientational ordering. Whereas it is generally accepted that, in *covalent* glasses, structural order on different length scales is *hierarchical*, i.e., the type of SRO present determines in turn the structural organization at the next level, viz., MRO, the converse of this has been suggested by Dubois *et al.* (1985) and Gaskell (1987) for the case of T–M glasses, namely, that the (stereochemical) SRO may be a *consequence* of the exist-

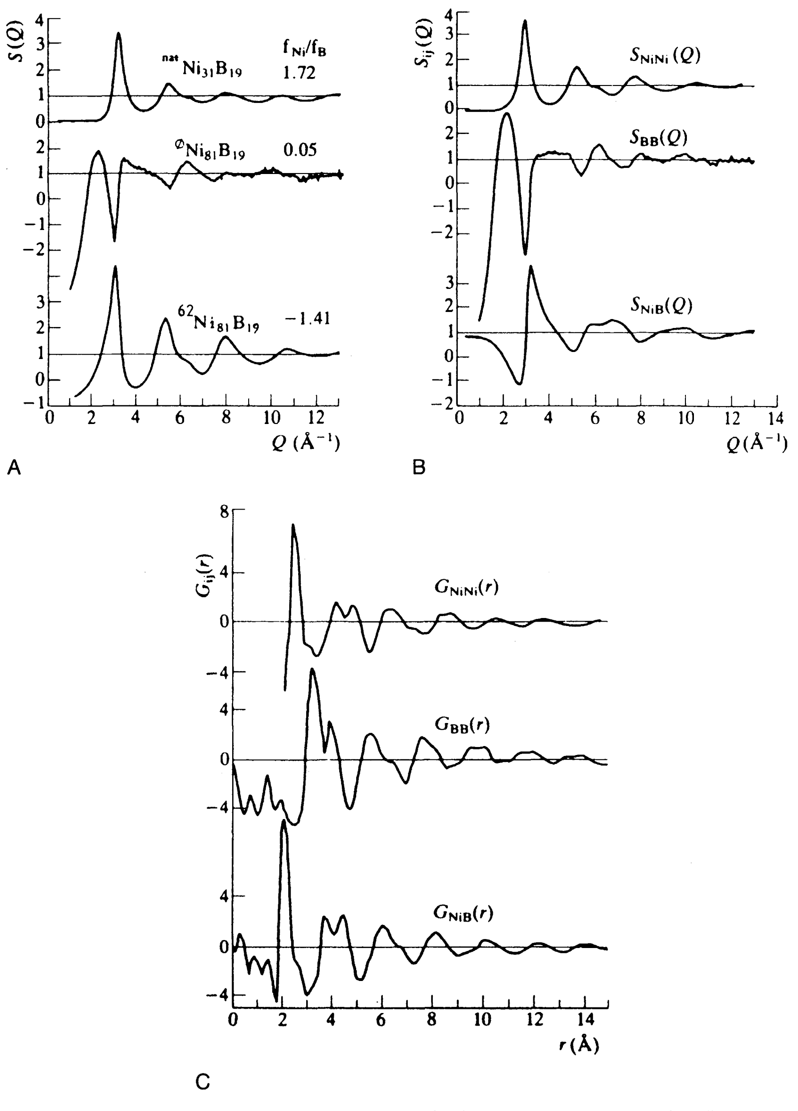

FIG. 20. Structural studies of glassy $Ni_{81}B_{19}$ using isotopic-substitution neutron diffraction (Lamparter *et al.*, 1982). (a) Structure factors for different isotopically substituted alloys, including the "null element" isotopic mixture $^{\phi}Ni$. (b) Partial structure factors obtained from the data shown in (a). (c) Partial reduced RDFs obtained by Fourier transformation of the $S_{ij}(Q)$ shown in (b).

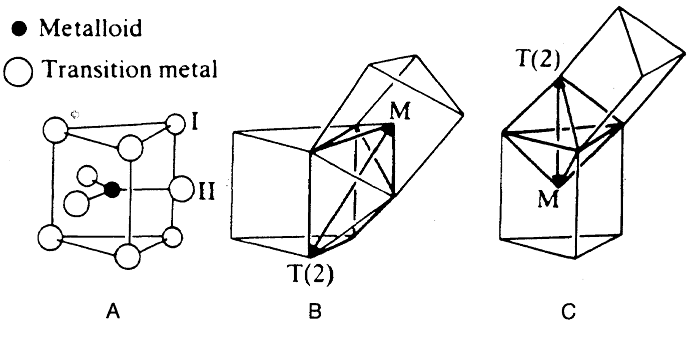

FIG. 21. (a) Trigonal prismatic packing of transition metals around a metalloid atom observed in many crystalline alloys. (b) Edge-sharing arrangement in the cementite (Fe_3) structure. (c) Edge-sharing arrangment in the Fe_3P structure with different metalloid–second nearest neighbor transition metal configuration.

ence of a well-defined MRO. An example of such a circumstance in the crystalline state is the occurrence of tetrahedra and octahedra arising from ordered close-packed arrays of atoms. In the case of crystalline T–M materials, the trigonal prismatic coordination of metalloid atoms can be regarded as arising from the introduction of "chemical twinning" planes (containing the M atoms) into a close-packed crystalline arrangement of the metal atoms (Hyde *et al.*, 1979); the composition of the T–M alloys is varied by changing the periodicity of the chemical twinning planes. Dubois *et al.* (1985) have suggested that a similar situation prevails in the case of glassy T–M alloys as well; here, it is proposed that the LRMRO is associated with domains of size ~10–20 Å, within each of which exist more or less ordered arrays of chemical twinning planes and along which are therefore located the trigonal prismatic units. Disorder is introduced into the model by the assumption that the orientation of twinning planes is different in each domain.

By contrast, the structural studies which have been carried out on glassy metal-metal alloys have revealed much less tendency for chemical ordering compared with that observed in T–M materials. This can be seen by reference to Fig. 22, in which are shown the first peaks in the total RDF for two amorphous alloys of late transition metals (T) with rare earths (RE), namely, *a*-$Fe_{64}Gd_{36}$ and *a*-$Co_{82}Gd_{18}$ (Cargill, 1975). The first peaks are clearly observed to be split into three components, corresponding, respectively, to T–T, T–RE, and RE–RE nearest neighbors in ascending order of distance. There is thus no evidence for strong chemical ordering as in glassy T–M alloys, and the structure of amorphous T–RE alloys can be described approximately by a random mixture of the constituent metal atoms in a DRP structure.

5. FUTURE PROSPECTS

In this final section, likely future trends in techniques for the determination of the structure of amorphous solids are outlined, laying emphasis on those methods discussed previously in this review. It is apparent that these new developments, both experimental and theoretical, will provide new and increasingly detailed structural information for amorphous materials in the near future.

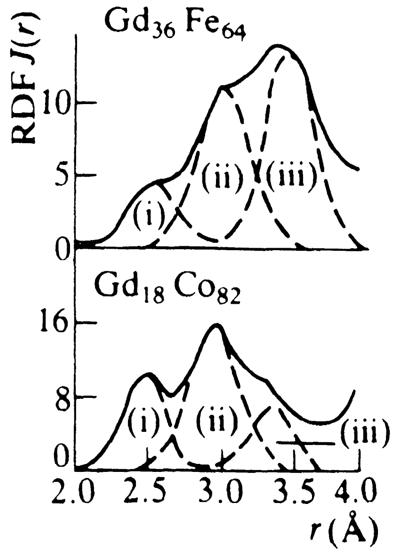

FIG. 22. First peaks of the total RDF for two late transition metal (T)–rare earth (RE) amorphous alloys (Cargill, 1975). In each case (i), (ii), and (iii) refer to T–T, T–RE, and RE–RE correlations, respectively.

5.1 X-Ray Absorption Spectroscopy

The use of the higher-brightness synchrotron sources shortly to be commissioned will enable more dilute systems to be investigated using fluorescence detection. Furthermore, such high-brightness x-ray sources will allow time-dependent XAS (and diffraction) measurements to be made using energy-dispersive detectors, so that the kinetics of structural changes may be followed. In addition, the newly developed technique of glancing-angle XAS, performed in total-reflection geometry, permits a depth-selective structural investigation of a surface region to be carried out using the evanescent x-ray wave as a probe. Preliminary experiments of this type have already been used to study leaching and corrosion processes at glass surfaces (Greaves, 1986), but higher x-ray photon fluxes should allow such experiments to be carried out in real time.

5.2 Nuclear Magnetic Resonance

It is perhaps in the field of NMR that the most significant developments are happening which promise to provide much new structural information for amorphous solids in the near future, despite the fact that the number of NMR-accessible nuclei is presently rather limited (but should be extended in the future). Three advances may be highlighted.

The first significant development to be discussed offers the prospect of a significant increase in resolution beyond that presently achievable using conventional MAS techniques. In the case of quadrupolar nuclei with values of nuclear spin $I \geqslant 1$ (which make up the majority of naturally occurring isotopes), MAS only removes the *first*-order term in the quadrupolar interaction (as long as the strength of the interaction is appreciably less than the spinning speed); the remaining second-order contribution to the quadrupolar interaction can still be strong enough so that the NMR lines are insufficiently narrowed by MAS operation to allow site-dependent chemical-shift differences to be discerned, although operation at high magnetic fields helps in this regard. The new technique of double sample rotation (Samoson *et al.*, 1988), in which a sample is rotated about *two* axes simultaneously, one being at the magic angle, allows even second-order quadrupolar interactions to be removed, leading to a significant improvement in resolution. This approach has been demonstrated for the case of ^{17}O in minerals (Chmelka *et al.*, 1989) but has not so far been applied in the case of glasses.

A second significant advance in NMR technique has been the development of the "multiple-quantum" interference method (Baum *et al.*, 1977). Normally, the Zeeman selection rule, $\Delta M = \pm 1$, applies to single-quantum transitions between nuclear spin levels. However, by means of the application of a particular rf pulse sequence, a system of N spins (each with $I = \frac{1}{2}$) can be forced to undergo essentially a cooperative transition in which the effective change in magnetic quantum number can be $\Delta M = N$ instead. The dipolar coupling between spins is employed to bring about the multiple-quantum transitions; the magnitude of this interaction depends on the internuclear distance as r^{-6}. Thus, for the case of completely isolated clusters each containing N spins, the maximum quantum transition possible is $\Delta M = N$, whereas for close clusters, or connected networks of spins, ΔM increases progressively as the "preparation" time in the rf pulse sequence is increased to allow time for more distantly separated spins to interact. This technique has been applied already to the case of protons in *a*-Si:H (Baum *et al.*, 1986; Gleason *et al.*, 1987), where it was found that device-quality material (with $\leqslant 10$ at. % H) appears to contain clusters of ~ 6 H atoms. In principle, this method could also be used to investigate clustering of other $I = \frac{1}{2}$ nuclei in glasses.

The final development to be discussed here offers the prospect of obtaining *direct* (bond-length) structural information from NMR measurements; this technique is "spin-echo double resonance" (SEDOR). In this, the dipolar interaction is again used to provide spatial information. A double resonance experiment is performed, in which the response at the resonant frequency of one type of nucleus is monitored while another type of nucleus is irradiated with rf radiation at its resonant frequency to cause spin flips. If the two nuclei are in dipolar spin contact, which essentially means in close physical proximity since the mediating dipolar interaction varies as r^{-6}, an influence of irradiation will be detected at the nucleus being monitored. From the behavior of the spin echo, an estimate can be obtained for the probable distribution of internuclear distances. This technique has been used so far to study the structural environment of dopants (e.g., B and P) in *a*-Si:H (Boyce *et al.*, 1987; Boyce and Ready, 1988), but the method could in principle also be used for other types of atoms in different amorphous systems.

GLOSSARY

Amorphous: A material lacking the long-range translational periodicity of a crystal (synonymous with noncrystalline).

Anomalous Scattering: Diffraction with scattering radiation having an energy close to that of an absorption edge for the radiation involved of an atom in a compound (alloy) material, with the result that the scattering factor contains complex and energy-dependent dispersion corrections.

Atom-Specific Structural Probe: An experimental technique for structure determination which is sensitive to the local structure around a selected element in a compound (alloy) material.

BO: Bridging oxygen.

Bridging: An anion which satisfies its normal twofold coordination (e.g., oxygen or a chalcogen) and connects two cation-centered coordination polyhedra.

Chalcogen: Element from group VI of the periodic table (e.g., S, Se, Te).

Chalcogenide: Compound material containing a chalcogen.

Chemical Order: The favoring of heteropolar bonds in a covalent compound material.

Chemically Ordered Network (CON): A continuous random network in which heteropolar bonds are favored.

Chemical-Shift Interaction: An interaction in nuclear magnetic resonance in which the resonant frequency of a nucleus is modified by the partial shielding of the external magnetic field due to the electronic charge distribution associated with the bonds to the atom containing the resonant nucleus.

Continuous Random Network (CRN): An idealized structure for a covalently bonded amorphous material, in which each atom adopts a coordination in accordance with its normal valence and there are no dangling bonds.

Coordination Number: The number of nearest-neighbor atoms surrounding an origin atom.

Coordination Polyhedron: The geometrical shape characterizing the fundamental structural unit of a covalently bonded solid, comprising a cation surrounded by nearest-neighbor anions.

Dangling Bond: The nonbonding orbital corresponding to a broken bond of an atom in a covalent material.

Dense Random Packing: An idealized model for the structure of a material held together by central forces (e.g., a metal), represented by a disordered aggregate of spheres.

Dihedral Angle: The torsion angle about a common bond required to bring into coincidence the projections onto the plane perpendicular to this bond of the other bonds comprising two connected coordination polyhedra.

Diffraction: The scattering of waves (e.g., x-rays, neutrons, or electrons) by pointlike objects (e.g., atoms).

Dipolar Interaction: An interaction between the dipole moments of two nuclei.

EFG: Electric field gradient.

EXAFS: Extended x-ray absorption fine structure.

Form Factor: The scattering intensity from a pointlike scattering entity.

FSDP: First sharp diffraction peak.

Glass: An amorphous solid exhibiting a glass transition.

Glass Transition: The point marking the transition from a liquid to a glass at which there is a discontinuity in derivative thermodynamic quantities (e.g., specific heat).

IR: Infrared.

IRMRO: Intermediate-range medium-range order.

Isomorphous Substitution: Partial replacement of an element in a compound (alloy) material by another element having a similar size and chemical characteristics, so that the overall structure is unperturbed.

Isotopic Substitution: Variation of the isotopic components of the elements in a material while keeping the overall atomic composition unchanged.

LRMRO: Long-range medium-range order.

Magic-Angle Spinning (MAS): A technique in nuclear magnetic resonance in which, by spinning a sample at a "magic" angle with respect to an external applied magnetic field, the interactions (dipolar, chemical-shift anisotropy, etc.) which otherwise would broaden the resonance signal are removed.

Medium-Range Order (MRO): The next higher level of structural organization at distances larger than that corresponding to short-range order.

Metalloid: Nonmetallic elements (e.g., C, P, Si, B, etc.) which form glassy alloys with metallic elements.

Molecular Dynamics (MD): A method for the simulation of the structure and atomic dynamics of liquids by following the time evolution of the classical motion of a collection of atoms interacting by means of a particular interaction potential.

NBO: Nonbridging oxygen.

Network Depolymerization: Change in the connectivity of the structure of a network former caused by the introduction of nonbridging (dangling-bond) sites accompanying the incorporation of network modifier cations.

Network Dimensionality: The number of dimensions traced out in a percolation process along covalent bonds in the structure of a covalently bonded material.

Network Former: A covalent material which, by itself, will form a glass.

Network Modifier: A cation (e.g., alkali) which causes coordination changes in the network-former structure, e.g., of the cation (charge in coordination polyhedron) or of the anion (network depolymerization with formation of nonbridging sites).

Neutron Scattering Length: The amplitude of scattering of neutrons from an atom.

NEXAFS: Near-edge x-ray absorption fine structure.

NMR: Nuclear magnetic resonance.

Nonbridging: An anion (e.g., oxygen or a chalcogen) which has a dangling bond or, equivalently, which is only singly coordinated.

Null Element: An isotopic mixture of an element for which the net neutron scattering length is zero.

Partial Correlation Function: The contribution to the total correlation function (e.g., radial distribution function) arising from pairs of specific types of atoms in a compound (alloy) material.

PDF: Pair distribution function.

Pnictogen: Element from group V of the periodic table (e.g., P, As, Sb).

Quadrupolar Interaction: An interaction between the quadrupole moment of a nucleus and the electric field gradient of the electronic charge distribution associated with the bonds to the atom.

Radial Distribution Function (RDF): The probability of finding an atom at a particular distance from an origin atom.

Random Covalent Network (RCN): A continuous random network structure of a compound material in which the distribution of bond types (heteropolar and homopolar) is determined statistically, i.e., by the composition.

RE: Rare earth.

SEDOR: Spin-echo double resonance.

Short-Range Order (SRO): Structural order of nearest-neighbor atoms around a given atom.

SRMRO: Short-range medium-range order.

Structure Factor: The interference function resulting from the diffraction (scattering) of waves from an array of scatterers (atoms) normalized to the scattering intensity (form factor) for each scatterer.

Superstructural Unit: A collection of coordination polyhedra comprising an effective structural unit in the structure of a covalently bonded amorphous solid.

TM: Transition metal.

TO: Transverse optic (phonon).

VDOS: Vibrational density of states.

VH: Vertical-horizontal (polarized Raman scattering).

Wrong Bond: Like-atom (homopolar) bond in a compound material.

X-Ray Scattering Factor: The amplitude of scattering of x rays from an atom.

XANES: X-ray absorption near-edge structure.

XAS: X-ray absorption spectroscopy.

INTRODUCTION

An amplifier magnifies the strength of a signal or wave form. It does so by extracting energy from a power supply (usually dc) and converting it into signal energy. This function makes it the single most important component in electronic engineering, its applications ranging from communications systems to instrumentation. In analog circuits, linear amplifiers are used most often to reproduce a weak input signal at a higher power while faithfully preserving its waveform. Amplifiers are also essential building blocks of digital circuits (*q.v.*) but here their nonlinear, or saturation, characteristics are used to implement logic gates. This article considers only linear amplifiers.

To appreciate the role of amplification, consider the familiar example of radio transmission and reception. In the broadcast studio, a microphone converts a voice or music into a weak electrical signal by responding to pressure variations in the air, which, after modulating the amplitude or frequency of a carrier sine wave selected for its favorable propagation characteristics, is then magnified by many amplifier stages to kilowatts of electromagnetic energy, and finally transmitted into space by an antenna. The intensity of these electromagnetic waves, monitored as power per unit area, will diminish as the inverse square of the distance away from the transmitter, inducing only a few microvolts, or perhaps millivolts, on the antenna of a receiver situated tens of miles away. For easy audibility, the received signal wave form, after extraction from the carrier, must be faithfully amplified in voltage to drive a loudspeaker coil, causing enough air to be displaced by the cone attached to that coil that a listener situated many feet away can easily hear the sounds being produced in the studio of the radio station. This example illustrates the alternating chain of of transducer and amplifier that recurs time and again in practice—microphone, amplifier, transmitter antenna, receiver antenna, amplifier, and loudspeaker. At the receiver, the role of the amplifier is to enhance the power level of a weak signal produced by one transducer (the antenna) in order to drive another transducer (the loudspeaker) at a power level which may be orders of magnitude higher. The amplifier does this by extracting signal-less power from a supply (the battery or ac mains) and converting it into signal power which is a magnified replica of the weak input.

The first electronic amplifiers relied on the modulation of electronic beams flowing in vacuum between electrodes held at a large potential difference, by applying the input signal to an intermediate electrode capable of modulating the beam. This was the vacuum tube (or valve in British terminology) based amplification device (see ELECTRON TUBES). Vacuum tubes were used widely for amplification until they were preempted in 1948 by the invention of what has turned out to be a far cheaper, more reliable and compact am-

plifying device, the semiconductor transistor. The rapid proliferation of this amplifying device heralded the electronics revolution.

1. SPECIFYING AMPLIFIER CHARACTERISTICS

There are four important characteristics that specify an amplifier: *gain, bandwidth, input impedance,* and *output impedance.* An amplifier may be designed to be driven by an input *voltage source,* and produces at its output a *voltage* which is a magnified replica of the input: this is called a voltage amplifier. To reduce a voltage loss across the series resistance of the source, the amplifier must have a high input impedance, while to drive an arbitrary load impedance with the amplified voltage without attenuation, the amplifier should have a low output impedance. The gain of a voltage amplifier is specified as a dimensionless quantity (volts/volt). Similarly, a current amplifier may be made, having a low input resistance to sample a current source driving its input, and a high output resistance to drive into the load the magnified input current without attenuation. The two remaining combinations of input and output stimulus type are a transimpedance amplifier, with current input and voltage output (whose gain is specified in volts/amp), and a transconductance amplifier, with voltage input and current output (Table 1). Choice of the amplifier type is determined by the application: while the voltage amplifier is most commonly encountered, a transimpedance amplifier must be used when the source is a current, as, e.g., the output current produced by a photodiode. It may be difficult in many instrumentation applications to determine whether a signal source with a certain resistive or capactive impedance should be considered a voltage or current source for the purpose of choosing the type of amplifier to follow it. One criterion is that the input impedance of the amplifier should not seriously attenuate the signal to be measured across the complete frequency range of interest. If, e.g., the source appears capacitive across the frequency range of interest, an amplifier with a high r_{in} will produce a very narrow bandwidth and cause the amplifier to perceive at its input the time integral of the source signal; in this case, an amplifier with low r_{in}, like a transresistance or current amplifier is more appropriate, for it will short out the capacitance and substantially extend the bandwidth at the input.

Table 1. Characteristics of amplifiers.

Type	Input	r_{in}	Output	r_{out}
Voltage	V	High	V	Low
Current	I	Low	I	High
Transresistance	I	Low	V	Low
Transconductance	V	High	I	High

Ideally, a linear amplifier should offer the same gain to an input signal, independent of the signal frequency. There are practical limits to this, however, for the amplifying devices and other components of the amplifier have capacitance in parallel with the signal path, which shunts signals to ground away from the output by an increasing degree as the signal frequency increases, until the shunting effect causes a substantial decrease in gain. The upper cutoff frequency of amplifiers is usually specified as that at which, for a fixed amplitude at the input, the power delivered by the amplified output signal to a resistive load decreases by a factor of 2. There may be a lower cutoff frequency as well, caused by other capacitors that have been inserted in series with the signal path for the purpose of decoupling the dc levels between different stages of the amplifier. Direct coupled amplifiers do not employ these series capacitors, and are capable of amplifying signals from dc to higher frequencies with uniform gain, limited only by the upper cutoff frequency. The difference between the upper and lower cutoff frequencies is the *bandwidth* of the amplifier in which signal frequencies experience a uniform gain.

Linear amplifier circuits are made out of amplifying devices, such as transistors or vacuum tubes, that are inherently nonlinear. Strictly speaking, amplifiers are always only approximately linear as long as the output signal swing is confined within certain limits. They become strongly nonlinear in saturation or cutoff, usually when the amplifier output reaches limits imposed by the positive and negative power supplies and no longer changes in response to the input signal. When this occurs, the amplified wave form is a clipped version of the input. To accommodate the largest input signal before distortion sets in at the output, the amplifier must be *biased* by choosing its dc operating point so that in the absence of the input signal, the output voltage lies in the middle of the positive and negative power supplies. Sometimes, when the bias points of two amplifier stages in cascade are unequal, the output dc of one stage must be blocked from the input of the next by a series capacitor, whose value is large enough to pass the signal frequencies of interest unattenuated, but which also introduces a lower cut-off frequency below which signals will be blocked.

Distortion, the deviation of the output wave form from the input wave form except for an amplitude scaling, is a measure of the nonlinearity in the amplifier. A distorting amplifier subject to a sinusoidal input at some frequency will produce at its output, in addition to amplified energy at this frequency, energy at integer multiple frequencies, or harmonics. The *total harmonic distortion*, the total power created in harmonics at the output relative to the power contained in the fundamental frequency, increases with the amplitude of the input.

2. TYPES OF SINGLE GAIN STAGES

The most common amplifier circuits using one transistor as the gain element are now described. Complex amplifier circuits may be decomposed into units of these stages connected together in some way. Bipolar transistor circuits (see TRANSISTORS, BIPOLAR) are illustrated here, although historically these circuits were built with vacuum tubes, and now may often use field-effect transistors (see TRANSISTORS, FIELD-EFFECT).

A brief introduction to bipolar transistor action is first given. This device is formed from a continuous semiconductor crystal containing two back-to-back junctions, in the form of either *npn* or *pnp* layers. In normal operation when the transistor is biased in the forward active region, the junction between the emitter and base (EB) is forward biased, injecting current carriers from the emitter into the base, which are swept into the collector across the favorable electric field at the reverse-biased collector-base (CB) junction. The magnitude of collector current (I_C) is controlled by the external current injected into the base (I_B) according to the current gain β. In addition, the electrical characteristics of the EB junction dictate that $I_C = I_S \exp(V_{BE}/V_T)$, where I_S, the reverse saturation current, is determined by the physical structure of a particular transistor and the physical constant $V_T = kT/q = 25$ mV at room temperature (300 K).

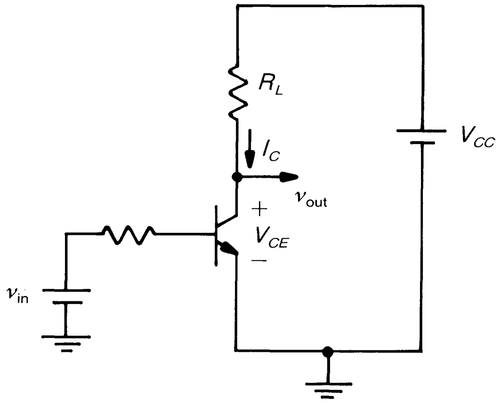

FIG. 1. The common-emitter bipolar transistor amplifier.

2.1 Common-Emitter Amplifier

This single-transistor amplifier (Fig. 1) affords the largest voltage gain. The input voltage is applied at the transistor base-emitter junction, which acts as a control on the current (I_C) that flows from collector to emitter. The circuit is called a common-emitter circuit, because the input and output voltages are referenced to the common emitter node. The voltage developed by the collector current flowing in the load resistor R_L defines the amplifier output. The amplifier is clearly nonlinear, being exponential due to the transistor characteristics in the forward active region, and its output voltage is limited by the positive and negative power supplies (V_{CC}, ground). More precisely, the transistor is cut off when I_C diminishes to zero, and the output current cannot go any lower; or it is saturated when V_{CE} tends to zero, when the output voltage cannot go any lower in response to the input. However, because most often a very small signal is applied at the input, the transistor current varies only over a small portion of the exponential nonlinearity, and so the transfer function around the quiescent operating, or bias, point may be approximated by a linear function, the derivative of the nonlinearity. Amplifier characteristics like the voltage gain (A), input resistance (r_{in}), and output resistance (r_{out}) may thus be expressed for small signals as follows:

$$A=R_L\frac{dI_C}{dV_{BE}}=\frac{I_C}{V_T}R_L, \tag{1}$$

$$r_{\text{in}}=\frac{dV_{BE}}{dI_B}=\frac{V_T}{I_B}, \tag{2}$$

$$r_{\text{out}}=R_L. \tag{3}$$

It is customary to denote bias currents and voltages by capital letters (e.g., I_C,V_{BE}) and small signals superimposed on these biases by small letters (e.g., i_c,v_{be}). The small-signal quantity dI_C/dV_{BE} is called the transconductance (g_m), while dV_{BE}/dI_B is called the diffusion resistance (r_π).

The common-emitter is the most frequently used gain stage, offering the largest gain of all single-transistor amplifiers with resistive loads. The transistor capacitances, whose magnitude is determined by the physical structure of the device, together with the source resistance R_S and load resistance R_L determine the bandwidth. When driven by a voltage source, r_{in} of the amplifier is made large by biasing it at a small base current (I_B). The collector current is then set by the value of transistor current gain β. To obtain a desired voltage gain, set by the I_CR_L product, an appropriate R_L must be chosen, which then sets the output resistance of the amplifier.

2.2 Common-Collector Stage

While the common-collector amplifier stage (Fig. 2) offers a voltage gain of almost 1, its use is principally as a buffer, because its input resistance is much higher and its output resistance much lower than the same transistor connected in the common-emitter configuration. These quantities are given by

$$A=\frac{g_mR_E}{1+g_mR_E}\sim 1, \tag{4}$$

$$r_{\text{in}}=r_\pi+\beta R_E, \tag{5}$$

$$r_{\text{out}}=(g_m+1/R_E)^{-1}. \tag{6}$$

A buffer stage may be connected, e.g., between two common-emitter gain stages in cascade, offering a high resistance to the output of the first stage, transferring the output voltage almost unaltered to the next gain stage with a low source resistance, so that the input resistance of the latter does not load down, and thus attenuate the gain of the first stage.

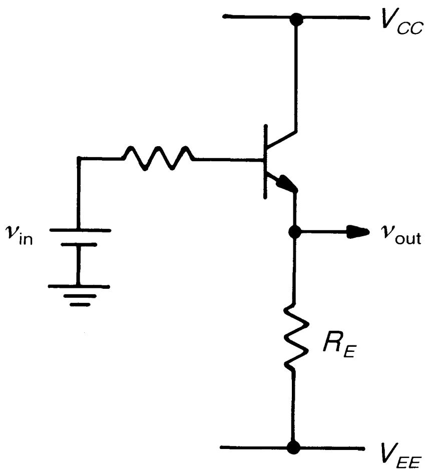

FIG. 2. The common-collector amplifier, or emitter follower.

Because the emitter of the transistor follows the applied input voltage with a gain of almost 1, this configuration is also known as an emitter follower.

2.3 Common-Base Stage

The common-base stage (Fig. 3) is used as a current buffer, in contrast to the common-collector, which acts as a voltage buffer. The common-base stage offers a low input resistance, and therefore is suitable to be driven by a current source. In normal operation, the emitter current of a transistor is very slightly larger than the collector current, so that the effective current transfer, or gain, is slightly less than unity. However, the output resistance at the collector is high, making the stage appear as an almost perfect current source.

One application of the common-base stage is as a buffer following a common-emitter stage, which, by offering a low resistance to the latter, suppresses the multiplication of the capacitance (C_{cb}) by the voltage gain, which is very often the dominant factor in reducing the bandwidth of a common emitter amplifier. This combination is called the cascode.

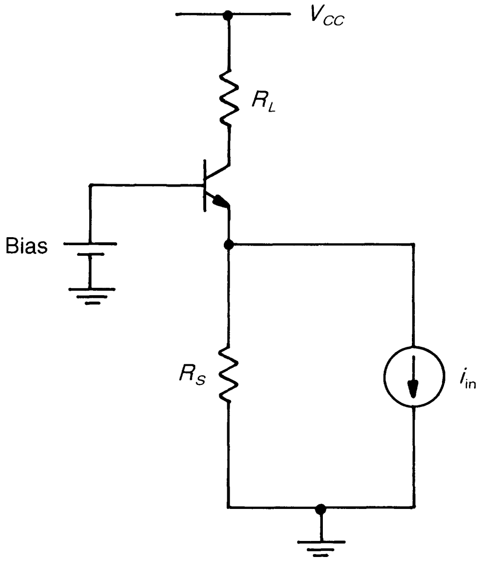

FIG. 3. The common-base amplifier.

2.4 FET Gain Stages

Field-effect transistors (FETs) work on different physical principles than the bipolar, but may be used as amplifiers in identical topologies to the bipolar transistor circuits described above. The field-effect transistor has a capacitive input which takes no dc current for operation, and is therefore used to make amplifiers that have a high input impedance at low frequencies. FET amplifiers have also become common recently because sometimes only these devices are available on complex integrated circuits.

3. DIFFERENTIAL AMPLIFIERS

In many instances, it is desirable to amplify only the *difference* in two signals, or the difference between a signal and a reference, while rejecting the average, or common-mode, component. The wires leading from a sensor like a thermocouple, e.g., that converts some physical quantity to a small voltage and transmits it to a remote amplifier may pick up greater interference and noise from the surroundings than the voltage generated by the thermocouple. A differential amplifier connected at the end of these wires will amplify only the thermocouple voltage, which appears as a potential difference between the wires, while rejecting the interference which would appear as an equal voltage on each wire relative to ground potential.

The classic differential amplifier (long-tailed pair in British terminology) is a pair of transistors biased by a high resistance or current source at their common emitter (Fig. 4). Two input signals (v_{i1},v_{i2}) are applied at the bases and the output is taken as the difference of the two collector voltages (v_{o1},v_{o2}). The amplifier responds in one way to balanced, antiphase inputs, and in another to equal, inphase signals at the inputs. For small balanced antiphase input signals, called a differential excitation, the emitter potential will tend to remain constant (by symmetry), so that $v_{be1} = v_{i1}$ and $v_{be2} = v_{i2}$, providing the full gain of a common-emitter stage at each collector. Equal and opposite signal currents, $g_m v_{i1} = -g_m v_{i2}$ will flow in the emitters. The difference of the collector voltages will double the signal amplitude. For equal, in-phase signals at the two inputs, called a common-mode excitation, the emitter will tend to follow the inputs, inducing a small current in the large resistance from the emitter to supply, which will split equally between the two transistors. The differential and common-mode gains are given by

$$A_{\mathrm{DM}} = g_m R_L, \tag{7}$$

$$A_{\mathrm{CM}} = R_L/2R_E, \tag{8}$$

where the fact that $g_m R_E = I_E R_E / 2V_T \gg 1$ implies $A_{\mathrm{DM}} \gg A_{\mathrm{CM}}$. The common-mode rejection

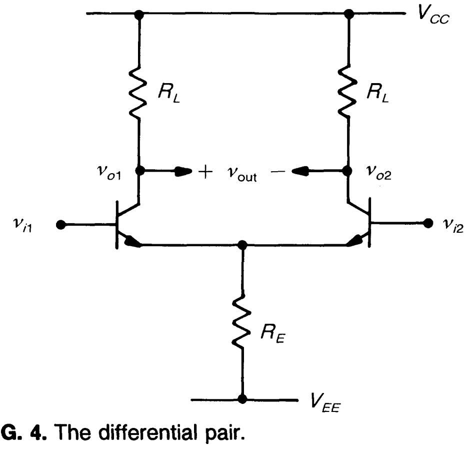

FIG. 4. The differential pair.

ratio is the factor by which the differential gain is greater than the common-mode gain.

In general, using linear superposition, two independent small input signals may be resolved into a balanced, antiphase component and a common-mode component. The response of the amplifier is the linear superposition of each component subjected to the appropriate gain.

4. OPERATIONAL AMPLIFIERS

Differential voltage amplifiers with a very high voltage gain and common-mode rejection ratio (ideally infinite), very high input resistance, and low output resistance are used as building blocks in feedback circuits that perform precise mathematical functions, like algebraic summation, integration, filtering, comparison, etc. These circuits are termed operational circuits, and the amplifiers used to make them operational amplifiers, or op amps. The operations are implemented by the electrical characteristics of passive elements used in feedback around the operational amplifier which serves either to decouple the interaction of two elements constituting the feedback loop, to invert the characteristics of one element, or simply to provide gain. In most cases, one or more passive elements connected between the output and inverting input introduce negative feedback around the op amp, implying that as long as the output of the op amp is not saturated and the gain of the op amp is assumed infinite, the differential voltage at its input will necessarily be zero. Any tendency of the differential input to deviate from zero would be overcome by the action of the negative feedback. Op amp circuits are analyzed and synthesized on the assumption that the differential voltage is zero in normal operation; this is called the virtual ground property. Thus, in the inverting amplifier [Fig. 5(a)] the voltage at the negative op amp input is held at 0 V by the action of feedback, forcing the current flowing from the applied input voltage to equal v_{in}/R_1. The output voltage, determined by this same current flowing through the feedback resistor R_0, is given by $v_{\text{out}}=-(R_0/R_1)v_{\text{in}}$, noting that no current flows into the very high input resistance of the op amp. The same circuit may be converted into a noninverting amplifier [Fig. 5(b)] by retaining the negative feedback connection, but applying the input v_{in} instead at the positive input. Again, negative feedback forces the differential voltage between the two op amp inputs to zero, implying that $v_{\text{out}}=(1+R_0/R_1)v_{\text{in}}$. This topology may be generalized to an algebraic weighted sum circuit [Fig. 5(c)] where a weighted resistive voltage divider sets up the voltage at the positive (noninverting) input of the op amp v_+, as given by

$$v_+\left(\frac{1}{R_0}+\frac{1}{R_{p1}}+\frac{1}{R_{p2}}+\cdots+\frac{1}{R_{pk}}\right)=\frac{v_{p1}}{R_{p1}}+\frac{v_{p2}}{R_{p2}}+\cdots+\frac{v_{pk}}{R_{pk}}. \tag{9}$$

Negative feedback through R_0 from the output to the negative (inverting) input of the amplifier then enforces the voltage $v_-=v_+$. Thus, the output voltage is given by

$$v_{\text{out}}=R_0\left(\frac{v_{p1}}{R_{p1}}+\frac{v_{p2}}{R_{p2}}+\cdots+\frac{v_{pk}}{R_{pk}}\,\frac{1+R_0\Sigma_1^{l+1}(1/R_{mi})}{1+R_0\Sigma_1^{k+1}(1/R_{pi})}-\frac{v_{m1}}{R_{m1}}-\frac{v_{m2}}{R_{m2}}-\cdots-\frac{v_{ml}}{R_{ml}}\right). \tag{10}$$

An arbitrary weighted sum may be obtained by selecting the resistor ratios $R_{m,n}/R_0$, and by making the sum of all the R_m equal to R_n after choosing appropriate values, as necessary, of the two free resistors R_{ml+1},R_{nk+1} connected to ground.

Time-domain functions like integration and differentiation may be performed with op amps which use the electrical properties of capacitors [Figs. 5(d) and 5(e)]. Finally, useful nonlinear functions may be implemented by using nonlinear devices in feedback. For example, an absolute value circuit may be constructed using two op amps and the rectification properties of diodes in the feedback loops [Fig. 5(f)]. For positive v_{in}, diode D_1 conducts but diode D_2 does not, so v_{in} appears unmodified at the output after passing through two unity-gain inverting amplifiers. For negative v_{in}, diode D_2 conducts but D_1 does not, and there is feedback from the output to both op amps. If the amplifiers are not saturated, the sum of feedback currents at the inverting input of the first op amp must equal

FIG. 5. (a) Inverting voltage amplifier using op amp; (b) noninverting amplifier using op amp; (c) weighted algebraic sum circuit; (d) a voltage integrator; (e) a voltage differentiator; (f) an absolute value circuit; (g) a logarithmic amplifier dependent on transistor characteristics; and (h) a logarithmic amplifier using the characteristics of a cascade of saturating amplifiers. One saturating amplifier is shown with its input-output characteristic. The logarithmic amplifier is obtained by summing the outputs of many such identical amplifiers in cascade.

v_{in}/R, which is only possible if $v_{out}=-v_{in}$. This produces the absolute value function.

The *I-V* characteristics of a *pn* junction may be used to make a logarithmic amplifier [Fig. 5(g)]. The output voltage $v_{out} = -V_T \log_e(v_{in}/RI_s)$ is indeed logarithmic but suffers from a very strong temperature dependence due to the terms I_s and V_T. A variety of ways have been used to reduce or eliminate this temperature dependence, principally relying on taking the difference in the output voltages of two logarithmic amplifiers, one driven by v_{in} and the other by a normalizing reference V_{ref}. This produces a ratiometric logarithmic output which varies proportionally with absolute temperature. This temperature dependence may be removed more simply by other methods. An altogether different method may also be used to produce a logarithmic amplifier, based on the saturation characteristics of an amplifier. If the outputs of a cascade of identical amplifiers are summed [Fig. 5(h)], an approximation to a logarithmic characteristic is obtained which is inherently independent of temperature.

Operational amplifiers are widely available as low-cost integrated circuits (*q.v.*), at times costing only as much as discrete transistors. For dc and low-frequency operation, their terminal characteristics are very close to the ideal, with input resistances of tens of megohms, output resistances of a few ohms, and dc gains exceeding 100 000. These characteristics deteriorate at high frequencies due to the frequency limits of the transistors constituting the op amp circuits, but more significantly due to a deliberate rolloff introduced in gain to ensure stable operation when feedback is applied. The gain may have decreased to unity from its large dc value at frequencies typically lying in the range of 1 to 10 MHz. This may introduce significant nonidealities in operational circuits at signal frequencies approaching the unity-gain frequency.

5. FEEDBACK AMPLIFIERS

Operational circuits are only one, somewhat ideal, instance of the use of negative feedback around amplifiers. Feedback evolved as a means of stabilizing amplifier characteristics, by subtracting a portion of the output signal from the applied input, and using the difference to drive the amplifier. The terminal characteristics are then strongly governed by the external, passive elements used in the feedback network, and become relatively independent of the lack of absolute accuracy in the gain of the active elements constituting the amplifier. Black, working at Bell Telephone Laboratories, first applied the notion of feedback in 1934 to stabilize fluctuations in the gain of vacuum tube amplifiers used in telephone repeaters by subtracting a fraction of the output voltage from the applied input, and feeding the *difference* to the amplifier input (Fig. 6).

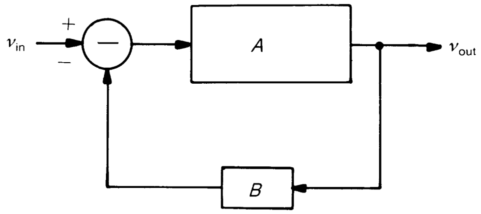

FIG. 6. Block diagram of a negative feedback loop. The quadranted circle at the input indicates the differencing operation between input and output variables (both assumed to be of the same type).

The transfer function of a voltage amplifier with gain *A*, around which negative feedback is applied by subtracting a fraction *B* of the output, is given by

$$\frac{v_{out}}{v_{in}}=\frac{A}{1+AB}. \tag{11}$$

As long as the *loop gain AB* is large, the closed-loop transfer function of the amplifier with feedback is almost equal to $1/B$, thus relatively insensitive to fluctuations in the open-loop amplifier gain *A*.

The use of feedback is illustrated here in a single-transistor amplifier, the emitter-degenerated voltage gain stage [Fig. 7(a)]. This resembles the standard common-emitter amplifier except that a resistor R_E has been inserted in the emitter circuit. Realizing that v_{in} applied at the base of the transistor modulates a current between the emitter and collector, and that this current flowing through R_C produces v_{out}, the implicit feedback loop becomes apparent; for an increase in v_{in} produces an increase in i_c through the transistor, which increases the voltage v_e, *subtracting* from the applied input to reduce the drive to the transistor $v_{be}=v_{in}-v_e$. A block diagram

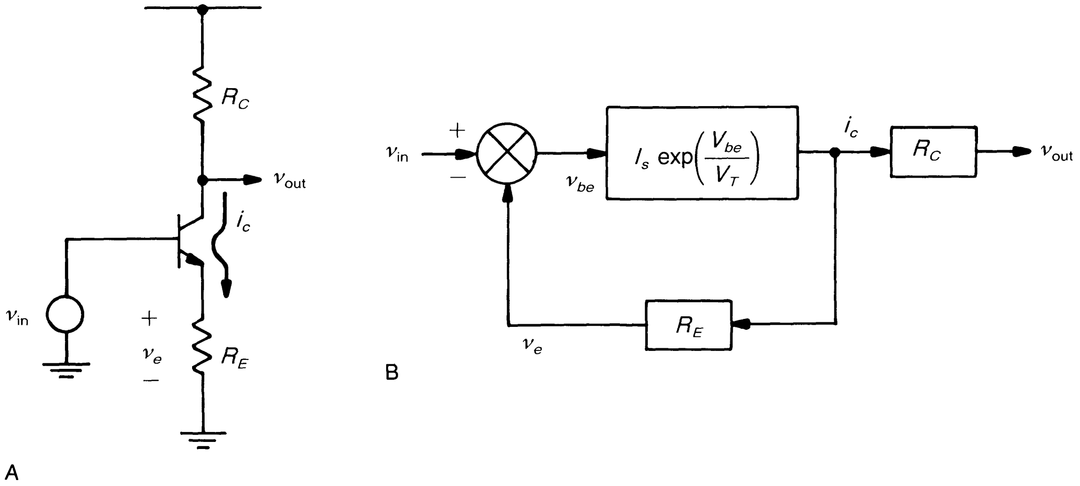

FIG. 7. (a) A single transistor feedback amplifier: the emitter degenerated stage; (b) feedback block diagram of emitter degenerated stage.

specifying the elements of the feedback loop is also shown [Fig. 7(b)]. If the loop gain is high, $i_c \approx v_{in}/R_E$, which implies that the gain

$$v_{out}/v_{in} \approx -R_C/R_E \tag{12}$$

is determined by the feedback element and becomes independent of the transistor characteristics. This is the virtue of feedback: the transistor in the circuit could be replaced by another of different characteristics (different I_s, that is); the temperature, on which transistor current depends exponentially, could be changed, or the bias current could be changed; but as long as the transistor remains in the active region, the gain of the amplifier does not change, being determined by the ratio of two resistors chosen by the user. This desensitization to the characteristics of the active device motivated the very first use of feedback in amplifiers, because vacuum tubes showed a notoriously large spread of characteristics in manufacture, and the characteristics of a given tube were liable to drift with aging.

After application of negative feedback, the gain available from the stage is reduced, because a smaller quantity than the applied input, $v_{in} - v_e$, appears as the effective drive to the amplifying element, whereas in the common-emitter amplifier, all of the input voltage drives the transistor. This reduction in gain is one disadvantage of feedback.

The signal in a feedback amplifier has to flow in a closed loop, forward through the amplifier and back through the feedback path, and after subtracting itself from the applied input, back into the amplifier. At some high signal frequency, the delay through this feedback loop may become comparable to the period at which the signal is varying: if the delay is equal to half the period of the sinusoid of frequency f_0, the signal will experience a phase lag of 180° after traveling through the feedback loop, and instead of subtracting from the applied input as had been intended at low frequencies, the fed back signal will *reinforce* it. If the magnitude of the loop gain (AB) at f_0 is 1 or more, a signal at this frequency can sustain or build itself without the application of an input. Thus, such a feedback amplifier is capable of *oscillation*, undesirable because a sustained sinusoidal output exists for no applied input. The amplifier is, in a manner of speaking, out of control.

Oscillation in a feedback amplifier may be prevented by introducing a stabilizing, or compensating, network in the feedback loop, whose function is to reduce the loop gain to less than 1 at the critical frequency f_0 where the loop phase shifts by 180°. Without this, the feedback amplifier is unusable. The exact conditions for the occurrence of oscillation in a feedback loop are described by the Nyquist criterion, which in its simplest form reduces to the conditions for oscillation described above. Operational amplifiers are compensated to remain stable under the largest dc loop gain a user may subject them to, which occurs when all of the output is subtracted from the input, corresponding to a closed-loop dc gain of 1 (because $B=1$, and the closed-loop transfer function is $1/B$). This means that at the frequency where the open-loop gain of the compensated op amp has rolled off to 1, the phase shift through the op amp is less than the critical 180° (typically, it is kept less than 135° for an added factor of safety). The resulting *unity gain frequency* together with the *dc gain* specify the two most important characteristics of the op amp. Compensation in this way inevitably compromises the bandwidth of an amplifier.

6. POWER AMPLIFIERS

While voltage amplifiers are encountered most often, power amplifiers are another class of circuits having many important applications. Their function is to deliver a signal to a load at an amplified *power level* which may be obtained with a voltage gain of only 1, but a much larger current swing than available directly from the driving source. Thus, the *product* of the signal voltage and current is amplified by this circuit. A power amplifier usually drives a large output signal, and may *distort* at the output due to the saturation or cutoff of the transistors in the circuit.

The simplest power amplifier is an emitter follower (Fig. 8). This has a voltage gain slightly less than 1, but converts current drawn from the power supplies into a signal driving the load. An *npn* emitter follower may provide a very large current for a positive output swing (because the exponential I_C-V_{BE} characteristic requires only a small increase in V_{BE} to produce a large change in output current), but the maximum current to produce a negative swing on the load is limited by the current source I_{EE}. If the output voltage swings more negative than $I_{EE}R_L$, the transistor will be deprived of all emitter current, severing the follower action between the input and output voltages. For a given load, a large undistorted swing requires a large power supply voltage and large I_{EE}, implying that in the absence of a signal, the transistor dissipates considerable power. Those power amplifiers which carry the maximum possible signal current in the quiescent condition are called *Class A* amplifiers. Their power conversion efficiency, defined as the maximum undistorted signal power delivered to the load for unit dc power extracted from the power supplies, is low (25% for the emitter follower) because a large fraction of the power is dissipated in the transistor itself. In that a large heat sink, necessarily bulky and expensive, capable of dispersing the generated heat to keep the transistor temperature at a reasonable value must be used, a Class *A* power amplifier is undesirable.

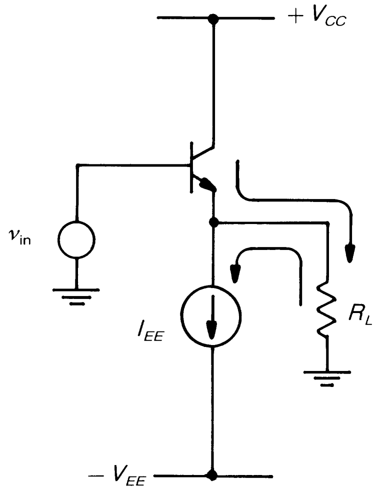

FIG. 8. The emitter follower as a class A power amplifier.

An improvement in efficiency is afforded by *Class B* power amplifiers. These circuits are designed to be normally off, only starting to conduct when current must be delivered to a load. Unlike the Class A amplifier described above, a standing current is not diverted to provide the load current; instead, two complementary transistors are biased back to back, so that one may act as an emitter follower when current must be sourced into the load from the positive power supply, while the other turns on to act as a current sink from the load to the negative power supply (Fig. 9). Only one of the transistors is on at a time when delivering current to the load; no standing current exists in the circuit in the absence of the load. The power conversion efficiency of this circuit is 75%.

The signal current must cross over from being provided by the *npn* transistor to the *pnp* transistor, and this action can give rise to some distortion. For to cause the *npn* to con-

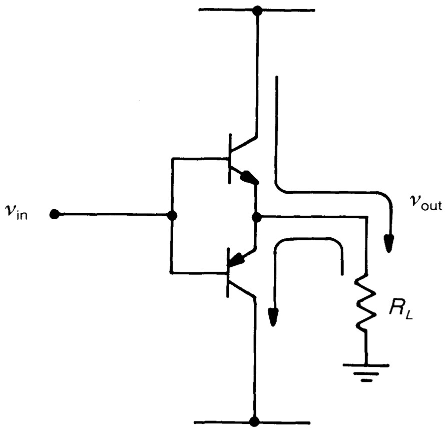

FIG. 9. A class B power amplifier using complementary transistors.

duct, v_{in} must become more positive than $V_{BE}(ON)$, while to cause the *npn* to conduct v_{in} must be more negative than $-V_{BE}(ON)$. This produces a dead band of $2V_{BE}(ON)$ around zero v_{in} over which the output voltage does not respond to the input. The crossover distortion may be overcome by inserting a fixed voltage source of 2 $V_{BE}(ON)$ between the two base terminals to bias both transistors at the edge of conduction. The signal is transmitted to the two bases separated by this offset voltage. The resulting power amplifier has some standing current flowing through the two transistors in series, which is usually quite small to bias them just at the edge of conduction, and so is called a *Class AB* power amplifier. These are most common in low-distortion audio power amplifier circuits.

7. NARROW-BAND AMPLIFIERS

Radio and TV communications signals, consisting of a carrier modulated by a signal with a bandwidth only a small fraction of the carrier frequency, are narrow band in the sense that useful energy is contained in only a small range around the carrier frequency. The carrier frequencies may extend from hundreds of kilohertz (AM) to tens of gigahertz (microwave). Amplifiers for such signals are also narrow band, i.e., their frequency response resembles the signal spectrum in that they offer gain only in the neighborhood of some well-defined center frequency, and the gain rolls off above and below this frequency. This characteristic may be obtained by using, e.g., a parallel *L-C* tuned circuit as the load to a common-emitter transistor amplifier stage (Fig. 10). Such an amplifier may also have a tuned input circuit, which provides an additional measure of *selectivity*, an important feature when the circuit is required to amplify only one of many closely spaced communications channels while filtering out, or rejecting, all the neighboring ones.

Using a small, low-loss inductor, it is possible to make a resonant circuit using the collector capacitance of the transistor itself in shunt with the inductor. This affords the possibility of obtaining gain across a bandwidth dictated by the Q factor of the tuned circuit at resonance, at frequencies well beyond the capability of a standard wide-band common-emitter amplifier with a resistive load, whose collector capacitance is detrimental in shunting high frequencies to ground. This principle of tuning out the detrimental capacitance underlies microwave amplifiers, which are almost always narrow band and offer modest amounts of gain centered at very high frequencies. The highest frequency at which gain may be obtained by this method is limited by transistor physics, for if the input signal varies at a rate faster than the time taken for a charge carrier to transit through the active region (e.g., the base for a bipolar), the effect of the input will tend to smear at the out-

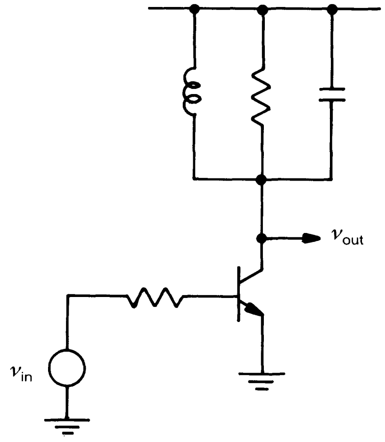

FIG. 10. A tuned amplifier using *L-C* resonant-circuit load.

put, reducing the gain. Thus, to make narrowband amplifiers at ever increasing frequencies, transistor structures with shorter carrier transit times through the active region are necessary, requiring ever more sophisticated technology for fabrication. Heterostructure transistors whose base regions are defined by growing layers a few molecules thick are the latest development in making very high-frequency active devices.

8. DISTRIBUTED AMPLIFIERS

Gains from dc to very high frequencies, often stretching into the microwave spectrum, may be obtained by embedding many stages of amplification into an artificial transmission line terminated in its characteristic impedance. A transmission line with a uniform inductance and capacitance per unit length possesses, ideally, an infinite bandwidth, limited in practice at many gigahertz by losses due to the nonzero resistance of the conductors and losses in the dielectric. With the inputs of many stages of identical amplifying devices connected in parallel by inductors, and their output terminals also connected in parallel by inductors, two transmission lines result consisting of discrete inductors in series and (amplifier) capacitors in parallel. If these are terminated in their characteristic impedance, a very wide-band signal may flow along the input line without attenuation, and the resulting output signals may be made to add up in phase at the output transmission line across a broad bandwidth.

This principle of distributed amplification has been used to make very wide-band microwave amplifiers and, more recently, monolithic microwave integrated circuit (MMIC) amplifiers.

9. NOISE IN AMPLIFIERS

Distortion due to the active devices sets the limit on the largest signal that is reproduced with fidelity by an amplifier. What sets the lower limit? Will an indefinitely small signal appear amplified at the output with fidelity? Random electrical noise in the amplifier components sets the lower limit, and so if a very small signal were applied at the input, the output would indeed contain an amplified replica of the input, which, however, would be overwhelmed in magnitude by the amplified noise. The most common instance of this phenomenon is in radio receivers, which may be receiving a very weak signal of only a few tens of microvolts from a distant transmitter, but which may be overwhelmed by noise at the output.

One source of noise, Johnson or thermal noise, is produced in any resistor by the random thermal agitation of electrons. On average, electrons stay uniformly distributed through the body of the resistor, but instantaneously more electrons may aggregate on one side than the other, producing an electric field between the resistor terminals whose magnitude and polarity varies randomly, but is zero on average. The laws of thermodynamics dictate that the maximum root mean square (rms) noise power available from the resistor is kTB, where k is Boltzmann's constant, T the absolute temperature, and B the bandwidth of observation. This means that the rms noise voltage at the terminals of an open-circuit resistor is

$$v_n(\mathrm{rms}) = (4kTRB)^{1/2}. \tag{13}$$

Another form of noise arises from the random diffusion of carriers across a potential barrier, as is the case in a diode or a junction in a bipolar transistor carrying a direct current. This shot noise appears as fluctuations in the direct current, with zero average but an rms value of

$$i_n(\mathrm{rms}) = (2qI_{\mathrm{dc}}B)^{1/2}. \tag{14}$$

A noise signal has a flat frequency spectrum extending from dc to extremely high frequencies. It may be thought of as constituted of sine waves at all possible frequencies of equal amplitude, added together in random phase. The wave form of noise in time appears like a "fuzz," whose strength is determined by the rms values given in the equations above.

The design of low-noise amplifiers involves choosing the operating points of the active devices and values of the resistors in the circuit so that the sum of their noise contributions amplified at the output does not overwhelm the smallest amplified signal. Radio and television receivers must be designed like this, and take advantage of the fact that they are narrow-band circuits, thus having a small noise bandwidth *B*. Much effort and ingenuity were expended in the early days of radio receivers to make highly sensitive low-noise amplifiers, culminating in the superheterodyne technique, where low-noise amplification is obtained by modulating the envelope of a strong, low-noise, single-frequency local oscillator signal in the receiver with the weak input signal close to the antenna, making the noise due to subsequent stages unimportant. This is now the standard technique employed in all communications receivers.

GLOSSARY

Amplifier: A device capable of magnifying signal power by using an input signal to modulate a reservoir of energy.

Analog Circuit: A circuit in which signal wave forms vary continuously in time and in magnitude.

Gain: Magnification.

Bandwidth: The range of signal frequencies across which uniformly maximum amplification is obtained.

Bipolar Transistor; Bipolar Junction Transistor (BJT): An amplifying device relying on the modulation of current at the output by the control of a potential barrier.

Bias: A nominal current or voltage to place the operating point of a device in a favorable region for amplification.

Common: A connection common to the input and output ports, usually ground.

Field-Effect Transistor (FET): An amplifying device relying on the modulation of a resistive region by an electric field to obtain amplification.

Feedback: Driving an amplifier derived from the difference of an applied input signal and the prevailing output signal (or some fraction, or some filtered version, or some nonlinearly modified version thereof).

Narrow Band: A small fractional bandwidth centered on some (usually high) frequency.

Distributed Circuit: Any circuit becomes distributed when the physical dimensions of its components and interconnections become comparable to the wavelength of signals propagating in it. Also, a circuit with a uniform impedance level throughout its extent.

Noise: Random fluctuations in current and voltage, usually very small, due to the microscopic agitations of charge carriers.

INTRODUCTION

The article on analytic methods is subdivided into the following five broad and interrelated subjects: functions of a complex variable, ordinary differential equations, partial differential equations, integral equations, and applied functional analysis. Throughout the article, emphasis is placed on methods of application involving physical problems and physical interpretations of solutions rather than on a rigorous mathematical presentation. Special cases of linear relations in one and two Cartesian dimensions are used to explain techniques. Extensions to more general cases and different coordinate systems are straightforward, in principle.

Section 1 is devoted to some aspects of complex variable theory needed in mathematical physics. The section begins with a discussion of complex variables and their representations, analytic and singular functions of a complex variable, important integral relations, and the Taylor and Laurent expansions. The Cauchy residue theorem is applied to obtain the Cauchy principal value of an integral and dispersion relations. A discussion of the uses of dispersion relations throughout physics is also given. The section is concluded with a brief discussion of physical applications of conformal transformations and Riemann surfaces.

Section 2, on ordinary differential equations, treats classes of physical problems that lead to first- and second-order ordinary linear differential equations. Procedures for obtaining solutions for first- and second-order ordinary linear differential equations are presented. Methods of applying initial and boundary conditions are discussed. Green's functions are introduced in connection with the variation of parameters method for solving second-order nonhomogeneous differential equations with variable coefficients. A brief introduction to numerical methods for solving first- and second-order ordinary differential equations is also presented.

In the section on partial differential equations (Sec. 3), some important partial differential equations involving the Laplacian operator are presented and explained. Separation of variables and Fourier transform methods for solving partial differential equations are illustrated. Green's functions for three-dimensional problems are discussed in this section. Extensions to cylindrical and spherical coordinates and to certain special functions in mathematical physics are discussed. The section is concluded with a brief presentation of numerical methods for solving partial differential equations.

An introduction to one-dimensional linear integral equations is given in Sec. 4. Discussions of classifications and methods of solution of integral equations are given. The essential difference between an integral- and a differential-equation formulation of a physical problem is discussed. The Abel problem is presented as an example of a physical problem that leads directly to an integral equation.

The focus of Sec. 5 is on applied functional analysis. The method of the calculus of variations is introduced in connection with finding the extremum of the definite integral of a functional, and techniques of variational calculus are applied to Hamilton's variational principle of mechanics. The Feynman path integral approach to quantum mechanics is presented as an example of functional integration.

1. FUNCTIONS OF A COMPLEX VARIABLE

1.1 Introduction

The imaginary number, $i = \sqrt{-1}$, was introduced into mathematics during the latter part of the sixteenth century. Imaginary numbers are needed since certain equations, for example, $x^2 + 1 = 0$, have no solutions that involve only real numbers. In physics, one writes the solution of the equation of motion for the linear harmonic oscillator, $\ddot{x} + \omega^2 x = 0$, in the form $x(t) = A \exp(i\omega t)$. Index of refraction is written in complex (containing real and imaginary parts) form in modern optics, and the wave function in quantum mechanics is often a complex quantity. How physical results are obtained from complex numbers or functions of a complex variable will be explained below. Complex variables are used throughout physics, and this section is devoted to discussions of some properties of complex variables that are useful in physical applications.

1.2 Complex Variables and Their Representations

A complex variable may be written in the general form

$$z=x+iy=re^{i\theta}. \qquad (1)$$

In Eq. (1), x and y are the respective real and imaginary parts of z and are written as $x=\text{Re}z$ and $y=\text{Im}z$; θ is the argument (phase) of z and is written as $\theta = \arg z = \theta_p + 2\pi n$ for $n=0,1,2,\ldots$; θ_p is the principal argument of z and varies from 0 to 2π; $e^{i\theta} = \cos\theta + i \sin\theta$ (Euler's formula); and $r=|z|$ is the absolute value (magnitude, modulus) of z where $r = (x^2 + y^2)^{1/2}$. The complex conjugate of z is denoted as z^* (for notational convenience, $\bar{z}$ is sometimes used to denote complex conjugate) and is obtained by changing the sign of the imaginary part (or imaginary terms) of z, $z^*=x-iy$. It is clear, and useful to note for physical purposes, that z^*z is a real quantity. Complex variables are subject to the same algebraic laws as real variables. The Argand diagram (z-plane diagram) is a convenient geometrical representation of a complex variable and is illustrated in Fig. 1.

On raising Eq. (1) to the nth power, one obtains

$$z^n=r^n(\cos\theta+i\sin\theta)^n=r^ne^{in\theta}$$
$$(n=0,\pm1,\pm2,\ldots \text{ and } z\neq0). \qquad (2)$$

Equation (2) is de Moivre's theorem and is often written as

$$(\cos\theta+i\sin\theta)^n=\cos(n\theta)+i\sin(n\theta). \qquad (3)$$

de Moivre's theorem may be used to obtain relations involving sines and cosines of multiple angles. On considering de Moivre's theorem for $n=2$, expanding the left-hand side, and equating corresponding real and imaginary parts, the following well-known relations are obtained: $\cos2\theta=\cos^2\theta-\sin^2\theta$ and $\sin2\theta=2\cos\theta\sin\theta$. For $n>2$, the binomial expansion may be used to expand the left-hand side of de Moivre's theorem, Eq. (3).

By use of de Moivre's theorem, the nth root of z may be written as

$$z^{1/n}=r^{1/n}\left[\cos\left(\frac{\theta+2\pi k}{n}\right)+i\sin\left(\frac{\theta+2\pi k}{n}\right)\right];$$
$$k=0,1,2,\ldots,n-1. \qquad (4)$$

The quantity $r^{1/n}$ represents the positive nth root of r. The square root of i, where $r=1$ and $\theta_p = \pi/2$, is found to illustrate the procedure for applying Eq. (4). Roots for $k=0$ and $k=1$, respectively, are

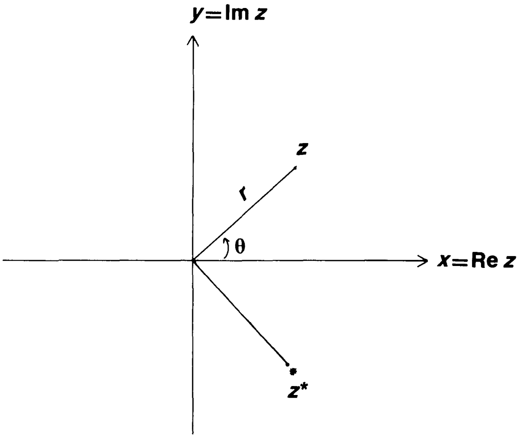

FIG. 1. Argand diagram.

$$z=\cos\left(\frac{\pi}{4}\right)+i\sin\left(\frac{\pi}{4}\right)=\frac{1+i}{\sqrt{2}} \tag{5}$$

and

$$z=\cos\left(\frac{3\pi}{4}\right)+i\sin\left(\frac{3\pi}{4}\right)=-\frac{1+i}{\sqrt{2}}. \tag{6}$$

The above two roots may be checked for correctness. The procedure used to calculate the square root of i can be applied to calculate the nth root of any quantity z ($z\neq 0$).

1.3 Analytic Functions of a Complex Variable

A function $f(z)$ of a complex variable is itself a complex quantity and may be written in terms of real and imaginary parts in the following manner:

$$f(z)=u(x,y)+iv(x,y). \tag{7}$$

The Argand diagram representations of z and $f(z)$ are respectively called z-plane and w-plane diagrams. The number $w=f(z)$ is the value of $f(z)$ at z. A single-valued function $f(z)$ is analytic (regular, holomorphic) at z_0 if it has a unique derivative at z_0 and at every point in the neighborhood of z_0. If a function fails to be analytic at some point z_0 but is analytic at points in the neighborhood of z_0, then z_0 is said to be a singular point (singularity) of $f(z)$. In this connection, note that the function $1/z$ is analytic everywhere except at $z=0$ (singular point). Liouville's theorem states that a function which is analytic for all z (including infinity) must equal a constant.

By analogy with the case of real variables, the derivative of a function of a complex variable is defined as

$$f'(z)=\lim_{\Delta z\to 0}\left(\frac{f(z+\Delta z)-f(z)}{\Delta z}\right)$$

$$=\lim_{\Delta z\to 0}\left(\frac{\Delta u+i\Delta v}{\Delta x+i\Delta y}\right). \tag{8}$$

The evaluation of Eq. (8) for the two paths (a) $\Delta x=0$ and $\Delta y\to 0$ and (b) $\Delta x\to 0$ and $\Delta y=0$ leads to

$$\frac{\partial u}{\partial x}+i\frac{\partial v}{\partial x}=-i\frac{\partial u}{\partial y}+\frac{\partial v}{\partial y}. \tag{9}$$

The Cauchy–Riemann conditions for analytic $f(z)$ result from equating corresponding real and imaginary parts of Eq. (9); the results are

$$\frac{\partial u}{\partial x}=\frac{\partial v}{\partial y} \quad \text{and} \quad \frac{\partial u}{\partial y}=-\frac{\partial v}{\partial x}. \tag{10}$$

If u and v possess continuous partial derivatives to second order, Eq. (10) leads to

$$\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}=0 \quad \text{and} \quad \frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}=0. \tag{11}$$

The equations in Eq. (11) are two-dimensional Laplace equations, and functions u and v (called harmonic or conjugate functions) are, therefore, solutions of the two-dimensional Laplace equations. The theory of analytic functions is extremely useful in solving problems in electrostatics, fluid mechanics, or whenever the two-dimensional Laplace equation occurs. The function $f(z)$ also satisfies the two-dimensional Laplace equation.

1.4 Contour Integrals

The integral of a function of a complex variable $f(z)$ is defined in a manner analogous to the case of real variable theory and may be written as

$$\int_C f(z)dz$$

$$\equiv \lim_{\substack{n\to\infty \\ \max|z_j-z_{j-1}|\to 0}} \left(\sum_{j=1}^{n} f(\xi_j)\,(z_j-z_{j-1})\right)$$

$$\equiv \int_{z_0}^{z'} f(z)dz. \tag{12}$$

The path (contour) of integration C is divided into n segments by points z_j, and ξ_j is a point between z_j and z_{j-1} (see Fig. 2). In complex variable theory, the integral in Eq. (12) is referred to as the contour integral of $f(z)$ along the path C from z_0 to z'. The integral around a closed path is denoted as $\oint f(z)dz$. The sign convention for contour integrals is as follows: When the path of integration is traversed such that the region of interest is on the left, the integral is considered positive. Regions in the complex plane are classified as either simply connected or multiply connected. Simply connected regions possess the following three equivalent properties: every closed path within the region contains only points that belong to the region, every closed path within the region can be shrunk to a point, and every scissors cut starting at an arbitrary point on the boundary and finishing at another point

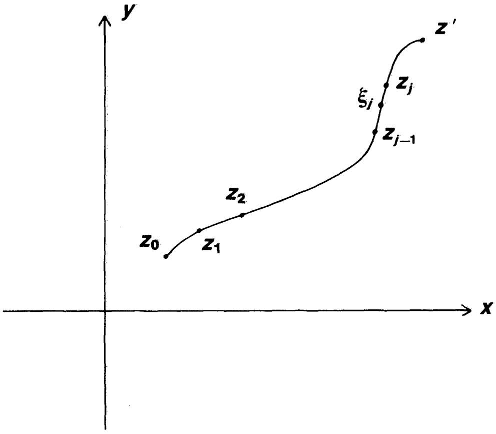

FIG. 2. Path for the contour integral in Eq. (12).

on the boundary separates the region into two unconnected pieces. Regions that are not simply connected are said to be multiply connected.

Two extremely important relations involving integrals of a function of a complex variable, the Cauchy integral theorem and the Cauchy integral formula, will now be discussed.

The CAUCHY INTEGRAL THEOREM: If $f(z)$ is analytic throughout a simply connected region Γ and C is a closed path within Γ, then

$$\oint_C f(z)dz=0. \tag{13}$$

Cauchy's integral theorem applies to special cases that are important in physics where the value of the integral of a function depends only on end points and is independent of the path taken between end points. The inverse of this theorem is also valid.

The CAUCHY INTEGRAL FORMULA is written as

$$\oint_C \frac{f(z)dz}{z-z_0}=2\pi\, if(z_0). \tag{14}$$

The function $f(z)$ in Eq. (14) is analytic within C, z_0 is within C, and the integrand is not analytic at $z = z_0$.

By use of the definition of $f'(z)$ and Cauchy's integral formula, the nth derivative of $f(z)$ evaluated at $z = z_0$ may be written as

$$f^{(n)}(z_0)=\frac{n!}{2\pi\, i}\oint_C \frac{f(z)dz}{(z-z_0)^{n+1}}. \tag{15}$$

Equation (15) will be used below in developing the Taylor expansion for $f(z)$.

1.5 The Taylor and Laurent Expansions

Two important series expansions, Taylor's series and Laurent's series, are valid for a function of a complex variable. If $f(z)$ is analytic in a region Γ and C is a circle within Γ with center at z_0 (see Fig. 3), then the Taylor expansion of $f(z)$ where $f^{(n)}(z_0) = n!a_n$ is

$$f(z)=\sum_{n=0}^{\infty} \frac{(z-z_0)^n}{n!} f^{(n)}(z_0) = \sum_{n=0}^{\infty} a_n(z-z_0)^n. \tag{16}$$

The Taylor expansion of $f(z)$ is obtained and applied in a manner similar to that in real variable theory. Classification of the zeros of $f(z)$ is made by use of Taylor's expansion of $f(z)$ as follows: (a) If $f(z)=0$ at $z = z_0$, the point z_0 is said to be a zero of $f(z)$. (b) If $a_0 = a_1 = \cdots = a_{m-1} = 0$ but $a_m \neq 0$, then $f(z)$ has a zero of order m at $z = z_0$. It is therefore clear that the conditions $f(z_0) = 0$ and $f'(z_0) \neq 0$ indicate the existence of a zero of order $m=1$ (called simple zero) at $z = z_0$.

The Laurent expansion of $f(z)$ has no real-variable counterpart and is key in the discussion of singularities and residues. If $f(z)$ is analytic in the interior and on the boundary of a circular ring between two circles C_1 and C_2 (see Fig. 4), it may be represented as a Laurent expansion which has the form

$$f(z)=\sum_{n=0}^{\infty} a_n(z-z_0)^n+\sum_{n=1}^{\infty} \frac{a_{-n}}{(z-z_0)^n}. \tag{17}$$

In Eq. (17), the coefficients a_n and a_{-n} have the forms

$$a_n=\frac{1}{2\pi i}\oint_C \frac{f(z)dz}{(z-z_0)^{n+1}},\quad n=0,1,2,\ldots, \tag{18}$$

and

$$a_{-n}=\frac{1}{2\pi i}\oint_C (z-z_0)^{n-1}f(z)dz,\quad n=1,2,\ldots. \tag{19}$$

The first series in the Laurent expansion, Eq. (17), is called the analytic part, and it converges everywhere within C_1. The second series in the Laurent expansion is the principal part which converges everywhere outside C_2. The quantity a_{-1} is the residue of $f(z)$ at $z = z_0$ and is given by

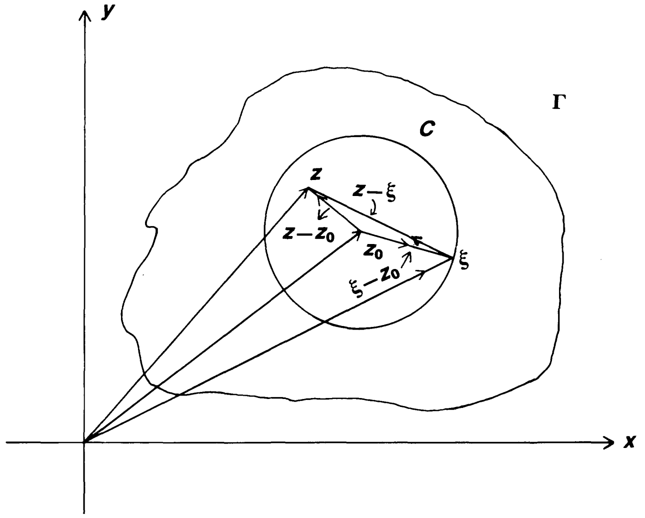

FIG. 3. Diagram for the Taylor expansion.

$$a_{-1}=\frac{1}{2\pi i}\oint_C f(z)dz. \tag{20}$$

In the above three equations, C is any circle between C_1 and C_2 that encloses z_0. Note that $2\pi i a_{-1}$ is the value of the integral in Eq. (20). For cases where the residue can be determined directly, an indirect method of evaluating definite integrals may be developed. First, the classification of isolated singularities and calculations of corresponding residues are considered.

A singularity at z_0 is said to be isolated if a circle of radius ϵ, containing no other singularities, can be drawn with z_0 as its center. Singularities are classified using the principal part of the Laurent expansion. If the first m terms in the principal part are different from zero but the remaining terms equal zero, then $f(z)$ has a singularity (a pole) of order m at z_0. When $m=1$, the pole is called a simple pole. If m is infinite, the singularity at z_0 is said to be an essential singularity. The residue of $f(z)$ at z_0 may be obtained by use of the following three methods.

1. The Laurent expansion directly [the coefficient of the $1/(z-z_0)$ term]. In the Laurent expansion

$$f(z)=\frac{1}{z^3}-\frac{1}{3!z}+\frac{z}{3!}-\frac{z^3}{7!}+\cdots, \tag{21}$$

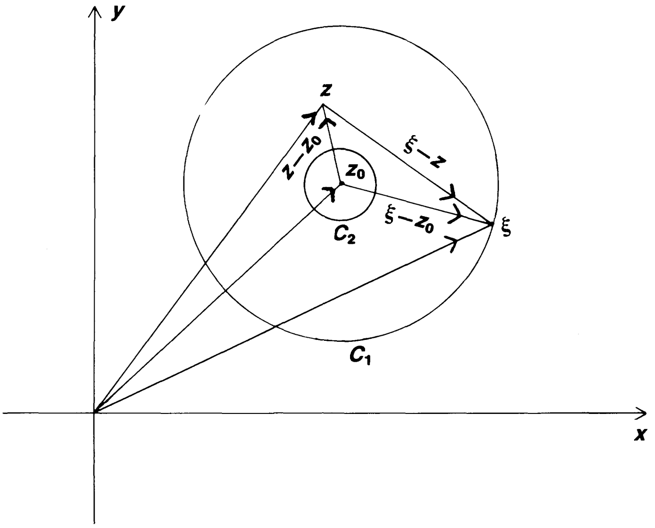

FIG. 4. Diagram for the Laurent expansion.

there is a third-order pole at $z=0$ with residue $a_{-1}=1/3!$.

2. The general formula

$$a_{-1}=\lim_{z\to z_0}\left(\frac{1}{(m-1)!}\,\frac{d^{m-1}\phi(z)}{dz^{m-1}}\right), \tag{22}$$

where

$\phi(z)=(z-z_0)^m f(z)$

for $\lim_{z\to z_0}[\phi(z)]$ analytic and nonzero.

To illustrate the procedure for applying the general formula, let us classify the singularities and calculate the residues of

$$f(z)=\frac{1}{(z^2+a^2)^2}$$

$$=\frac{1}{(z+ia)^2(z-ia)^2} \quad \text{for} \quad a>0. \tag{23}$$

There are singularities at $z=\pm ia$. Note that $m=2$, $\phi(ia)$ is nonzero and analytic, and the residue is $1/(4ia^3)$ when $z=ia$. In a similar manner, the residue for the singularity at $-ia$ is $-1/(4ia^3)$.

3. If $f(z)=g(z)/h(z)$ where $g(z_0)\neq 0$, $h(z_0)=0$, but $h'(z_0)\neq 0$, then

$$a_{-1}=\frac{g(z_0)}{h'(z_0)}\,. \tag{24}$$

For analytic $A(z)$ in $f(z)=A(z)/\sin z$, method **3** may be used to calculate the residue. There are singularities at $z=n\pi$ for $n=0, \pm 1, \pm 2,\ldots$; here the quantity $h(n\pi)$ equals zero, but $h'(n\pi)$ is different from zero. These poles are therefore simple poles and the residue is $a_{-1}=(-1)^n A(n\pi)$.

1.6 The Cauchy Residue Theorem

The Cauchy residue theorem and Cauchy principal value of an integral result from the applications of the Cauchy integral theorem and the Cauchy integral formula. The residue theorem and principal value of an integral are extremely important in physics.

CAUCHY'S RESIDUE THEOREM: If $f(z)$ is analytic within and on a closed region Γ (except at a finite number of isolated singular points z_j within Γ), then (see Fig. 5)

$$\oint_\Gamma f(z)dz$$

$$=2\pi i \sum_{j=1}^{n} a_{-1}z_j$$

$$=2\pi i \sum_{j=1}^{n} [\text{enclosed residue of } f(z)]. \tag{25}$$

For a simple pole on the path of integration (see Fig. 6), the residue theorem yields

$$\oint_C f(z)dz=\pi i a_{-1}. \tag{26}$$

The extension of the residue theorem to cases of simple poles on the path of integration is

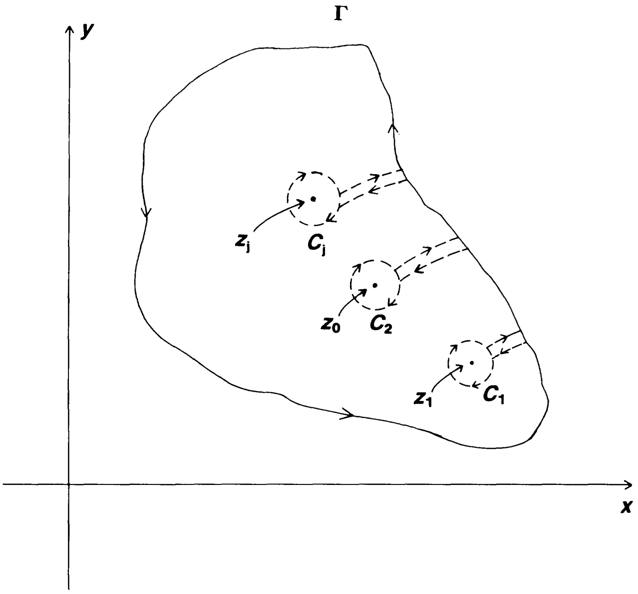

FIG. 5. Diagram for the Cauchy residue theorem.

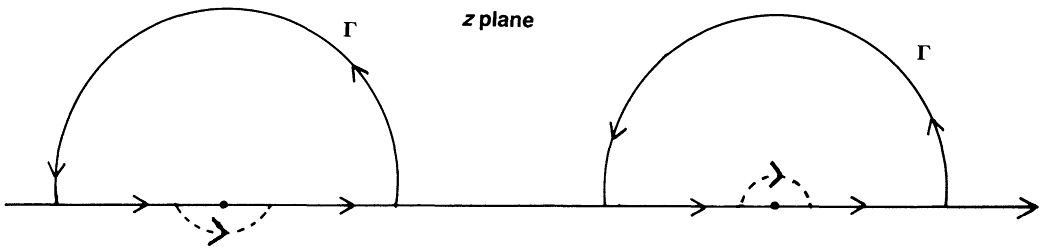

FIG. 6. Simple pole on the path.

important in physics, and the residue theorem is written as

$$\oint_C f(z)\,dz = 2\pi i \sum_{j=1}^{n} (\text{enclosed residue}) + \pi i \sum_{k=1}^{m} (\text{residue of simple poles on path}). \qquad (27)$$

The residue theorem may be used to evaluate certain definite integrals that occur when solving physical problems, and the procedure for evaluating four types of integrals will now be illustrated.

TYPE 1 INTEGRALS:

$$I_1 = \int_0^{2\pi} f(\sin\theta, \cos\theta)\,d\theta.$$

It is assumed that the integrand $f(\sin\theta, \cos\theta)$ contains no singularities other than poles. If $z = e^{i\theta}$ (unit circle), then

$$\sin\theta = \frac{e^{i\theta} - e^{-i\theta}}{2i} = \frac{z^2 - 1}{2iz}$$

and

$$\cos\theta = \frac{e^{i\theta} + e^{-i\theta}}{2} = \frac{z^2 + 1}{2z}.$$

In terms of z, the integral I_1 becomes

$$I_1 = -i \oint_{\substack{\text{unit}\\ \text{circle}}} f\left(\frac{z^2-1}{2iz}, \frac{z^2+1}{2z}\right)\frac{dz}{z} = 2\pi \sum (\text{residue within the unit circle}). \qquad (28)$$

The analysis for Type 1 integrals may be used to evaluate the following integral:

$$I_1 = \int_0^{2\pi} \frac{d\theta}{5 + 4\cos\theta} = -i \oint_{\substack{\text{unit}\\ \text{circle}}} \frac{dz}{(2z+1)(z+2)} = \frac{2\pi}{3}. \qquad (29)$$

TYPE 2 INTEGRALS: If (a) $f(z)$ is analytic in the upper-half plane except for a finite number of enclosed singularities z_j and/or simple poles x_k on the real axis, and (b) $zf(z)$ approaches zero as $|z|$ approaches infinity, then

$$I_2 = \int_{-\infty}^{\infty} f(x)\,dx = 2\pi i \sum_{j=1}^{n} a_{-1,z_j} + \pi i \sum_{k=1}^{m} a_{-1,x_k}. \qquad (30)$$

By use of the analysis for Type 2 integrals, let us evaluate

$$I_2 = \int_{-\infty}^{\infty} \frac{dx}{1+x^2} = \oint_{\text{semicircle}} \frac{dz}{(z-i)(z+i)} = \pi. \qquad (31)$$

TYPES 3 AND 4 INTEGRALS: If (a) $f(z)$ is analytic in the upper-half plane except at a finite number of enclosed singular points and/or simple poles on the real axis and (b) $f(z)$ approaches zeros as $|z|$ approaches infinity, then integrals of the form

$$\int_{-\infty}^{\infty} f(x)\exp(imx)\,dx$$

yield I_3 and I_4 where

$$I_3=\int_{\infty}^{\infty} f(x)\cos mx\, dx=-2\pi \sum_{\text{enclosed}} \mathrm{Im}\{\text{residue}[\, f(z)\exp(imz)]\}$$
$$-\pi \sum_{\substack{\text{on the}\\ \text{path}}} \mathrm{Im}\{\text{residue}[\, f(z)\exp(imz)]\} \qquad (32)$$

and

$$I_4=\int_{\infty}^{\infty} f(x)\sin mx\, dx=2\pi \sum_{\text{enclosed}} \mathrm{Re}\{\text{residue}[\, f(z)\exp(imz)]\}$$
$$+\pi \sum_{\substack{\text{on the}\\ \text{path}}} \mathrm{Re}\{\text{residue}[\, f(z)\exp(imz)]\}. \qquad (33)$$

The application of Type 3 integrals is similar to that for Type 4 integrals. Type 4 may be used to evaluate

$$I_4=\int_{-\infty}^{\infty} \frac{\sin x\, dx}{x}$$
$$=\pi \sum \mathrm{Re}\{\text{residue}[\exp(iz)/z]\}=\pi. \qquad (34)$$

1.7 The Cauchy Principal Value and Dispersion Relations

On returning to the case of a simple pole on the real axis, note that it is useful to express the result in terms of the Cauchy principal value of an integral. The integral of a function $f(x)$ which has a simple pole at $x=x_0$ for x_0 within $[a,b]$ may be written as

$$\int_a^b f(x)dx=\lim_{\epsilon\to 0}\left[\int_a^{x_0-\epsilon} f(x)dx + \int_{x_0+\epsilon}^{b} f(x)dx\right]$$
$$\equiv \mathrm{P}\int_a^b f(x)dx. \qquad (35)$$

The symbol P in front of an integral indicates the Cauchy principal value of the integral and means carry out the limiting process in Eq. (35). Note that the Cauchy principal value may exist even if the regular value of the integral does not exist; for example, $\mathrm{P}\int_{-1}^{1} dx/x^3=0$.

Dispersion relations (also known as spectral representations, Kronig–Kramers relations, and Hilbert transforms) result from the analytic properties of the complex representation of physical quantities and the Cauchy residue theorem. Originally, Kronig and Kramers were concerned with the dispersion of light and the relation between the real (dispersive) and imaginary (absorptive) parts of the index of refraction at different frequencies. The basic idea of dispersion relations is applied in areas ranging from electronic design to quantum field theory. Here, general forms for dispersion relations will be presented. For a physical quantity $\chi(\omega)$ which approaches zero as ω approaches infinity and is analytic in the upper-half plane (see Fig. 7), consider the evaluation of the integral

$$\oint_{\Gamma} \frac{\chi(\omega)d\omega}{\omega-\omega_0}. \qquad (36)$$

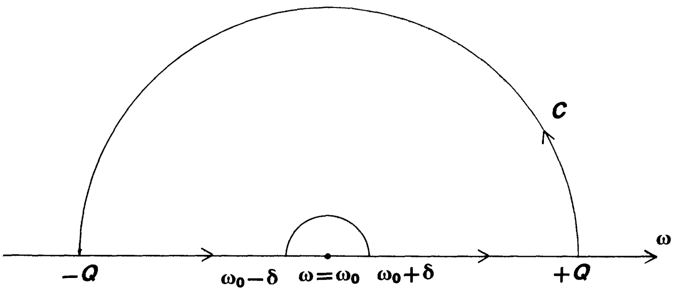

FIG. 7. Contour for Eq. (36).

By use of the Cauchy residue theorem for a simple pole at ω_0 on the contour and the physical property that $\chi(\omega)$ approaches zero as ω approaches infinity, Eq. (36) yields

$$-\chi(\omega_0)=\frac{i}{\pi}\,\mathrm{P}\int_{-\infty}^{\infty}\frac{\chi(\omega)d\omega}{\omega-\omega_0}. \tag{37}$$

On equating corresponding real and imaginary parts in Eq. (37), the dispersion relations are obtained:

$$\begin{aligned}\mathrm{Re}\chi(\omega_0)&=\frac{1}{\pi}\,\mathrm{P}\int_{-\infty}^{\infty}\frac{\mathrm{Im}\chi(\omega)d\omega}{\omega-\omega_0},\\ \mathrm{Im}\chi(\omega_0)&=-\frac{1}{\pi}\,\mathrm{P}\int_{-\infty}^{\infty}\frac{\mathrm{Re}\chi(\omega)d\omega}{\omega-\omega_0}.\end{aligned} \tag{38}$$

The equations in Eq. (38) express one part of an analytic function in terms of an integral involving the other part and are called dispersion relations. In electronics, one has $Z(\omega)=R(\omega)+iX(\omega)$ where Z is impedance, R is resistance, and X is reactance. Dispersion relations may be used to express resistance in terms of reactance. Dispersion relations for light (complex index of refraction $\eta = n_c + ia\alpha$) yield relations between dispersive power and absorption. In addition, a large number of definite integrals may be evaluated by use of the dispersion relations. Dispersion relations applied to $f(z)=\cos x + i \sin x$ lead to values of integrals with integrands of forms $(\sin x)/x$ and $(\cos x)/x$ for limits of integration from minus infinity to plus infinity.

1.8 Conformal Transformations

An analytic function $w=f(z)=u(x,y)+iv(x,y)$ for $z=x+iy$ is completely characterized by two pairs of variables (x,y) and (u,v). Riemann developed a mode of visualizing the relation $w=f(z)$ which uses two separate complex planes, z plane for (x,y) and w plane for the corresponding (u,v). By use of the two-plane picture, the equation $w=f(z)$ defines the transformation (relation, correspondence, or mapping) between the two planes. That is to say, $w=f(z)$ may be used for mapping a set of points (locus, figure) in the z plane (or w plane) into the corresponding figure in the w plane (or z plane). For physical problems, the basic idea involves transforming the geometry of a complicated problem in the z plane into a simpler geometry in the w plane, solving the problem with the simpler geometry, and inverting the transformation to obtain the desired solution in the z plane. The most important class of transformations used in solving physical problems are those that preserve the angle between two straight lines (conformal transformations). The angle-preserving property of conformal transformations will now be illustrated: Assume that two lines intersect at $z=a$ in the z plane and at $w=f(a)$ in the w plane, with elements of length along two lines given respectively by $dz_1=|dz_1|\exp(i\theta_1)$ and $dz_2=|dz_2|\exp(i\theta_2)$. The corresponding elements of length in the w plane are $dw_1=|dz_1|\,|f'(z)|\exp[i(\phi+\theta_1)]$ and $dw_2=|dz_2|\times|f'(z)|\exp[i(\phi+\theta_2)]$ since $dw=dz|f'(z)|\times\exp(i\phi)$. Finally, note that the direction of the corresponding lines in the w plane is rotated by ϕ, but the angle between the lines in the z plane $(\theta_2 - \theta_1)$ equals the angle between the lines in the w plane $[(\phi+\theta_2)-(\phi+\theta_1)]$.

Four often used elementary transformations are the following.

1. TRANSLATION: $w = z + z_0$ for z_0 constant. The transformation equations are

$$\begin{aligned}&w=(x+x_0)+i(y+y_0),\\ &u=x+x_0,\\ &v=y+y_0.\end{aligned} \tag{39}$$

2. MAGNIFICATION: $w=az$ for constant and real a. The transformation equations are

$$w=ax+iay,\quad u=ax,\quad \text{and}\quad v=ay. \tag{40}$$

3. ROTATION: $w = z_0 z$. Here one may write

$$w=\rho\exp(i\phi)=r_0 r\exp[i(\theta+\theta_0)]. \tag{41}$$

The angle in the w plane is $\phi=\theta+\theta_0$ where θ_0 is the angle of rotation and r_0 corresponds to the magnification.

4. INVERSION: $w=1/z$. In polar form, w may be written as

$$w=\rho\exp(i\phi)=\frac{1}{r}\exp(-i\theta). \tag{42}$$

The transformation equations for inversion are

$$\begin{aligned}&u=\frac{x}{x^2+y^2},\quad v=-\frac{y}{x^2+y^2},\\ &x=\frac{u}{u^2+v^2},\quad y=-\frac{v}{u^2+v^2}.\end{aligned} \tag{43}$$

The following transformation is also useful in physical applications: $w = z^2$ which yields $w = \rho \exp(i\phi) = r^2 \exp(i2\theta)$or $\rho = r^2$ and $\phi = 2\theta$ with transformation equations given by $u = x^2 - y^2$ and $v = 2xy$. Here one finds that a circle with radius r_0 is mapped into a corresponding circle with radius $R = r_0^2$, and θ_0 is mapped into $2\theta_0$. In potential theory, the two-dimensional Laplace equation is to be solved with appropriate boundary conditions. Note that the transformation $w = z^2$ maps the right angle in the z plane into a straight line in the w plane (see Fig. 8) where boundary conditions may be applied more conveniently.

In connection with the transformation $w = z^2$ (and other multivalued functions), note that the transformation is conformal except at $w=0$ which is called a branch point, and separately maps the upper- and lower-half planes of the z plane into the whole w plane (points z and $-z$ are mapped into the same points in the w plane). The inverse transformation $z = \sqrt{w}$ cannot be unique. The quantity z may be written as

$$z = \sqrt{\rho} \exp\left(i \frac{\phi}{2}\right) = \sqrt{\rho} \exp\left(i \frac{\phi_p}{2} + i\pi k\right). \tag{44}$$

Odd and even values of k in Eq. (44) yield opposite signs for z. In describing values of a unit circle about the origin in the z plane for $k=0$, it is found that (a) $z = 1$ for $\phi_p = 0$ and (b) $z = -1$ when $\phi_p = 2\pi$. When $k=1$, the values become (a) $z = -1$ when $\phi_p = 0$ and (b) $z = 1$ when $\phi_p = 2\pi$. One may avoid the double values by assuming a cut, which may not be crossed, from zero to infinity along the u axis in the w plane. Riemann introduced the scheme of two planes (sheets, surfaces) joined edge to edge at the cut as a way to combine cases for $k=0$ (all evens) and $k=1$ (all odds) and to eliminate the cut. For example, a lower sheet contains the set of values for $k = 0$ and an upper sheet contains the values for $k = 1$ (see Fig. 9).

The function $\sqrt{w}$ is analytic over the whole Riemann surface (two sheets) except at the branch point, $w=0$. In summary, it is found that the w plane is mapped into two sheets (Riemann surface). The concept of Riemann surfaces has broad application in physics.

2. ORDINARY DIFFERENTIAL EQUATIONS

2.1 Introduction

A differential equation is an equation which contains derivative(s), and it may be either an ordinary or a partial differential equation. Ordinary differential equations contain derivative(s) with respect to one independent variable, and partial differential equations contain partial derivatives with respect to two or more independent variables.

The order of a differential equation is the order of the highest derivative appearing in the equation. The degree of a differential equation is the power of the highest derivative after fractional powers of all derivatives have been removed. If the dependent variable and all of its derivatives are to first power without a product of the dependent variable and a derivative, the differential equation is said to be linear. If a differential equation is not linear, it is classified as nonlinear.

Applications of appropriate physical laws to a large number of physical problems lead to differential equations. In general, a physical process is described by use of a differential equation with appropriate boundary conditions in space and/or initial conditions in time and/or an integral equation. The boundary and/or initial conditions determine from

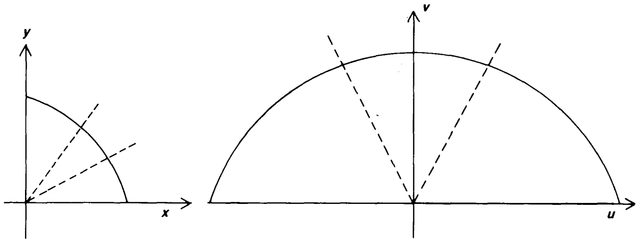

FIG. 8. Diagram for the transformation $w = z^2$.

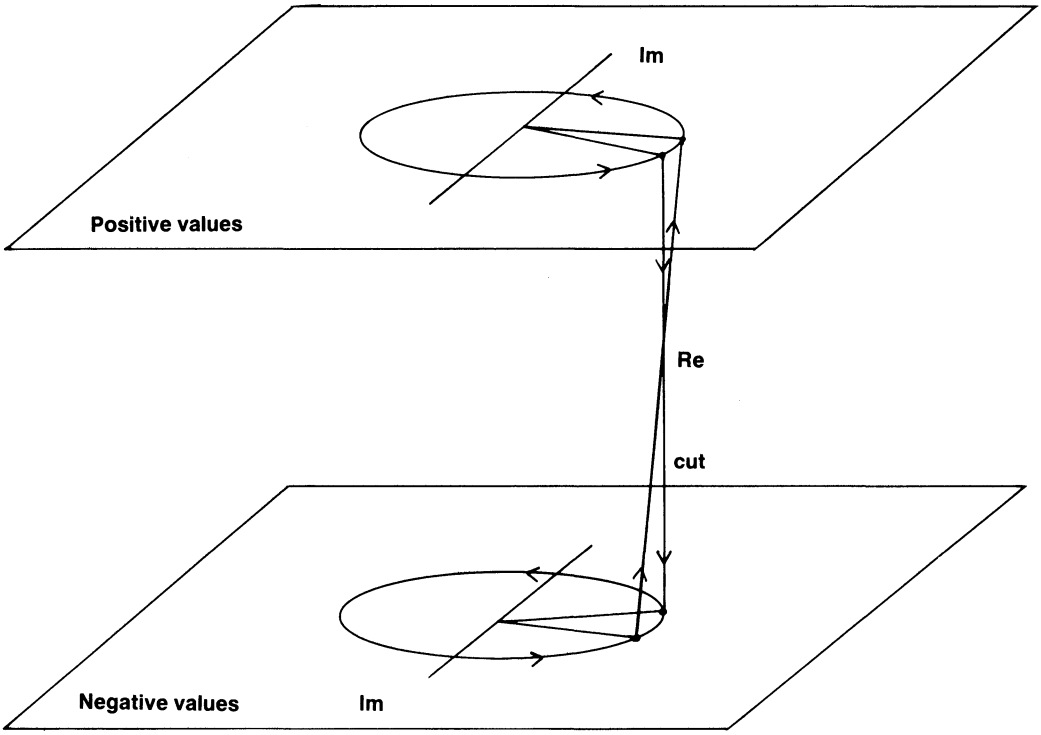

FIG. 9. Riemann surface.

the many possible solutions the one that describes the specific physical phenomenon involved.

The main purpose here concerns the development of solutions for differential equations which adequately describe physical processes under investigation. The mathematical subjects of existence and uniqueness theorems for solutions of differential equations will not be discussed.

An elementary introduction to the subject of ordinary differential equations, as it relates to the needs in solving physical problems, can be reduced to that of treating linear (or reducible to the linear form) first- and second-order differential equations. This presentation is devoted to the construction of solutions and physical applications of such ordinary differential equations.

First- and second-order linear ordinary differential equations have the following standard forms, respectively:

$$\frac{dy}{dx}+p(x)y=Q(x) \quad \text{or} \quad y'+p(x)y=Q(x) \tag{45}$$

and

$$\frac{d^2y}{dx^2}+p(x)\frac{dy}{dx}+q(x)y=f(x)$$

or

$$y''+p(x)y'+q(x)y=f(x). \tag{46}$$

In Eqs. (45) and (46), the notations $y' = dy/dx$ and $y'' = d^2y/dx^2$ have been used. When time t is the independent variable, one writes $\dot{y} = dy/dt$ and $\ddot{y} = d^2y/dt^2$. If the right-hand side of Eqs. (45) or (46) equals zero, the equation is classified as homogeneous; otherwise, the equation is classified as nonhomogeneous (inhomogeneous).

2.2 First-Order Linear Differential Equations

The formulation of many physics problems leads to first-order differential equations, and this section is devoted to solutions of such problems.

2.2.1 Separable Differential Equations. Differential equations that can be put in the form $g(y)dy=f(x)dx$ are called separable differential equations since the left-hand side is a function of y only and the right-hand side is a function of x only. For $dy=f(x)dx$, the general solution is

$$y=\int f(x)dx+C. \tag{47}$$

Since the general solution of a first-order differential equation results from one integration, it will contain one arbitrary constant. Similarly, the general solution of a second-order ordinary differential equation will contain two arbitrary constants. Values of arbitrary constants are determined by use of physical boundary or initial conditions.

EXAMPLE 2.1: In the radioactive decay of nuclei, the process is governed by the following differential equation: $dN/dt=-\lambda N$ with initial condition $N(t=0)=N_0$. The number of parent nuclei present at time t is represented by $N(t)$, and the decay constant λ is characteristic of the particular nuclei involved. The negative sign is used to indicate that the number of nuclei decreases with time. Let us find $N(t)$ subject to the indicated initial condition.

SOLUTION: The differential equation may be written in the form

$$dN/N=-\lambda\, dt$$

with general solution

$$\ln N=-\lambda t+C_1 \text{ or } N(t)=C_2 \exp(-\lambda t). \tag{48}$$

The value of the constant of integration is determined by use of the initial condition, $N(t=0)=N_0$; the initial condition leads to $N(0)=N_0=C_2$. The specific (particular) solution of the problem is the familiar relation

$$N(t)=N_0e^{-\lambda t}. \tag{49}$$

2.2.2 Exact Differential Equations. The general first-order differential equation, $dy/dx=f(x,y)$, may be written in the form

$$M(x,y)dx+N(x,y)dy=0. \tag{50}$$

The total (exact) differential of $F(x,y)=C$ (where F is continuous with continuous derivatives) is

$$dF=\left(\frac{\partial F}{\partial x}\right)_y dx+\left(\frac{\partial F}{\partial y}\right)_x dy=0.$$

Note that the general differential equation in Eq. (50) is exact if

$$M(x,y)=\left(\frac{\partial F}{\partial x}\right)_y \quad \text{and} \quad N(x,y)=\left(\frac{\partial F}{\partial y}\right)_x . \tag{51}$$

Since it is assumed that $F(x,y)$ has continuous first derivatives, note that

$$\left(\frac{\partial M}{\partial y}\right)_x=\left(\frac{\partial N}{\partial x}\right)_y . \tag{52}$$

The condition indicated in Eq. (52) is both necessary and sufficient for Eq. (50) to be an exact differential equation.

EXAMPLE 2.2: Determine whether the following differential equation is exact and find its solution if it is exact: $(4x^3+6xy+y^2) \times dx/dy=-(3x^2+2xy+2)$.

SOLUTION: The standard form of this differential equation is $(4x^3+6xy+y^2)dx+(3x^2+2xy+2)dy=0$; it is exact since the condition in Eq. (52) is satisfied. The solution of the original differential, therefore, has the form $F(x,y)=C$. The function $F(x,y)$ is obtained as follows:

$$\frac{\partial F}{\partial x}=4x^3+6xy+y^2$$

or

$$F(x,y)=x^4+3x^2y+y^2x+f(y) \tag{53}$$

and

$$\frac{\partial F}{\partial y}=3x^2+2xy+2$$

or

$$F(x,y)=3x^2y+y^2x+2y+g(x). \tag{54}$$

Functions $f(y)$ and $g(x)$ arise from integrating with respect to x and y, respectively. For consistency, it is required that $f(y)=2y$ and $g(x)=x^4$. The solution of the original differential equation is $x^4+3x^2y+xy^2+2y=C$.

2.2.3 Solution of the General Linear Differential Equation. A good feature of first-order linear differential equations is that the general equation in this category can be solved. It can be shown that the general solution of Eq. (45) may be obtained from the formula

$$y(x)=\exp\left(-\int p(x)dx\right)\times\int Q(x)\exp\left(\int p(x)dx\right)dx+C\exp\left(-\int p(x)dx\right). \tag{55}$$

If the first-order linear differential equation is separable, the method of Sec. 2.2.1 for separable equation should be followed, and the method of Sec. 2.2.2 for exact differential equations yields solutions for exact differential equations. The formula in Eq. (55) will now be applied to obtain the general solution of the differential equation generated by applying Kirchhoff's loop method to the circuit in Fig. 10.

EXAMPLE 2.3: The appropriate differential equation and initial condition for the circuit in Fig. 10 are

$$L\frac{dI}{dt}+RI=E, \text{ where } I(0)=0. \tag{56}$$

On applying the formula in Eq. (55) for $p(x)=R/L$ and $Q(x)=E/L$ and initial condition, the solution of Eq. (56) reduces to

$$I(t)=\frac{E}{R}[1-\exp(-Rt/L)]. \tag{57}$$

Differential equations of the form $y' + p(x)y = Q(x)y^n$ where $n>1$ (Bernoulli's equation) often occur in physical problems. Bernoulli's type of nonlinear first-order differential equation can be reduced to the linear form by use of the transformation $z = y^{1-n}$, $z' + (1 - n)p(x)z = (1 - n)Q(x)$. The differential equation with dependent variable z can be solved by use of the formula in Eq. (55).

EXAMPLE 2.4: The motion of a particle in a viscous fluid with Stokes damping, av, and Newtonian damping, bv^2, is characterized by an equation of motion of the form $\dot{v} + \alpha v = -\beta v^2$ subject to $v(0) = v_0$. This equation of motion is of the Bernoulli form where $n=2$, $Q(t)=-\beta$, and $p(t)=\alpha$, and the general solution is obtained from

$$z=v^{-1}=-\beta/\alpha+C\exp(\alpha t). \tag{58}$$

The particular solution is

$$v(t)=\frac{\alpha v_0}{(\alpha+v_0\beta)\exp(\alpha t)-\beta v_0}. \tag{59}$$

A graph of Eq. (59) characterizes the speed of the particle as a function of time. To obtain position as a function of time, replace v with $\dot{x}$ and solve the resulting first-order differential equation for $x(t)$.

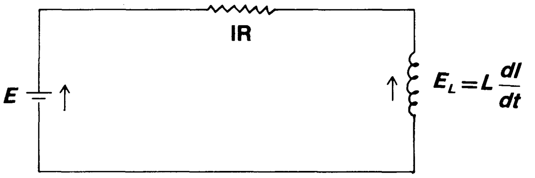

FIG. 10. Diagram for Example 2.3.

2.3 Second-Order Linear Differential Equations

The superposition of solutions principle, stated here in the form of two theorems, will be assumed valid for second-order linear homogeneous differential equations.

THEOREM 1: The set of all solutions of an nth-order linear homogeneous differential equation forms an n-dimensional vector space (see ALGEBRAIC METHODS).

For a second-order differential equation, Theorem 1 means that $y = y_1 + y_2$ is a solution of $y'' + p(x)y' + q(x)y = 0$ if y_1 and y_2 are two linearly independent solutions of the original differential equation.

THEOREM 2: A necessary and sufficient condition that solutions y_1 and y_2 of a second-order linear differential equation be linearly independent is that the Wronskian of these solutions be different from zero. The Wronskian of y_1 and y_2 is the determinant with elements $a_{11}=y_1$, $a_{12}=y_2$, $a_{21}=y_1'$, and $a_{22} = y_2'$.

2.3.1 Homogeneous Differential Equations with Constant Coefficients. The standard form for the general second-order homogeneous differential equation with constant coefficients is $y'' + p_0 y' + q_0 y = 0$ which may be written as $(D^2 + p_0 D + q_0)y = 0$ where $D= d/dx$. The procedure for solving differential equations in this category involves treating $D^2 + p_0 D + q_0 = 0$, the auxiliary or characteristic equation, algebraically and using techniques for solving first-order differential equations. The roots of the auxiliary equation (quadratic) may be real and unequal, real and equal, or a complex-conjugate pair. For real and unequal roots a and b of the auxiliary equation, the differential equation may be written in the symbolic form $(D-a)u=0$ where $u=(D-b)y$. The form of the general solution becomes $y(x) = c_1e^{ax} + c_2e^{bx}$ when the two indicated first-order differential equations are solved. If the roots of the auxiliary equation are a complex-conjugate pair $a^*=b$, the solution of the differential equation has the same form as the case for real and unequal roots with a^* replacing b. The solution of the differential equation for real and equal roots of the auxiliary equation is obtained from solving the two indicated first-order differential equations $(D-a)u=0$ where $u=(D-a)y$; the form of the general solution is $y(x) = (c_1x + c_2)e^{ax}$.

EXAMPLE 2.5: Consider the motion of a particle of mass m initially at rest and subject to a restoring force of $-kx$ and a damping force of $-a\dot{x}$. The equation of motion of this particle is $m\ddot{x}=-kx-a\dot{x}$. The equation of motion in standard form is $\ddot{x}+2\delta\dot{x}+\omega^2x=0$ where $\omega^2 = k/m$ and $2\delta=a/m$ (the factor 2 is used for convenience). Find the solution of the equation of motion for the following cases:

1. $\delta=0$ (no damping);

2. $\delta = \omega$ (critical damping);

3. $\delta<\omega$ (light damping); and

4. $\delta>\omega$ (heavy damping).

Case 1: The equation of motion for $\delta = 0$ reduces to $\ddot{x} + \omega^2x = 0$ with solution

$$\begin{aligned} x(t) &= c_1e^{i\omega t}+c_2e^{-i\omega t} \\ &= A\cos\omega t+B\sin\omega t \\ &= X_0\cos\omega t \text{ for } x(0)=X_0 \\ &\quad \text{and } \dot{x}(0)=0. \end{aligned} \tag{60}$$

The motion without damping is oscillatory and periodic (with constant amplitude X_0).

Case 2: For $\delta\neq 0$ and $\omega\neq 0$, the solutions of the corresponding auxiliary equation are $-\delta+\Delta$ and $-\delta-\Delta$ where $\Delta = \sqrt{\delta^2-\omega^2}$. The solution of the equation of motion for critical damping $\delta=\omega$ is

$$\begin{aligned} x(t) &= (c_1t+c_2)e^{-\delta t} \\ &= X_0(\delta t+1)e^{-\delta t} \text{ for } x(0)=X_0 \\ &\quad \text{and } \dot{x}(0)=0. \end{aligned} \tag{61}$$

Here the motion is not oscillatory and approaches equilibrium at a rapid rate.

Case 3: The solution for light damping $\delta<\omega$ using $\Delta' = \sqrt{\omega^2-\delta^2}$ is

$$\begin{aligned} x(t) &= (A\cos\Delta' t+B\sin\Delta' t)e^{-\delta t} \\ &= X_0\left(\cos\Delta' t+\frac{\delta}{\Delta'}\sin\Delta' t\right)e^{-\delta t} \\ &\quad \text{for } x(0)=X_0 \text{ and } \dot{x}(0)=0. \end{aligned} \tag{62}$$

In this case, the motion is oscillatory with decreasing amplitude (not periodic).

Case 4: The solution for heavy damping $\delta>\omega$ is

$$\begin{aligned} x(t) &= \frac{(\delta+\Delta)}{2\Delta}X_0\exp[(-\delta+\Delta)t] \\ &\quad +\frac{(\Delta-\delta)}{2\Delta}X_0\exp[-(\delta+\Delta)t]. \end{aligned} \tag{63}$$

The motion in this case is not oscillatory and approaches equilibrium at a rate less rapid than for critical damping.

2.3.2 Nonhomogeneous Differential Equations with Constant Coefficients.

The standard form for second-order non-homogeneous differential equations with constant coefficients is $y''+p_0y'+q_0y=f(x)$, and the two widely used methods for solving differential equations in this category are (a) $y = y_h + y_p$ where y_h is the solution of the corresponding homogeneous equation and y_p is any solution of the original nonhomogeneous differential equation, and (b) successive integration. The method of successive integration involves writing the differential equation in the factored form $(D-a)u=f(x)$ where $u=(D-b)y$, and solving the two indicated first-order differential equations.

Physical problems are often solved by use of the first method since y_p can often be obtained without difficulty. Systematic methods for finding y_p for three types of nonhomogeneous terms (polynomial, exponential, and sine and/or cosine) will now be given.

1. The nonhomogeneous term $f(x)$ is a polynomial of degree $n\geqslant 0$.

(A) If zero is not a root of the characteristic equation, then assume

$y_p=A_0+A_1x+\cdots+A_nx^n$.

(B) If zero is a single root of the characteristic equation, then assume

$$y_p=x(A_0+A_1x+\cdots+A_nx^n).$$

(C) If zero is a double root of the characteristic equation, then assume

$$y_p=x^2(A_0+A_1x+\cdots+A_nx^n).$$

2. The nonhomogeneous term $f(x)$ is of the form $C\exp(kx)$.

(A) If k is not a root of the characteristic equation, then assume

$$y_p=A\exp(kx).$$

(B) If k is a single root of the characteristic equation, then assume

$$y_p=Ax\exp(kx).$$

(C) If k is a double root of the characteristic equation, then assume

$$y_p=Ax^2\exp(kx).$$

3. The nonhomogeneous term $f(x)$ is of the form $\sin kx$, $\cos kx$, or $\sin kx+\cos kx$.

(A) If ik is not a root of the characteristic equation, then assume

$$y_p=A\cos kx+B\sin kx.$$

(B) If ik is a single root of the characteristic equation, then assume

$$y_p=Ax\cos kx+Bx\sin kx.$$

Values for constants in the assumed expression for y_p are obtained when that expression is substituted into the original nonhomogeneous differential equation.

EXAMPLE 2.6: The equation of motion for a mass attached to the end of a vertical spring fixed at the other end is $\ddot{y}+\omega^2y=-g$ where g is the acceleration due to gravity. The general solution of the homogeneous equation, $\ddot{y}+\omega^2y=0$, is $y_h=A\cos\omega t+B\sin\omega t$. By use of inspection, it is clear that $y_p=-g/\omega^2$ is a solution of the original nonhomogeneous equation. The solution of the equation of motion for $y(0)=Y_0$ and $\dot{y}(0)=0$ is

$$\begin{aligned}y(t)&=y_h+y_p\\&=A\cos\omega t+B\sin\omega t-\frac{g}{\omega^2}\\&=\left(Y_0+\frac{g}{\omega^2}\right)\cos\omega t-\frac{g}{\omega^2}.\end{aligned}\tag{64}$$

A graph of Eq. (64) characterizes the motion, position as a function of time, of this particle.

2.3.3 Homogeneous Differential Equations with Variable Coefficients. The general procedure used to solve differential equations of the form $y''+p(x)y'+q(x)y=0$ is the power-series method. The power-series method due to Frobenius and Fuchs yields the following two kinds of information concerning the nature of the solution for $x\neq0$: form of the solution as a result of the nature of $p(x)$ and $q(x)$, and form of the solution as indicated by the nature of the solution of the indicial equation. As normally needed in solving physical problems, the general form of the power series solution is

$$y(x)=\sum_{\lambda=0}^{\infty}a_\lambda x^{\lambda+k}\text{ for }a_0\neq0.\tag{65}$$

EXAMPLE 2.7: Consider the differential equation $xy''+2y'+xy=0$. By use of the power-series method, obtain the indicial equation and its two solutions, recursion formula, and general solution of the differential equation. On substituting Eq. (65) into the differential equation to be solved, one obtains

$$\sum_{\lambda=0}^{\infty}a_\lambda(\lambda+k+1)(\lambda+k)x^{\lambda+k-2}+\sum_{\lambda=0}^{\infty}a_\lambda x^{\lambda+k}=0.\tag{66}$$

The basic plan at this stage is to write the result using a single sum. On replacing λ with $\lambda'+2$ in the first sum, the power of x in the first sum becomes the same as that in the second sum. Equation (66) now becomes

$$a_0k(k+1)x^{k-2}+a_1(k+1)(k+2)x^{k-1}+\sum_{\lambda=0}^{\infty}\{a_{\lambda+2}(\lambda+k+3)(\lambda+k+2)+a_\lambda\}\times x^{\lambda+k}=0.\tag{67}$$

Since terms in Eq. (67) are linearly independent, it is required that

$$a_0k(k+1)=0\quad\text{(indicial equation)},\tag{68}$$

$$a_1(k+1)(k+2)=0,\tag{69}$$

and

$$a_{\lambda+2}(\lambda+k+3)(\lambda+k+2)+a_\lambda=0\quad\text{(recursion formula)}.\tag{70}$$

The indicial equation results from equating the coefficient of the lowest power of the variable to zero. In this case, the solutions of the indicial equation are $k=0$ and $k=-1$. When $k=0$, $a_1=0$ because of Eq. (69). The coefficient a_1 is arbitrary when $k=-1$, and two independent solutions of the original differential equation may be obtained by use of $k=-1$ since a_0 is arbitrary by hypothesis. The form of the solution becomes

$$y(x)=\sum_{\lambda=0}^{\infty} a_\lambda x^{\lambda-1}. \tag{71}$$

Coefficients in Eq. (71) are obtained from the recursion formula using $k=-1$. The general expressions for even and odd expansion coefficients, respectively, are

$$\begin{aligned} a_{2j}&=\frac{(-1)^j a_0}{(2j)!}, \\ a_{2j+1}&=\frac{(-1)^j a_1}{(2j+1)!}, \quad j=0,1,2,\dots . \end{aligned} \tag{72}$$

The general solution of the original differential equation is obtained by substituting coefficients in Eq. (72) into Eq. (71).

2.3.4 Nonhomogeneous Differential Equations with Variable Coefficients. Variation of parameters and Green's-function methods are normally used to solve nonhomogeneous linear differential equations with variable coefficients that occur in physics. The standard form for these differential equations is

$$y''+p(x)y'+q(x)y=f(x). \tag{73}$$

The method of variation of parameters due to Lagrange will now be used to solve Eq. (73) subject to the conditions given below. Assume the solution has the form

$$\begin{aligned} y(x)&=C_1 y_1+C_2 y_2 \\ &=v_1(x)y_1+v_2(x)y_2. \end{aligned} \tag{74}$$

In Eq. (74), y_1 and y_2 are two linearly independent solutions of the corresponding homogeneous differential equation, and constant parameters C_1 and C_2 are replaced with functions v_1 and v_2. Functions v_1 and v_2 are unknown parameters to be determined. If $v_1' y_1 + v_2' y_2 = 0$, and $f(x)$ is continuous in the region of interest, then the solution of the original differential equation, Eq. (73), is obtained by use of

$$y(x)=-y_1\int\frac{f(x)y_2dx}{W(y_1,y_2)}+y_2\int\frac{f(x)y_1dx}{W(y_1,y_2)}. \tag{75}$$

The quantity $W(y_1,y_2)$ is the Wronskian of y_1 and y_2.

On using Eq. (75) to solve $y'' - (2y'/x) + (2y/x^2) = (\ln x)/x$ for $x\neq0$, it is found that $y_1=x$ and $y_2=x^2$ are two linearly independent solutions of the corresponding homogeneous equation, the Wronskian equals x^2, and the solution becomes

$$\begin{aligned} y(x)=&-x[(\ln x)^2/2+\ln x+1] \\ &-C_1x+C_2x^2. \end{aligned}$$

Equation (75) will now be put in the form of a definite integral that is useful in solving initial or boundary value problems. Let x be a point in the closed interval $[a,b]$ such that the first term in Eq. (75) is replaced by a definite integral from x to b and the second term in Eq. (75) is replaced by a definite integral from a to x. In terms of the indicated two definite integrals, Eq. (75) becomes

$$\begin{aligned} y(x)&=\int_a^x \frac{y_1(t)y_2(x)f(t)dt}{W(t)} \\ &\quad+\int_x^b \frac{y_1(x)y_2(t)f(t)dt}{W(t)} \\ &=\int_a^b G(x,t)f(t)dt. \end{aligned} \tag{76}$$

The function $G(x,t)$ in Eq. (76) is called the Green's function for Eq. (73) subject to the appropriate boundary conditions. The Green's function is defined by

$$G(x,t)=\begin{cases} \dfrac{y_1(t)y_2(x)}{W(t)}\equiv G_1 & \text{for } a\leqslant t\leqslant x, \\ \dfrac{y_1(x)y_2(t)}{W(t)}\equiv G_2 & \text{for } x\leqslant t\leqslant b. \end{cases} \tag{77}$$

Note that the Green's function depends only on y_1, y_2, and the Wronskian. The quantity $W(t)$ means $W(y_1(t),y_2(t))$. The value of the Green's-function approach is related to the fact that initial or boundary conditions are incorporated in the formulation of the problem in a natural manner. At $t=a$, $G_1(x,t)$ satisfies the boundary condition imposed on $y(x)$, and $G_2(x,t)$ satisfies the boundary condition for $y(x)$ at $t=b$. On applying the Green's- function method to solve $y''=6x$ subject to

$y(0)=y(1)=0$, it is found that $y_1 = x$ and $y_2 = x - 1$ are two linearly independent solutions of the homogeneous equation, the Wronskian equals unity, the Green's functions become $G_1(x,t) = t(x-1)$ for $0 \leqslant t \leqslant x$ and $G_2(x,t) = x(t-1)$ for $x \leqslant t \leqslant 1$, and the solution of the differential equation is $y(x) = \int_0^1 G(x,t) 6t\, dt = x^3 - x$.

2.4 Some Numerical Methods for Ordinary Differential Equations

Numerical methods are treated in detail elsewhere in this *Encyclopedia* (see NUMERICAL METHODS), and a summary of essential features related to solutions of ordinary differential equations is given in this section. In general, the numerical solution of a differential equation consists of a table of values of the dependent variable for corresponding values of the independent variable.

2.4.1 The Improved Euler Method for First-Order Differential Equations. The basic idea of Euler's method for solving first-order ordinary differential equations is to convert the differential equation (continuous) to a difference equation (discrete). The general form for a first-order ordinary differential equation will now be written as

$$\frac{dy}{dx}=f(x,y). \tag{78}$$

By use of the definition of a derivative, one may write

$$\begin{aligned}\frac{dy}{dx} &= \lim_{\Delta x \to 0} \frac{\Delta y}{\Delta x} \\ &= \lim_{\Delta x \to 0} \left(\frac{y(x+\Delta x)-y(x)}{\Delta x} \right) = f(x,y).\end{aligned} \tag{79}$$

The scheme of the finite difference method involves writing Eq. (79) as

$$y(x_{n+1})=y(x_n)+f(x_n,y_n)\Delta x. \tag{80}$$

Equation (80) is the Euler algorithm for solving first-order ordinary differential equations. The notations in Eq. (80) have the following meanings: $x_{n+1} = x_n + \Delta x$, and $y(x_{n+1}) = y_{n+1}$. To apply Euler's method, select the interval size Δx, evaluate $y(x)$ at x_0, and evaluate $f(x,y)$ at x_0, y_0; the result for $y(x_1)$ is

$$y(x_1)=y(x_0)+f(x_0,\ y_0)\Delta x. \tag{81}$$

A second iteration with inputs $y(x_1)$ from Eq. (81) and $f(x_1, y_1)$ yields $y(x_2)$; the result is

$$y(x_2)=y(x_1)+f(x_1,\ y_1)\Delta x. \tag{82}$$

The iteration is continued to yield a numerical solution of the required first-order ordinary differential equation in the region of interest. A systematic procedure for calculating the error involved during each iteration does not exist for Euler's method.

To improve the simple Euler method, the class of first-order differential equations is restricted to those whose solutions can be expanded in a Taylor series. Neglecting terms of order $O((\Delta x)^3)$, one obtains

$$\begin{aligned}y(x_{n+1}) &= y(x_n)+\Delta x f(x_n,y_n) \\ &\quad + \frac{(\Delta x)^2}{2}\left(\frac{\partial f(x_n,y_n)}{\partial x} \right. \\ &\quad \left. + f(x_n,y_n)\frac{\partial f(x_n,y_n)}{\partial y} \right).\end{aligned} \tag{83}$$

Equation (83) is referred to as the improved Euler method and will be used to obtain the solution of first-order ordinary differential equations.

EXAMPLE 2.8: The equation of motion for a certain particle is $\dot{v} + \alpha v = g$ where $\alpha=0.01$ s^{-1}, $g=9.8$ m s^{-2}, and $v(0)=0$. The analytical solution of this equation of motion is

$$v(t)=\frac{g}{\alpha}\,(1-e^{-\alpha t}). \tag{84}$$

Find the numerical solution of this equation of motion by use of the improved Euler method.

SOLUTION: The general form of the improved Euler method for the differential equation $\dot{v} = g - \alpha v$ is

$$\begin{aligned}v(t_{n+1}) &= v(t_n)+f(t_n,v_n)\Delta t+\frac{(\Delta x)^2}{2}\left(\frac{\partial f(t_n,v_n)}{\partial t} \right. \\ &\quad \left. + f(t_n,v_n)\frac{\partial f(x_n,v_n)}{\partial v} \right).\end{aligned} \tag{85}$$

For arbitrary Δt in Eq. (85), the quantities reduce to

$$\begin{aligned} &f(t_n,v_n)=g-\alpha v(t_n), \quad \frac{\partial f(t_n,v_n)}{\partial t}=0, \\ &\frac{\partial f(t_n,v_n)}{\partial v}=-\alpha. \end{aligned} \tag{86}$$

The essential programming statement for calculating the numerical solution of the original differential equation is

$$v(n+1)=v(n)+[g-\alpha v(n)][\Delta t-\alpha(\Delta t)^2/2]. \tag{87}$$

2.4.2 The Runge–Kutta Method for First-Order Differential Equations. There exist many methods for finding numerical solutions of first-order ordinary differential equations, and the fourth-order Runge–Kutta method is probably the most often used method. As with the Euler and the improved Euler methods, the essential problem is to generate a table of values for x and y for the differential equation $y'=f(x,y)$ when $y(x)$ at $x = x_0$ is given. The task is to develop a method for finding y_1 at $x_0+ \Delta x$, y_2 at $x_0+2\Delta x$, and successive values for y_n throughout the range of interest. For calculating successive values of $y(x_n)$ in the differential equation $y'=f(x,y)$, Runge–Kutta methods use a recurrence formula in the form

$$y_{i+1}=y_i+\Delta x \sum_{i=1}^{n} a_i k_i. \tag{88}$$

Of the many parameters a_i and k_i in Eq. (88), some are chosen arbitrarily and others are obtained by use of the Taylor series involving one and two variables. The order of the Runge–Kutta approximation is indicated by the value of n in Eq. (88). Evaluation of the parameters in Eq. (88) for $n>4$ in the Runge–Kutta approximation is straightforward but involves tedious algebraic manipulations. For $h=\Delta x$, the formula for the fourth-order Runge–Kutta method reduces to

$$y_{i+1}=y_i+\tfrac{1}{6}(k_1+2k_2+2k_3+k_4)+O(h^5). \tag{89}$$

The parameters in Eq. (89) are determined by use of

$$k_1=hf(x_i,y_i),\ k_2=hf\left(x_i+\frac{h}{2},y_i+\frac{k_1}{2}\right),$$

$$k_3=hf\left(x_i+\frac{h}{2},y_i+\frac{k_2}{2}\right),$$

$$k_4=hf(x_i+h,y_i+k_3).$$

EXAMPLE 2.9: Find the numerical solution of the differential equation in Example 2.8 by use of the fourth-order Runge–Kutta method.

SOLUTION: The general form of the Runge–Kutta method for the differential equation $\dot{v} = g - \alpha v$ is

$$v(n+1)=v(n)+\tfrac{1}{6}(k_1+2k_2+2k_3+k_4). \tag{90}$$

The k parameters reduce to $k_1 = h[g - \alpha v(n)]$, $k_2 = h\{g - \alpha[v(n + h/2)+k_1/2]\}$, $k_3 = h\{g - \alpha[v(n + h/2) + k_2/2]\}$, and $k_4 = h\{g - \alpha[v(n + h) + k_3]\}$.

2.4.3 Second-Order Differential Equations. Numerical solutions of second-order differential equations are obtained by first reducing them to a system of first-order differential equations and applying the methods for solving first-order differential equations. The general second-order differential equation may be written as

$$\frac{d^2y}{dx^2}=f(x,y,y'). \tag{91}$$

For $z=dy/dx$, Eq. (91) reduces to the following pair of first-order differential equations:

$$\frac{dz}{dx}=f(x,y,z) \quad\text{and}\quad \frac{dy}{dx}=z=g(x,y,z). \tag{92}$$

The procedure for solving Eq. (91) is to solve the first equation in Eq. (92) with condition $y'(0)$ and use that result as an input for the second equation in Eq. (92) to obtain the solution $y(x)$ with condition $y(0)$.

3. PARTIAL DIFFERENTIAL EQUATIONS

3.1 Introduction

Physical problems involving two or more independent variables are often described by use of partial differential equations. Partial differential equations contain partial derivatives with respect to two or more independent variables. The procedures for determining order, degree, whether linear or nonlinear, and whether homogeneous or nonhomogeneous for partial differential equations are the same as for ordinary differential equations. Some methods for solving partial differential equations are direct integration, characteristics, separation of variables, Fourier and Laplace transforms, and Green's functions. Appropriate boundary (space) and/or initial (time) conditions must be applied to the general solution of a partial differential equation to obtain a suitable solution for the problem under investigation. Three common types of boundary conditions are Dirichlet, specification of the solution at each point on the boundary; Neumann, specification of the normal derivative of the solution at each point on the boundary; and Cauchy, specification of both initial value(s) and the Dirichlet or Neumann condition.

The following equations are examples of important partial differential equations in physics involving the Laplacian operator,

$$\nabla^2=\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}:$$

$$\nabla^2 u=0;\ \text{Laplace's equation.} \tag{93}$$

The function $u(x,y,z)$ in Eq. (93) may represent electric potential in a charge-free region, gravitational potential in a region free of matter, or steady-state (time-independent) temperature in a region without a heat source.

$$\nabla^2 u=f(x,y,z);\ \text{Poisson's equation.} \tag{94}$$

The function $u(x,y,z)$ in Eq. (94) may represent electric potential, gravitational potential, or steady-state temperature in regions with respective sources denoted by $f(x,y,z)$.

$$\nabla^2 u=\frac{1}{\sigma}\frac{\partial u}{\partial t};\ \text{heat conduction (or diffusion) equation.} \tag{95}$$

In Eq. (95), the function $u(x,y,z,t)$ may represent a time-dependent temperature in a region without a heat source or concentration of a diffusing substance. The constant σ is called the diffusivity.

$$\nabla^2 u=\frac{1}{v^2}\frac{\partial^2 u}{\partial t^2};\ \text{mechanical wave equation.} \tag{96}$$

The function $u(x,y,z,t)$ in Eq. (96) may represent the motion of a vibrating string or membrane, and v is the speed of the wave motion.

$$\left\{-\frac{\hbar^2}{2m}\nabla^2+V(x,y,z)\right\}\Psi=i\hbar\frac{\partial\Psi}{\partial t};\ \text{Schrödinger's equation.} \tag{97}$$

Schrödinger's wave equation is the basic equation of motion of a microscopic particle of mass m, and $\Psi(x,y,z,t)$ is called the wave function. The potential energy of the particle is represented by $V(x,y,z)$, and other quantities in this equation have their usual meaning.

This section on partial differential equations is mainly devoted to the physical applications of linear second-order homogeneous partial differential equations in two independent variables; the general form for equations in this category is

$$A\frac{\partial^2 u}{\partial x^2}+2B\frac{\partial^2 u}{\partial x\partial y}+C\frac{\partial^2 u}{\partial y^2}+D\frac{\partial u}{\partial x}+E\frac{\partial u}{\partial y}+Fu=0. \tag{98}$$

In Eq. (98), the coefficients may be functions of x and y, and properties of the solution of the differential equation depend on the relative magnitudes of the coefficients. Based on the coefficients, partial differential equations are classified as elliptic, hyperbolic, or parabolic for $AC-B^2$ greater than zero, less than zero, or equal to zero, respectively. This classification is related to the general equation of a conic section ($Ax^2+2Bxy+Cy^2=1$) representing an ellipse, a hyperbola, or a parabola. According to these classifications, note that Laplace's equation is elliptic, the mechanical wave equation is hyperbolic, and the heat conduction (diffusion) and Schrödinger equations are parabolic. The geometrically related classifications are not of primary importance when solving the differential equation by use of analytical methods but do reflect the nature of the boundary conditions. Solutions of elliptic equations must satisfy conditions on a closed boundary. In this section, the focus will be on separation of variables and Fourier transforms as methods for solving the partial differentials involved in physical applications. The method of separation of variables is illustrated in the following four sections. The Fourier transform method is presented in Sec. 3.6, and Sec. 3.7 is devoted to the Green's-function method for three-dimensional problems.

3.2 The Time-Independent Schrödinger Wave Equation

The method of separation of variables will now be used to obtain the time-independent Schrödinger wave equation. Assuming that

$\Psi(x,y,z,t) = \psi(x,y,z)T(t)$ in Eq. (97) and dividing both sides of the resulting equation by ψT, the result obtained is

$$\frac{1}{\psi}\left(-\frac{\hbar^2}{2m}\right)\nabla^2\psi + V(x,y,z) = \frac{i\hbar}{T}\frac{dT}{dt} \equiv E. \tag{99}$$

Since the left-hand side of Eq. (99) is a function of space only and the right-hand side is a function of time only (time has been separated from the space variables), each side must equal a constant (separation constant) that is independent of space and time. The separation constant is a physical parameter when solving physical problems and has the dimensions of energy, denoted by E, in Eq. (99). Equation (99) leads to

$$T(t) = C\exp(-iEt/\hbar), \tag{100}$$

$$\left(-\frac{\hbar^2}{2m}\nabla^2 + V(x,y,z)\right)\psi = E\psi. \tag{101}$$

Equation (101) is the time-independent (steady-state) Schrödinger wave equation. Analyses of solutions of Eq. (101) for various potentials and use of fundamental postulates of quantum theory form the major part of the study of quantum mechanics.

3.3 One-Dimensional Mechanical Wave Equation

Here the one-dimensional mechanical wave equation characterizing the motion of a string fixed at the ends $u(0,t) = u(L,t) = 0$ with initial configuration such that $u(x,0) = 2hx/L$ for x in the closed interval $[0,L/2]$ and $u(x,0) = 2h(L-x)/L$ for x in the closed interval $[L/2,L]$ is solved. The string is initially at rest which means that the partial derivative of $u(x,t)$ with respect to t evaluated at $t=0$ equals zero, $u_t(x,0) = 0$ (see Fig. 11). The method of separation of variables is applied to the equation

$$\frac{\partial^2 u}{\partial x^2} = \frac{1}{v^2}\frac{\partial^2 u}{\partial t^2}. \tag{102}$$

Assume $u(x,t) = X(x)T(t)$ in Eq. (102) and divide the resulting equation by XT. The result is

$$\frac{1}{X}\frac{d^2X}{dx^2} = \frac{1}{v^2}\frac{1}{T}\frac{d^2T}{dt^2}. \tag{103}$$

Since the left-hand side of Eq. (103) is a function of x only and the right-hand side is a function of time only, the two sides must equal a constant (separation constant). The separation constant is denoted by $-\lambda^2$. The square is used for convenience as will be seen below. The negative sign is selected since an oscillatory solution is anticipated. Boundary conditions, however, will determine the required sign for the separation constant. Equation (103) leads to the following two ordinary differential equations

$$\frac{d^2X}{dx^2} + \lambda^2 X = 0 \text{ with solution}$$

$$X(x) = A\cos\lambda x + B\sin\lambda x \tag{104}$$

and

$$\frac{d^2T}{dt^2} + \lambda^2 v^2 T = 0 \text{ with solution}$$

$$T(t) = C\cos\lambda vt + D\sin\lambda vt. \tag{105}$$

The general solution of Eq. (102) is

$$u(x,t) = (A\cos\lambda x + B\sin\lambda x)(C\cos\lambda vt + D\sin\lambda vt). \tag{106}$$

Boundary and initial conditions will now be used to determine the values of the arbitrary

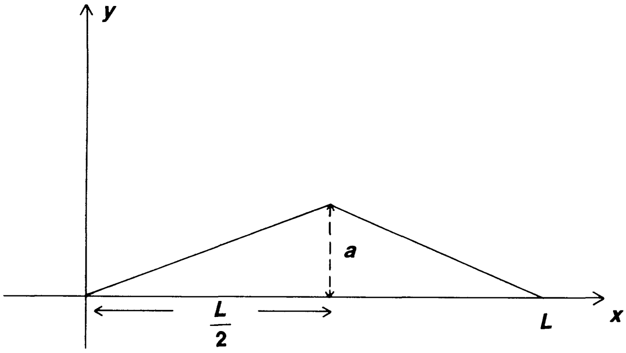

FIG. 11. Initial configuration of the string.

constants in Eq. (106). The first end-point condition $u(0,t)=0$ in Eq. (106) leads to $A=0$. The second end- point condition $u(L,t)=0$ requires that $\sin \lambda L=0$ for a nontrivial solution or $\lambda_n=n\pi/L$ where n ranges from unity to infinity. The solution now reduces to

$$u(x,t)=\sum_{n=1}^{\infty} B_n \sin\left(\frac{n\pi x}{L}\right)\left[C_n \cos\left(\frac{n\pi vt}{L}\right) + D_n \sin\left(\frac{n\pi vt}{L}\right)\right]. \qquad (107)$$

Condition $u_t(x,0)=0$ substituted into the partial derivative of $u(x,t)$ with respect to t requires that $D_n=0$ for all n, and the resulting solution becomes

$$(x,t)=\sum_{n=1}^{\infty} B_n' \sin\left(\frac{n\pi x}{L}\right)\cos\left(\frac{n\pi vt}{L}\right); \qquad B_n'=B_nC_n. \qquad (108)$$

The B_n' coefficients in Eq. (108) are evaluated by use of the Fourier sine series. A detailed discussion of the Fourier series method is given elsewhere in this *Encyclopedia* (see FOURIER AND OTHER MATHEMATICAL TRANSFORMS). Here a summary of Fourier series concepts needed in solving boundary valued problems is presented.

The Fourier representation of $f(x)$ in the closed interval $[-L,L]$ is

$$f(x)=\frac{a_0}{2}+\sum_{n=1}^{\infty}\left[a_n \cos\left(\frac{n\pi x}{L}\right)+b_n \sin\frac{n\pi x}{L}\right]. \qquad (109)$$

Coefficients in Eq. (109) are determined by use of (Euler's formulas)

$$a_n=\frac{1}{L}\int_{-L}^{L} f(x)\cos\left(\frac{n\pi x}{L}\right)dx, \quad n=0,1,2,\ldots, \qquad (110)$$

and

$$b_n=\frac{1}{L}\int_{-L}^{L} f(x)\sin\left(\frac{n\pi x}{L}\right)dx, \quad n=1,2,3,\ldots. \qquad (111)$$

Equation (109) is valid in $[-L,L]$ when $f(x)$ is single valued, is bounded, has at most a finite number of maxima and minima, and has at most a finite number of discontinuities. If $f(x)$ is an even function, $f(x)=f(-x)$, the Fourier cosine series results, and the Fourier sine series results when $f(x)$ is odd, $f(x)=-f(-x)$.

The final condition for Eq. (108), $u(x,0)=2hx/L$ for $[0,L/2]$ and $u(x,0)=2h(L-x)/L$ for $[L/2,L]$, leads to a Fourier sine series from which the B_n' may be obtained. The expression for the B_n' coefficients is

$$\begin{aligned}
B_n' &= \frac{2}{L}\int_0^L f(x)\sin\left(\frac{n\pi x}{L}\right)dx \\
&= \frac{4h}{L^2}\left[\int_0^{L/2} x\sin\left(\frac{n\pi x}{L}\right)dx + L\int_{L/2}^{L} \sin\left(\frac{n\pi x}{L}\right)dx - \int_{L/2}^{L} x\sin\left(\frac{n\pi x}{L}\right)dx\right] \\
&= \frac{8h}{n^2\pi^2}\sin\left(\frac{n\pi}{2}\right) \quad \text{for } n \text{ odd}, \\
&= 0 \quad \text{for} \quad n \text{ even}.
\end{aligned} \qquad (112)$$

The particular solution of Eq. (102) reduces to

$$u(x,t)=\frac{8h}{\pi^2}\sum_{\text{odd}}^{\infty}\left[\frac{(-1)^{(n-1)/2}}{n^2} \times \sin\left(\frac{n\pi x}{L}\right)\cos\left(\frac{n\pi vt}{L}\right)\right]. \qquad (113)$$

The motion of the string is such that only odd-harmonics occur and is symmetrical about the midpoint.

3.4 One-Dimensional Heat Conduction Equation

The method of separation of variables will now be applied to solve the one-dimensional heat conduction equation for the temperature distribution $u(x,t)$ in a rod of length L such that $u(0,t)=u(L,t)=0$ and $u(x,0)=T_0 \times\exp(-ax^2)$. The one-dimensional heat conduction equation is

$$\frac{\partial^2 u}{\partial x^2}=\frac{1}{\sigma}\frac{\partial u}{\partial t}. \tag{114}$$

In Eq. (114), substitute $u(x,t)=X(x)T(t)$ and divide the resulting equation by XT; the resulting two ordinary differential equations for separation constant $-\lambda^2$ are

$$\frac{d^2X}{dx^2}+\lambda^2X=0 \quad \text{with solution}$$

$$X(t)=A\cos\lambda x+B\sin\lambda x \tag{115}$$

and

$$\frac{dT}{dt}+\lambda^2\sigma T=0 \text{ with solution}$$

$$T(t)=C\exp(-\lambda^2\sigma t). \tag{116}$$

The general solution of Eq. (114) is

$$u(x,t)=(A\cos\lambda x+B\sin\lambda x) \times[C\exp(-\lambda^2\sigma t)]. \tag{117}$$

Conditions $u(0,t)=u(L,t)=0$ lead to $A=0$ and $\lambda_n=n\pi/L$ for $n=1, 2,\ldots$, respectively. The final condition yields

$$u(x,0)=T_0\exp(-ax^2)=\sum_{n=1}^{\infty} B'_n\sin\left(\frac{n\pi x}{L}\right). \tag{118}$$

Equation (118) is just a Fourier sine series, and the B'_n coefficients are given by

$$B'_n=\frac{2}{L}\int_0^L T_0\exp(-ax^2)\sin\left(\frac{n\pi x}{L}\right)dx$$

$$=\frac{4T_0}{n\pi} \text{ for } n \text{ odd}, \tag{119}$$

$$=0 \text{ for } n \text{ even}.$$

The particular relation for the temperature distribution in the rod is therefore given by

$$u(x,t)=\frac{4T_0}{\pi}\sum_{\text{odd}}^{\infty}\frac{1}{n}\sin\left(\frac{n\pi x}{L}\right)\exp\left(-\frac{n^2\pi^4\sigma t}{L}\right). \tag{120}$$

3.5 The Two-Dimensional Laplace Equation

Laplace's equation is an example of an elliptic differential equation, and solutions of Laplace's equations are called harmonic functions. The electric potential $u(x,y)$ at points inside a rectangle (see Fig. 12) will now be determined from the solution of the two-dimensional Laplace equation with the indicated boundary conditions:

$$\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}=0; \quad u(0,y)=u(a,y)=u(x,\infty)=0$$

$$\text{and} \quad u(x,0)=u_0. \tag{121}$$

Separation of variables with separation constant $-\lambda^2$ yields

$$\frac{d^2X}{dx^2}+\lambda^2X=0 \text{ with solution}$$

$$X(x)=A\cos\lambda x+B\sin\lambda x \tag{122}$$

and

$$\frac{d^2Y}{dy^2}-\lambda^2Y=0 \text{ with solution}$$

$$Y(y)=C\exp(\lambda y)+D\exp(-\lambda y). \tag{123}$$

The general solution of Eq. (121) is

$$u(x,y)=(A\cos\lambda x+B\sin\lambda x)[C\exp(\lambda y) +D\exp(-\lambda y)]. \tag{124}$$

Condition $u(x,\infty)=0$ requires that $C=0$, condition $u(0,y)=0$ leads to $A=0$, and condition $u(a,y)=0$ gives $\lambda_n=n\pi/a$ for $n=1, 2, 3,\ldots$. The general solution now reduces to

$$u(x,y)=\sum_{n=1}^{\infty} B'_n\sin\left(\frac{n\pi x}{a}\right)\exp\left(-\frac{n\pi y}{a}\right),$$

$$B'_n=B_nD_n. \tag{125}$$

The final condition is used to determine the values of B'_n as follows:

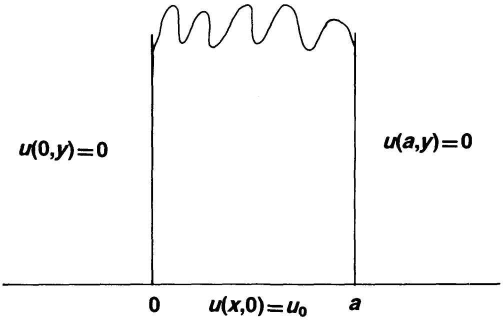

FIG. 12. Boundary configuration for Eq. (121).

$$u(x,0)=u_0=\sum_{n=1}^{\infty} B_n' \sin\left(\frac{n\pi x}{a}\right). \tag{126}$$

Equation (126) is just a Fourier sine series, and the B_n' are given by

$$\begin{aligned} B_n' &= \frac{2}{a}\int_0^a u_0 \sin\left(\frac{n\pi x}{a}\right)dx = -\frac{4u_0}{n\pi} \text{ for } n \text{ odd,} \\ &= 0 \text{ for } n \text{ even.} \end{aligned} \tag{127}$$

The particular solution, expression for the potential at points within the rectangle in Fig. 12, is therefore

$$u(x,y) = -\frac{4u_0}{\pi}\sum_{\text{odd}}^{\infty}\frac{1}{n}\sin\left(\frac{n\pi x}{a}\right)\exp\left(-\frac{n\pi y}{a}\right). \tag{128}$$

The extension to more than two independent variables is straightforward. While the presentation has been restricted to Cartesian coordinates, inclusion of other coordinate systems (for example, cylindrical and spherical) may be carried out in the usual manner. In general, time-independent equations involving the Laplacian operator may be put in the form of Helmholtz's differential equation, $\nabla^2 u + k^2 u = 0$, when the appropriate k is used. Hence, solutions of Helmholtz's equation in various coordinate systems apply to all problems involving the Laplacian operator. In spherical coordinates (r,θ,ϕ), use of separation of variables, the power-series method, and the appropriate k for Helmholtz's equation lead to the following special functions: spherical harmonics, associated Legendre polynomials and Legendre polynomials, associated Laguerre polynomials and Laguerre polynomials, and spherical Bessel functions. Bessel functions result when cylindrical coordinates (ρ,ϕ,z) are used in Helmholtz's differential equation.

3.6 Fourier Transform Method

Methods of integral transforms are treated in detail elsewhere in the *Encyclopedia* (see FOURIER AND OTHER MATHEMATICAL TRANSFORMS). This section is devoted to the technique for solving differential equations (ordinary and partial) by use of the Fourier transform method. The one-dimensional Fourier transform pairs in symmetrical notation are given by

$$\begin{aligned} F(k) &= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} f(x)e^{ikx}dx, \\ f(x) &= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} F(k)e^{-ikx}dk. \end{aligned} \tag{129}$$

In Eq. (129), $F(k)$ is referred to as the Fourier transform of $f(x)$, and $f(x)$ is the inverse transform of $F(k)$. The convention for quantum-mechanical problems involves a sign change in the exponents. Relations in Eq. (129) may be extended to multiple dimensions in a natural manner. The basic idea of the Fourier transform method for solving differential equations (ordinary or partial) is to transform the original equation (ordinary or partial) into a simpler equation (algebraic or ordinary differential) that can be easily solved. The required solution of the original differential equation is then obtained by finding the inverse transform of the solution of the simpler equation which is in transform space.

EXAMPLE 3.1: By use of the Fourier transform method, solve the ordinary differential equation, $\ddot{x} + 2\alpha\dot{x} + w_0^2 x = f(t)$ subject to conditions that $x(t)$ and $\dot{x}(t)$ go to zero as t goes to plus and minus infinity.

SOLUTION: On taking the Fourier transform of each term in the original differential, the result is

$$\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} \ddot{x}(t)e^{i\omega t}dt + \frac{2\alpha}{\sqrt{2\pi}}\int_{-\infty}^{\infty} \dot{x}(t)e^{i\omega t}dt + \frac{\omega_0^2}{\sqrt{2\pi}}\int_{-\infty}^{\infty} x(t)e^{i\omega t}dt = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} f(t)e^{i\omega t}dt. \tag{130}$$

By use of partial integration and the conditions that $x(t)$ and $\dot{x}(t)$ approach zero as t approaches plus and minus infinity, Eq. (130) reduces to the algebraic equation

$$-\omega^2 X(\omega) - 2\alpha i\omega X(\omega) + \omega_0^2\, X(\omega) = F(\omega). \tag{131}$$

On solving the algebraic equation in Eq. (131) for $X(\omega)$ and inverting the transform, the solution $x(t)$ is obtained:

$$x(t) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{F(\omega)e^{-i\omega t}d\omega}{\omega_0^2 - \omega^2 - 2i\alpha\omega}. \tag{132}$$

The integral in Eq. (132) can be evaluated by use of the methods of calculus of residues when $f(t)$ is known.

EXAMPLE 3.2: By use of the Fourier transform method, solve the one-dimensional heat conduction equation for the temperature distribution $T(x,t)$ such that $T(x,t)$ and $T_x(x,t)$ approach zero as x approaches plus and minus infinity and $T(x,0)=T_0\exp(-ax^2)$ for constant a.

SOLUTION: Here, one transforms out the space variable so that the resulting equation will be a first-order ordinary differential equation in t. On taking the Fourier transform of each term in the one-dimensional heat conduction equation, one obtains

$$\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{\partial^2 T}{\partial x^2}e^{ikx}dx$$

$$=\frac{1}{\sigma}\frac{1}{\sqrt{2\pi}}\frac{\partial}{\partial t}\int_{-\infty}^{\infty}T(x,t)e^{ikx}dx. \qquad (133)$$

By use of partial integration and the conditions that $T(x,t)$ and $T_x(x,t)$ approach zero as x approaches plus and minus infinity, Eq. (133) reduces to

$$\frac{\partial T(k,t)}{\partial t}+\sigma k^2 T(k,t)=0. \qquad (134)$$

The solution of Eq. (134) is

$$T(k,t)=A(k)e^{-\sigma k^2 t}=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}T(x,t)e^{ikx}dx. \qquad (135)$$

Substituting the condition $T(x,0)=T_0\times\exp(-ax^2)$ into Eq. (135) yields

$$A(k)=\frac{T_0}{\sqrt{2a}}\exp\left(-\frac{k^2}{4a}\right). \qquad (136)$$

The solution in transform space (k space) is therefore

$$T(k,t)=\frac{T_0}{\sqrt{2a}}\exp\left(-\frac{1+4\sigma at}{4a}\right)k^2. \qquad (137)$$

The solution in x space is obtained when the k-space solution in Eq. (137) is inverted; the result is

$$T(x,t)=\frac{T_0}{\sqrt{1+4\sigma at}}\exp\left(\frac{-ax^2}{1+4\sigma at}\right). \qquad (138)$$

The convolution theorem,

$$\int_{-\infty}^{\infty}f(x-\xi)g(\xi)d\xi$$

$$=\int_{-\infty}^{\infty}F(k)G(k)\exp(-ikx)dk,$$

may be used to find the inverse transform when the solution in transform space is the product of two functions $F(k)G(k)$.

3.7 Green's Functions in Potential Theory

Here the three-dimensional Fourier transform method will be used to solve Poisson's equation for the electric potential $\phi(\mathbf{r})$ due to a volume charge density $\rho(\mathbf{r})$, and the three-dimensional Green's function will be defined. Poisson's equation is written as

$$\nabla^2\phi(\mathbf{r})=-\rho(\mathbf{r})/\epsilon_0\,. \qquad (139)$$

The quantity ϵ_0 is the permittivity of free space. The Fourier transform of $\phi(\mathbf{r})$ has the form

$$\Phi(\mathbf{k})=\frac{1}{(2\pi)^{2/3}}\int_{-\infty}^{\infty}\phi(\mathbf{r})\exp(i\mathbf{k}\cdot\mathbf{r})d^3r. \qquad (140)$$

A shorthand notation for triple integral, $d^3r=dx\,dy\,dz$, is used in Eq. (140). On taking the Fourier transform of both sides of Eq. (139), the solution in transform space [subject to the conditions that $\phi(\mathbf{r})$ and $\partial\phi/\partial r$ approach zero as r approaches plus and minus infinity] becomes

$$\Phi(\mathbf{k})=\rho(\mathbf{k})/k^2\epsilon_0. \qquad (141)$$

The inverse transform of $\Phi(\mathbf{k})$ yields the solution $\phi(\mathbf{r})$, and the result is

$$\begin{aligned}\phi(\mathbf{r})&=\frac{1}{(2\pi)^{3/2}}\int_{-\infty}^{\infty}\frac{\rho(\mathbf{k})}{k^2\epsilon_0}\exp(-i\mathbf{k}\cdot\mathbf{r})d^3r\\&=\frac{1}{(2\pi)^3}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{\rho(\mathbf{r}')}{k^2\epsilon_0}\\&\quad\times\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')]d^3k\,d^3r'\\&=\frac{1}{(2\pi)^2\epsilon_0}\int_{-\infty}^{\infty}\rho(\mathbf{r}')G(\mathbf{r},\mathbf{r}')d^3r'. \qquad (142)\end{aligned}$$

The function $G(\mathbf{r},\mathbf{r}')$, Green's function for the operator ∇^2, is given by

$$G(\mathbf{r},\mathbf{r}')=\int_{-\infty}^{\infty}\frac{\exp[-i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')]d^3k}{k^2}.$$

When spherical polar coordinates are chosen where $d^3k=-\,k^2d(\cos\theta)d\phi\,dk$ and $\mathbf{r}-\mathbf{r}'$ is assumed to be along the polar axis, the expression for the Green's function reduces to $G(\mathbf{r},\mathbf{r}')=2\pi^2/|\mathbf{r}-\mathbf{r}'|$.

Physically, the Green's function $G(\mathbf{r},\mathbf{r}')$ is the electric potential at point $\mathbf{r}$ due to a point charge located at $\mathbf{r}'$. For a volume charge density $\rho(\mathbf{r}')$, the potential at $\mathbf{r}$ is given by $\int\rho(\mathbf{r}')G(\mathbf{r},\mathbf{r}')d^3r'$. In differential equation form, this analysis may be written as $\nabla^2G(\mathbf{r},\mathbf{r}')=-4\pi\delta(\mathbf{r}-\mathbf{r}')$ subject to appropriate boundary conditions for $G(\mathbf{r},\mathbf{r}')$. The Dirac delta function $\delta(\mathbf{r}-\mathbf{r}')$ means

$$\delta(x-x')\delta(y-y')\delta(z-z')$$

with properties $\delta(\mathbf{r}-\mathbf{r}')=0$ for $\mathbf{r}-\mathbf{r}'\neq0$ and $\int_{-\infty}^{\infty}\delta(\mathbf{r}-\mathbf{r}')d^3r'=1$. For Dirichlet boundary conditions, $G(\mathbf{r},\mathbf{r}')=0$ on the boundary surface enclosing the charge distribution $\rho(\mathbf{r}')$. It can be shown that the Neumann problem requires appropriate nonzero values for the normal derivative of the Green's function on the boundary surface. Use of the Green's-function method simplifies the problem of applying boundary conditions.

3.8 Numerical Methods for Partial Differential Equations

Numerical methods in partial differential equations form a vast subject and are treated in detail elsewhere in this *Encyclopedia* (see NUMERICAL METHODS). Here the focus is on essential concepts involved in converting a partial differential equation to its corresponding difference equation by use of finite difference methods. One should consult the references for a detailed discussion of the various special techniques for finding numerical solutions, convergence of solutions, and stability of the various methods.

3.8.1 Fundamental Relations in Finite Differences.

First differences Δ_xu and Δ_yu for positive h and k are defined by

$$\Delta_xu=\frac{u(x+h,y)-u(x,y)}{h},$$

$$\Delta_yu=\frac{u(x,y+k)-u(x,y)}{k}.$$

The corresponding second differences are defined by

$$\Delta_{xx}u=\frac{u(x+h,y)-2u(x,y)+u(x-h,y)}{h^2}$$

and

$$\Delta_{yy}u=\frac{u(x,y+k)-2u(x,y)+u(x,y-k)}{k^2}.$$

For notational convenience, Δx and Δy are replaced with h and k, respectively, in the above finite difference equations, and k replaces Δt in Secs. 3.8.3 and 3.8.4.

3.8.2 Two-Dimensional Laplace Equation: Elliptic Equation.

The two-dimensional Laplace equation in terms of finite differences reduces to

$$u(x,y)=\tfrac{1}{4}[u(x+h,y)+u(x-h,y)+u(x,y+h)+u(x,y-h)].$$

The computational procedure involves replacing $u(x,y)$, for example, a potential, at a particular grid point (see Fig. 13) by the average value of its four closest neighbors. The function $u(x,y)$ or its derivative must be specified at all points surrounding a given region.

3.8.3 One-Dimensional Heat Conduction Equation: Parabolic Equation.

In terms of finite differences, the one-dimensional heat conduction equation reduces to

$$u(x,t+k)=\frac{\sigma k}{h^2}[u(x+h,t)-2u(x,t)+u(x-h,t)]+u(x,t). \qquad (143)$$

The numerical solution involves determining the initial values of $u(x,t)$ at various x locations (see Fig. 14 for the space-time grid) and applying Eq. (143) to obtain the $u(x,t)$ at other times.

3.8.4 One-Dimensional Wave Equation: Hyperbolic Equation.

The finite-difference representation of the one-dimensional wave equation reduces to

$$u(x,t+k)=\frac{k^2v^2}{h^2}[u(x+h,t)-2u(x,t)+u(x-h,t)]+2u(x,t)-u(x,t-k). \qquad (144)$$

The starting value for $u(x,t+k)$ is determined from the initial conditions (see Fig. 15), and remaining values are determined by use of Eq. (144).

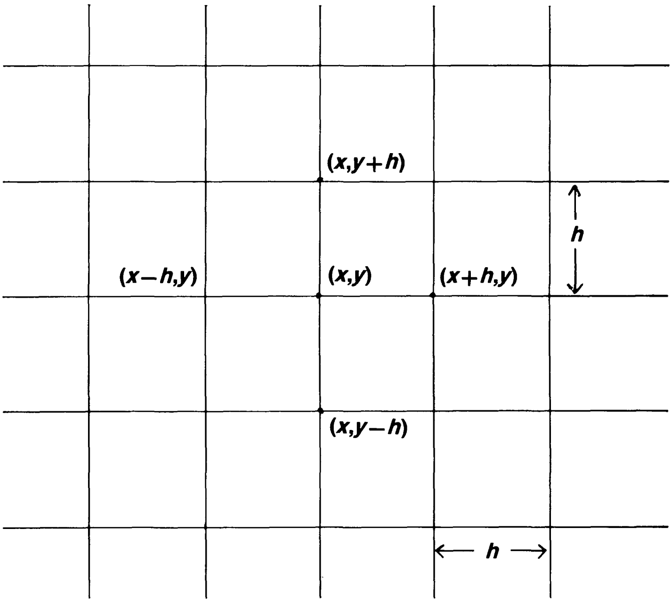

FIG. 13. Grid representation for Laplace's equation.

4. INTEGRAL EQUATIONS

4.1 Introduction

This section is devoted to a discussion of solutions and applications of one-dimensional linear integral equations of the first and second kinds. The formulations of many problems in physics lead to either differential or integral equations. Certain problems can only be represented by integral equations of the general form

$$u(x)=f(x)+\lambda\int_a^b k(x,s)u(s)ds. \tag{145}$$

Equation (145) is an integral equation since the unknown function $u(x)$ appears in the integrand. Functions $f(x)$ and $k(x,s)$ are to be given, and λ is a known parameter used here for convenience. The function $f(x)$ is called

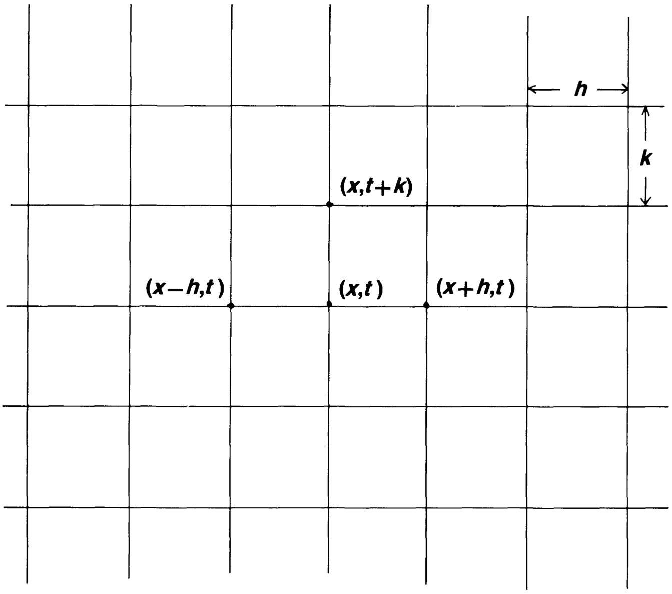

FIG. 14. Space-time grid for the heat equation.

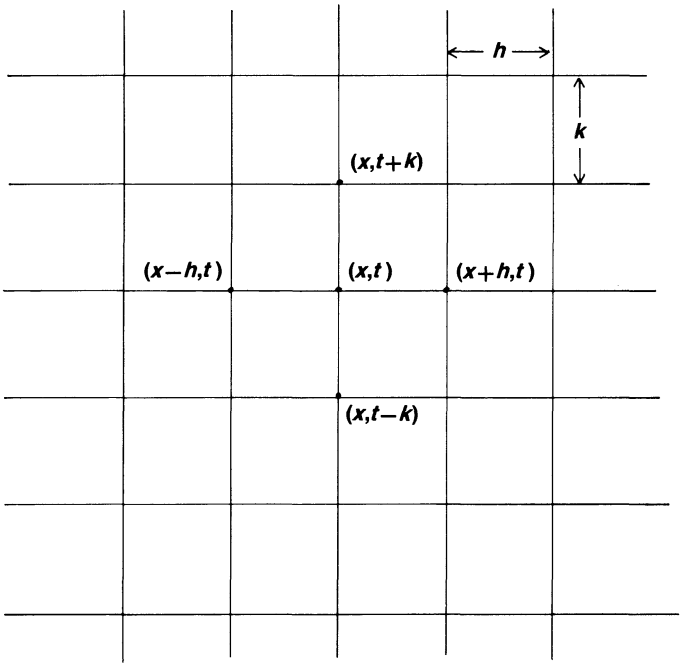

FIG. 15. Space-time grid for the wave equation.

the free term, and $k(x,s)$ is referred to as the kernel (nucleus). Quantities $f(x)$, $k(x,s)$, and λ may be either real or complex but are considered real in this section. Equation (145) is a linear integral equation since u is linear. An integral equation is singular if either (or both) of the limits of integration is infinite and/or if the kernel becomes infinite in the range of integration. When $f(x)$ equals zero, Eq. (145) is classified as a homogeneous integral equation. If the kernel is continuous in the closed region $[a,b]$, then Eq. (145) is classified as a Fredholm-type integral equation of the second kind. The equation (where the upper limit is a variable)

$$u(x)=f(x)+\lambda\int_a^x k(x,s)u(s)ds \qquad (146)$$

is known as a Volterra-type integral equation of the second kind. Fredholm integral equations of the first kind have the form

$$f(x)=\int_a^b k(x,s)u(s)ds. \qquad (147)$$

Volterra-type integral equations of the first kind have the form

$$f(x)=\int_a^x k(x,s)u(s)ds. \qquad (148)$$

In summary, classifications are Fredholm type if the limits of integration are fixed and Volterra type if one limit is variable, and first kind if the unknown function appears only in the integrand and second kind if the unknown function appears both in the integrand and outside the integrand.

Physical problems may be formulated as differential equations with appropriate boundary and/or initial conditions, integral equations, or either differential or integral equations. An essential difference in the formulation is that boundary conditions are imposed on general solutions of differential equations while boundary conditions are incorporated within the formulation of integral equations. While there exist procedures of converting differential equations to integral equations, use of integral equations seems more appropriate when formulations of problems lead directly to integral equations, or when solutions of the corresponding integral equations are easier to obtain than those for the corresponding differential equations. Laplace and Fourier transforms as well as dispersion relations are examples of singular integral equations of the first kind.

It is important to note that certain problems in classical mechanics, transport and diffusion phenomena, scattering theory, and other areas of physics can be formulated only by use of integral equations; the number of such problems is very small when compared to those leading to differential equations. In general, the theory of solution techniques needed in solving integral equations is not as familiar to physicists as techniques for solving differential equations. Integral equations are seldom treated in detail in introductory mathematical physics textbooks but are, however, discussed in advanced books in theoretical physics and mathematical physics. See Further Reading for some excellent books on integral equations. Many integral equations encountered in physics are normally solved by use of intuitive analytical methods, intuitive approximation methods and numerical techniques, or Laplace or Fourier transform methods.

Some systematic methods for solving nonsingular and linear integral equations are transform theory, Neumann series, separable kernel, Schmidt–Hilbert theory, Wiener–Hopf theory, and numerical. The Wiener–Hopf method is a different type of transform method which may be applied to certain integral equations with displacement kernels, $k(x,s)=k(x-s)$. Schmidt–Hilbert theory is an approach that applies to integral equations with Hermitian kernels, $k(x,s)=k^*(s,x)$. Fredholm theory involves representing the kernel as an infinite series of degenerate kernels (Sec. 4.2) and reducing the integral equation to a set of algebraic equations. Numerical solutions of Volterra equations involve reducing the original equations to linear algebraic equations, successive approximations and numerical evaluation of integrals. Numerical techniques for Fredholm equations involve solving a system of simultaneous equations.

4.2 Integral Equations with Degenerate Kernels

A subset of Fredholm equations of the first and second kinds with degenerate (separable) kernels can be solved by reducing them to a system of algebraic equations. In general, degenerate kernels may be written as

$$K(x,s)=\sum_{j=1}^{N} g_j(x)\phi_j(s). \tag{149}$$

In Eq. (149), it is assumed that $g_j(x)$ and $\phi_j(s)$ are linearly independent quantities, respectively. Substituting Eq. (149) into Eq. (145) yields

$$u(x)=f(x)+\lambda\sum_{j=1}^{N} g_j(x)C_j. \tag{150}$$

The coefficients C_j are given by

$$C_j=\int_a^b \phi_j(s)u(s)ds. \tag{151}$$

The solution of Eq. (145) has now been reduced to finding the C_j from the indicated algebraic equations and substituting the C_j into Eq. (150).

EXAMPLE 4.1: By use of the degenerate kernel method, find the solution of $u(x)=x+\lambda\int_0^1 xsu(s)ds$. The integral equation becomes

$$u(x)=x+\lambda x\int_0^1 su(s)ds=x+\lambda xC. \tag{152}$$

The coefficient C reduces to

$$C=\int_0^1 su(s)ds=\int_0^1 s(s+\lambda sC)ds=\frac{1}{3-\lambda}. \tag{153}$$

The second step in Eq. (153) results when the second step of Eq. (152) is substituted into the first step of Eq. (153). From Eqs. (152) and (153), the solution of the original equation is $u(x)=3x/(3-\lambda)$. It is seen that solutions exist for values of λ different from 3.

EXAMPLE 4.2: By use of the degenerate kernel method, find the solution of $u(x) = x + \frac{1}{2}\int_{-1}^{1}(s + x)ds$. The equation becomes

$$u(x)=x+\frac{C_1}{2}+\frac{xC_2}{2}. \tag{154}$$

The coefficients C_1 and C_2 are

$$C_1=\int_{-1}^{1} su(s)ds=\frac{2-C_2}{3} \quad\text{and}$$

$$C_2=\int_{-1}^{1} u(s)ds=C_1 \quad\text{or}\quad C_1=C_2=1. \tag{155}$$

On substituting the values for C_1 and C_2 into Eq. (154), the solution of the original equation becomes $u(x)=(3x+1)/2$.

4.3 Integral Equations with Displacement Kernels

If the kernel is of the form $k(x-s)$, it is referred to as a displacement kernel. Fredholm equations of the first and second kinds with displacement kernels and limits from minus infinity to plus infinity or from zero to plus infinity can normally be solved by use of Fourier and Laplace transform methods, respectively. Here the Fourier transform approach for solving integral equations with displacement kernels will be illustrated. Taking the Fourier transform of each term in Eq. (145) yields

$$\int_{-\infty}^{\infty} u(x)\exp(ikx)dx = \int_{-\infty}^{\infty} f(x)\exp(ikx)dx + \lambda\int_{-\infty}^{\infty}\left(\int_{-\infty}^{\infty} K(x-s)u(s)ds\right) \times\exp(ikx)dx. \tag{156}$$

In transform space, Eq. (156) is $u(k)=F(k)+\lambda K(k)u(k)$. The solution in x space is obtained when the inverse transform of $u(k)$ is taken, and the result becomes

$$u(x)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{F(k)\exp(-ikx)dk}{1-\lambda K(k)}. \tag{157}$$

4.4 The Neumann Series Method

Consider the set of Fredholm equations of the second kind such that

$$\int_a^b |f(x)|^2dx \quad \text{and} \quad \int_a^b |K(x,s)|^2ds$$

are bounded. Assume the solution may be written as a power series, Neumann series (also known as Liouville–Neumann series), with form

$$u(x)=\sum_{n=0}^{\infty}\lambda^n u_n(x). \tag{158}$$

Terms in the successive approximation are obtained by substituting the Neumann series into the Fredholm equation, Eq. (145), and equating coefficients of like powers of λ; the results are

$$u_0=f(x);$$

$$u_1(x)=\int_a^b K(x,s)u_0ds;\ \ldots;$$

$$u_n(x)=\int_a^b K(x,s)u_{n-1}(s)ds. \tag{159}$$

It can be shown that the Neumann series converges for all values of λ for Volterra equations and converges for small values of λ for Fredholm equations; techniques exist for improving the convergence in the Fredholm case. Numerical techniques may be used to evaluate terms in the Neumann series.

4.5 The Abel Problem

The section on integral equations is concluded with the earliest application of integral equations to a physical problem, Abel's problem. The Abel problem is as follows: Consider a bead sliding on a smooth wire under the influence of gravity and find the curve for which the time of descent is a given function of the initial position.

Let the starting position of the bead be (x_0, y_0) and position of the bead at time t be (x,y) such that y equals zero at the end of the fall. The speed of the bead at (x,y) for ds an element of arc length along the path is determined from the conservation of energy principle and is given by

$$\frac{ds}{dt}=\sqrt{2g(y_0-y)}.$$

If the shape of the curve is $u(y)$, then $ds=u(y)dy$ and the time of descent is given by

$$T=\int_0^{y_0}\frac{u(y)dy}{\sqrt{2g(y_0-y)}}.$$

The Abel problem is to find the curve $u(y)$ for which the time T of descent is a given function $f(y_0)$ of the initial vertical position, and the result is obtained from the integral equation (Abel's equation):

$$f(y_0)=\int_0^{y_0}\frac{u(y)dy}{\sqrt{2g(y_0-y)}}. \tag{160}$$

It can be shown that the curve in question is a portion of a cycloid.

5. APPLIED FUNCTIONAL ANALYSIS

5.1 Introduction

Concepts of functions (of one variable) and operators were introduced into mathematics in connection with the development of calculus during the latter part of the seventeenth century. In general, an operator applied to a given function yields a new function. The problem of finding an extremum (maximum or minimum) of a function is carried out in the usual manner by use of ordinary calculus, but the general problem of finding the stationary value (an extremum) of certain definite integrals that occur in mathematical physics is the subject matter of the branch of mathematics called the calculus of variations.

In relation to the calculus of variations, the process of connecting (mapping) each function $y(x)$ in $[a,b]$ with a number represented by the definite integral $\int_a^b F(y,y',x)dx$ (where $y'=dy/dx$) which depends on $y(x)$ was given the name functional during the end of the nineteenth century. The basic idea of functional analysis is that problems are often easier to solve if a function is considered to be a member of a whole space of functions, X. The space X is assumed to carry a metric, have a linear space structure, and be infinite dimensional. The concept of a metric involves topological and geometrical language while linear operators on X involve concepts of linear algebra, and relations among these concepts constitute linear functional analysis.

A function which depends on one or more functions rather than on discrete variables is referred to as a functional. The domain of a functional is a space of admissible functions. More precisely, functionals are continuous linear maps, from a normed space into itself or into some other normed space. The basic ingredient of the various definitions of a functional and of functional analysis is the existence of a linear space with a topology.

The main topics in Secs. 1–4 (functions of a complex variable and analytic functions, ordinary and partial differential equations, Fourier series and Fourier transform theory, and integral equations) are technically topics in functional analysis even though the topology and geometry of the linear spaces involved were not stressed. Mathematically, a valid argument can be made that concluding this article with a discussion of functional analysis is analogous to putting the cart before the horse. This argument, however, neglects the applications-of-techniques approach emphasized throughout the article.

In mathematical physics, functional analysis often involves discussions connected with the calculus of variations; theory of ordinary and partial differential equations; integral equations and transform theory; spectral theory involving eigenvalues, eigenfunctions, and Fourier series expansion theory involving orthogonal functions; functional calculus used in the path integral formulation of quantum mechanics, quantum field theory, and statistical mechanics; C^* algebra; and the theory of distributions. In mathematics, functional analysis often involves the general theory of linear normed spaces, the topological structure of linear spaces and continuous transformations, measure spaces and general theories of integration, spectral theories, C^* algebra, distribution theory, and number theory.

In this section, the original problem of functional analysis (the calculus of variations) and applications of functional integration to quantum mechanics, quantum field theory, and statistical mechanics will be discussed.

5.2 Stationary Values of Certain Definite Integrals

Consider the following definite integral of the functional $F(y,y',x)$ where F is a known function of y, y' (where $y'=dy/dx$), and x, but $y(x)$ is unknown:

$$J=\int_{x_1}^{x_2} F(y,y',x)dx. \tag{161}$$

A fundamental problem in the calculus of variations (a problem which occurs frequently in mathematical physics) is that of finding a function $y(x)$ such that the functional J is stationary (an extremum; a minimum in most cases of physical interest). The basic procedure here is to evaluate the integral for a slightly modified path $y(x,\alpha)=y(x,0)+\alpha\eta(x)$ where $\eta(x_1)=\eta(x_2)=0$ (all paths pass through the end points) and show that the change in the value of the integral due to the change in the path becomes zero. The function $\eta(x)$ is an arbitrary differentiable function, and α is a small scale factor (see Fig. 16). The function $y(x,\alpha)$ describes neighboring paths where $\delta y = y(x,\alpha) - y(x,0) = \alpha\eta(x)$ is the variation (hence the name calculus of variations) of $y(x,0)$ at some x. The delta symbol, δ, was introduced by Lagrange to denote a variation (a virtual change) and means a change made in an arbitrary manner. Both dy and δy denote infinitesimal changes in y, but dy means an infinitesimal change in $y(x)$ produced by dx while δy is an infinitesimal change which produces $y+\delta y$. It is straightforward to show that $d\delta y/dx = \delta\, dy/dx$ and $\delta\int_{x_1}^{x_2} F(y,y',x)dx = \int_{x_1}^{x_2} \delta F(y,y',x)dx$. On substituting $y(x,\alpha) = y(x,0) + \alpha\eta(x)$ into Eq. (161) and differentiating both sides of the resulting equation with respect to α, one obtains

$$\frac{dJ(\alpha)}{d\alpha} = \int_{x_1}^{x_2} \left(\frac{\partial F}{\partial y}\eta(x) + \frac{\partial F}{\partial y'}\eta'(x) \right) dx. \tag{162}$$

Integrating the second term in Eq. (162) by parts and using the fact that $\eta(x)$ is arbitrary yield

$$\frac{\partial F}{\partial y} - \frac{d}{dx}\left(\frac{\partial F}{\partial y'} \right) = 0. \tag{163}$$

Equation (163) is known as Euler's equation and its solution yields the $y(x)$ which makes J an extremum (minimum). An alternative and often used approach for obtaining Euler's equation makes use of expanding the right-hand side of δF in a Taylor's series with two variables; the result becomes

$$\delta F = F(y+\alpha\eta, y'+\alpha\eta', x) - F(y,y',x)$$
$$= \alpha\left(\frac{\partial F}{\partial y}\eta + \frac{\partial F}{\partial y'}\eta' \right). \tag{164}$$

Higher-order terms in the Taylor expansion may be used to determine the nature of the extremum (maximum or minimum), and neglected here since α is a small parameter. As a result of substituting Eq. (164) into the integrand for δJ, integrating the second term by parts as before, and setting $\delta J/\alpha = 0$, one obtains the Euler equation in Eq. (163).

The above processes of obtaining Euler's equation, Eq. (163), may be extended to functionals involving several dependent and/or independent variables; for example, the variational process applied to $F(y_1,\ldots,y_n, y_1', \ldots, y_n', x)$ yields the following set of Euler's equations:

$$\frac{\partial F}{\partial y_k} - \frac{d}{dx}\left(\frac{\partial F}{\partial y_k'} \right) = 0 \quad (k=1,2,\ldots,n). \tag{165}$$

EXAMPLE 4.3: By use of the variational calculus method (Euler's equation), determine the equation of the shortest path between two points (x_1,y_1) and (x_2,y_2) in Cartesian coordinates.

SOLUTION: The element of distance along the path between the two points is given by

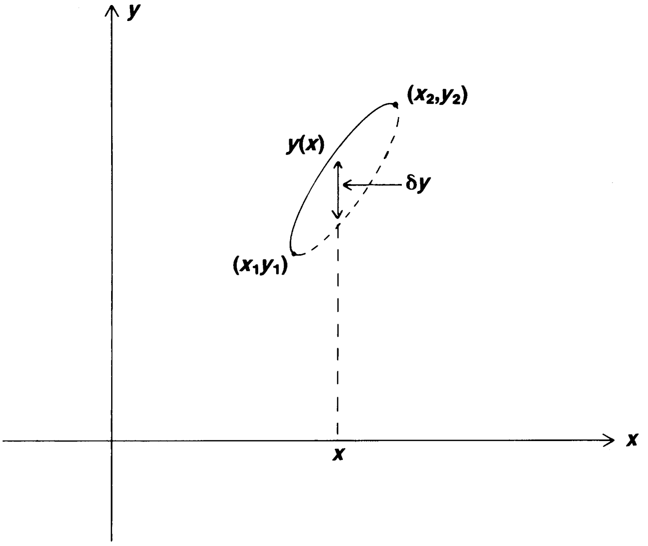

FIG. 16. A varied path between (X_1,Y_1) and (X_2,Y_2).

1. $ds=\sqrt{dx^2+dy^2}$.

The expression for the distance between the two points is therefore

2. $s=\int_{x_1}^{x_2}\sqrt{1+(y')^2}dx$, where $y'=\frac{dy}{dx}$.

For $F(y,y',x)=\sqrt{1+(y')^2}$, the differential equation for the equation of the shortest path between the two points, Euler's equation, reduces to

3. $\frac{dy}{dx}=A$ since $\frac{\partial F}{\partial y}=0$ and

$$\frac{\partial F}{\partial y'}=\frac{y'}{\sqrt{1+(y')^2}}.$$

The equation of the shortest path between the two points is therefore that of a straight line, $y(x)=Ax+B$.

EXAMPLE 4.4: (THE BRACHISTOCHRONE PROBLEM). The brachistochrone (shortest time) problem, first formulated and solved by Johann Bernoulli in 1696, is one of the first variational problems. The problem is as follows: Consider a bead of mass m which slides, under the influence of gravity, down a frictionless wire bent into the appropriate shape. The goal is to find the equation (shape of the wire) of the path along which the bead travels so that the time is a minimum.

SOLUTION: For convenience, it is assumed that the bead starts from rest at the origin of a coordinate system (see Fig. 17). Since this is a conservative system, the following relations are valid: $T_1+V_1=T_2+V_2$, $V_2=-mgy$, $T_1=V_1=0$, $T_2=\frac{1}{2}mv^2$, and $v=\sqrt{2gy}$. The expression for the time required for the bead to travel from the origin to point (x,y) is therefore given by

1. $t=\int\frac{\sqrt{dx^2+dy^2}}{\sqrt{2gy}}$

$$=\int_0^{y_2}\frac{\sqrt{1+(x')^2}dy}{\sqrt{2gy}},\quad x'=\frac{dx}{dy}.$$

The unknown function $y(x)$ must be determined such that the time is a minimum. On applying Euler's equation with

$$F=\left(\frac{1+(x')^2}{y}\right)^{1/2}$$

and independent variable y, one obtains

2. $x=\int\frac{Ay\,dy}{\sqrt{y-A^2y^2}}$ since

$$\frac{\partial F}{\partial x}=0\quad\text{and}\quad\frac{\partial F}{\partial x'}=\frac{x'}{\sqrt{y[1+(x')^2]}}=A.$$

On letting $A=1/\sqrt{2a}$ and making the change of variable $y=a(1-\cos\theta)$, the above integral reduces to $x=a(\theta-\sin\theta)$

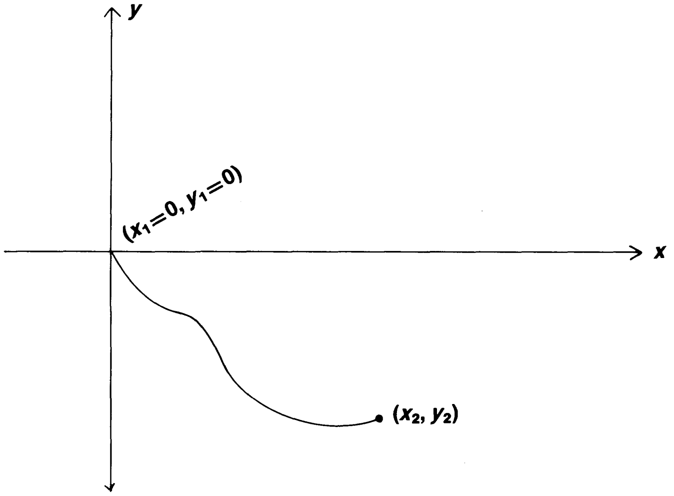

FIG. 17. Diagram for the brachistochrone example.

+const. The path that yields a minimum time of travel is in the form of parametric equations $x=a(\theta-\sin\theta)$ and $y=a(1-\cos\theta)$, equations for a cycloid that passes through the origin.

5.3 Hamilton's Variational Principle in Mechanics

5.3.1 Introduction. Mechanics is the study of the motions (including rest) of physical objects. The laws of classical mechanics are valid for macroscopic objects (size larger than 10^{-10} m), and the laws of quantum mechanics are valid in the microworld (object size smaller than 10^{-10} m). In this section, the focus is on the study of classical mechanics. Widely used equivalent formulations of classical mechanics are Newtonian mechanics (1687), Lagrangian mechanics (1788), Hamiltonian mechanics (1834), and Hamilton–Jacobi theory (1837).

Formulations of classical mechanics developed since Newtonian mechanics are generalizations and equivalent representations of Newtonian mechanics. These generalizations do not lead to new information but offer different ways of approaching problems. Certain problems can be solved by use of all four approaches with equal amounts of ease (or difficulty). Other problems are more amenable to solution by use of one approach than by use of the others. The specific nature of the problem to be solved usually dictates the approach that should be used.

Newton's second law is the basic equation of motion in the Newtonian picture of mechanics. In Lagrangian mechanics, Lagrange's equations are the required set of equations of motion for the system (particle or group of particles) under investigation. Hamilton's canonical equations are basic to Hamiltonian mechanics, and the Hamilton–Jacobi equation is the foundation of the Hamilton–Jacobi theory.

The approach in this section begins with Hamilton's variational principle for conservative systems (where the forces acting on the system may be derived from a potential function) from which Lagrange's equations will be developed by use of the variational calculus method. By use of a Legendre transformation, the Hamiltonian and subsequently Hamilton's canonical equations are obtained.

The variational technique used in mechanics was developed mainly by Euler and Lagrange and is a mathematical formulation of mechanics in which kinetic energy and potential energy play an essential role. In Newtonian mechanics, forces play the central role.

5.3.2 Generalized Coordinates. Linearly independent quantities $\{q_k\}=q_1,\ldots,q_k$ that completely define the position (configuration) of a system as a function of time are called generalized coordinates. Quantities $\{q_k\}$ are said to be linearly independent if $\sum_k \alpha_k q_k=0$ implies that $\alpha_k=0$ for all k. Generalized coordinates may be selected to match the conditions of the problem to be solved. The number of generalized coordinates that must be used to define uniquely the position of a system represents the number of degrees of freedom for the system. The corresponding quantities $\{\dot{q}_k\}$ are called generalized velocities.

The simultaneous specification of $\{q_k\}$ and $\{\dot{q}_k\}$ for a system determines the mechanical state of the system at that time, and subsequent motion is obtained from the solutions $q_k(t)$ of the appropriate equations of motion. The appropriate second-order differential equations expressing the relations among generalized coordinates q_k, generalized velocities $\dot{q}_k$, and generalized accelerations $\ddot{q}_k$ are called equations of motion for the system under investigation.

Although the set of generalized coordinates used to solve a problem is not unique, a proper set of generalized coordinates is that set which leads to an equation of motion whose solution has a straightforward physical interpretation. No general rule exists for obtaining a proper set of generalized coordinates.

5.3.3 Lagrange's Equations. Hamilton's variational principle asserts that the actual motion of a particle or system of particles (conservative system) from its initial configuration at time t_1 to its configuration at time t_2 is such that

$$\delta S=\delta\int_{t_1}^{t_2} L(q_k,\dot{q}_k)dt=0. \qquad (166)$$

In Eq. (166), $q_k=q_k(t)$, $L=T-V$ is defined as the Lagrangian for the system under investigation, $L\,dt$ is called the action, and

$$S=\int_{t_1}^{t_2} L\,dt$$

denotes the action integral. The quantities T and V are kinetic and potential energy, respectively.

Among the infinite number of trajectories $q(t)$ that connect the end points $q(t_1)$ and $q(t_2)$, the physical (actual) path yields a stationary value for the action integral. The action is therefore a functional of the functions $q_k(t)$ satisfying the boundary conditions that all trajectories pass through the end points. By use of the variational technique leading to Eq. (165), one finds that $q(t)$ is obtained from the following set of differential equations:

$$\frac{\partial L}{\partial q_k}-\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}_k}\right)=0, \quad k=1,2,\ldots,n. \qquad (167)$$

The equations in Eq. (167) are called Lagrange's (or Euler–Lagrange) equations. Lagrange's equations, the equations of motion for the system under investigation, are a set of n second-order differential equations. The general solutions of these equations contain $2n$ arbitrary constants of integration. The values of these $2n$ arbitrary constants are determined when the initial state (initial values for the q_k and $\dot{q}_k$ at $t=0$) of the system is specified.

Quantities $\partial L/\partial \dot{q}_k$ and $\partial L/\partial q_k$ are defined to be canonical momenta (also called conjugate or generalized momenta) and generalized forces, respectively,

$$p_k=\frac{\partial L}{\partial \dot{q}_k} \quad \text{and} \quad F_k=\frac{\partial L}{\partial q_k}. \qquad (168)$$

By use of the definitions in Eq. (168), it is observed that Lagrange's equations may be considered a generalized version of Newton's second law where generalized force equals the rate of change of canonical momentum.

Basic conservation laws of mechanics result from invariance of the Lagrangian under time translation— conservation of energy, coordinate translation—conservation of canonical momentum, translation in space—conservation of total linear momentum, and rotation in space—conservation of angular momentum. In spite of the important role of the Lagrangian, it is not a unique function for a system since the equations of motion for the system, Lagrange's equations, are unchanged if $df(q_k,t)/dt$ is added to the Lagrangian.

5.3.4 Format for Solving Problems by Use of Lagrange's Equations. The following steps should be used when applying Lagrange's equations.

1. Draw a detailed diagram. Specify the degrees of freedom and the level where potential energy V equals zero.
2. Write down the appropriate expressions for T, V, and L.
3. Write down the specific set of Lagrange's equation(s).
4. Work out the terms in the set of equations in Step 3.
5. Solve the resulting equation(s) of motion subject to the given initial conditions.

5.4 Formulation of Hamiltonian Mechanics

It has been shown that Hamilton's variational principle combined with techniques of the calculus of variations transforms the process of finding the solution of a mechanical problem to that of obtaining solutions for Lagrange's equations. Hamilton developed a procedure for transforming Lagrange equations to a simpler (canonical) form by replacing them (a set of n second-order differential equations) with a set of $2n$ first-order differential equations now called Hamilton's canonical equations of motion.

5.4.1 Derivation of Hamilton's Canonical Equations. The Lagrangian is a function of q_k and $\dot{q}_k$; now the change of variable $\dot{q}_k \rightarrow p_k$ where $p_k=\partial L/\partial \dot{q}_k$ will be made. By use of a Legendre transformation [new function equals the old function minus (the derivative of the old function with respect to the old variable) times the old variable; the physical and geometrical content of the new and old functions is the same], one obtains

$$-H\equiv L-\sum_{k=1}^{n} p_k\dot{q}_k. \qquad (169)$$

The negative sign in Eq. (169) is by convention. The new function $H(q_k,p_k)$ contains the same geometrical and physical content as $L(q_k,\dot{q}_k)$ and is called the Hamiltonian of the system. Note that the action integral may now be written as

$$S=\int_{t_1}^{t_2}\left(\sum_{k=1}^{n} p_k\dot{q}_k-H\right)dt. \qquad (170)$$

Applying the variational techniques of Sec. 5.2 to Eq. (170) yields

$$\dot{q}_k=\frac{\partial H}{\partial p_k} \quad \text{and} \quad \dot{p}_k=-\frac{\partial H}{\partial q_k}. \tag{171}$$

The equations in Eq. (171) are referred to as Hamilton's canonical equations of motion (or simply Hamilton's equations). Hamilton's equations can be used to develop the specific set of equations of motion for the system under investigation in terms of the phase space variables q_k and p_k. Note that Lagrange's equations consist of n second-order differential equations whereas Hamilton's equations form a set of $2n$ first-order differential equations. For a conservative system, it can be shown that the Hamiltonian equals the total energy of the system ($H=T+V$).

5.4.2 Format for Solving Problems by Use of Hamilton's Equations. In solving problems by use of Hamiltonian mechanics, the following five-step procedure is highly recommended.

1. Write out the Lagrangian as in Lagrangian mechanics, $L=T-V$.
2. Solve the equation $p_k=\partial L/\partial \dot{q}_k$ for $\dot{q}_k$ and eliminate $\dot{q}_k$ from the Lagrangian.
3. Construct the Hamiltonian for the system, $H = \sum_{k=1}^{n} \dot{q}_k\, p_k - L$.
4. Obtain Hamilton's equations, $\dot{q}_k=-\partial H/\partial p_k$ and $\dot{p}_k=-\partial H/\partial q_k$.
5. Solve the $2n$ first-order differential equations (equations of motion) developed in step 4.

5.4.3 Poisson's Brackets. The total time derivative of a function $f(q_k, p_k)$ is

$$\begin{aligned}\frac{df}{dt}&=\sum_{k=1}^{n}\left(\frac{\partial f}{\partial q_k}\dot{q}_k+\frac{\partial f}{\partial p_k}\dot{p}_k\right)\\ &=\sum_{k=1}^{n}\left(\frac{\partial f}{\partial q_k}\frac{\partial H}{\partial p_k}-\frac{\partial f}{\partial p_k}\frac{\partial H}{\partial q_k}\right)=\{f,H\}.\end{aligned} \tag{172}$$

Hamilton's equations were used in obtaining Eq. (172). The last quantity in Eq. (172) is called a Poisson bracket. A Poisson bracket is defined by

$$\{f,g\}=\sum_{k=1}^{n}\left(\frac{\partial f}{\partial q_k}\frac{\partial g}{\partial p_k}-\frac{\partial f}{\partial p_k}\frac{\partial g}{\partial q_k}\right). \tag{173}$$

Hamilton's canonical equations in terms of Poisson brackets are given by

$$\begin{aligned}\dot{q}_k&=\frac{\partial H}{\partial p_k}=\{q_k,H\},\\ \dot{p}_k&=-\frac{\partial H}{\partial q_k}=\{p_k,H\}.\end{aligned} \tag{174}$$

Two variables ξ_i and ϕ_i are said to be canonically conjugate if

$$\{\xi_i,\xi_k\}=\{\phi_i,\phi_k\}=0 \quad \text{and} \quad \{\xi_i,\phi_k\}=\delta_{ik}. \tag{175}$$

The Kronecker delta function is defined by

$$\delta_{ik}=\begin{cases}1; & i=k,\\ 0; & i\neq k.\end{cases} \tag{176}$$

The quantities q_j and p_j are canonically conjugate variables since $\{q_j,p_k\}=\delta_{jk}$ and $\{q_j,q_k\}=\{p_j,p_k\}=0$; these three Poisson brackets are referred to as fundamental Poisson brackets.

5.5 Continuous Media and Fields

Thus far, only conservative systems composed of discrete particles have been considered. The Lagrangian of a system composed of N free particles may be written as

$$L=\sum_{i=1}^{N} L_i. \tag{177}$$

The extension of the above analysis to a system with an infinite number of degrees of freedom (a continuous medium) is achieved by replacing the subscript k with a continuous variable (say $\mathbf{x}$), q_k with a new function $q_k \rightarrow Q(\mathbf{x},t)$, the sum with an integral $\sum_i \rightarrow \int d^3x$, and canonical momenta with canonical momentum density given by $\pi(\mathbf{x})=\partial\mathscr{L}/\partial\dot{Q}$ where $\mathscr{L}$ is the Lagrangian density. The quantity $Q(\mathbf{x},t)$ is called a field. To denote several fields, the notation $Q_\alpha(\mathbf{x},t)$ may be used. The parameter α distinguishes among the different fields. From a mathematical point of view, a field is a set of functions of space-time, and these functions satisfy a set of partial differential equations. The corresponding Hamilton's variational principle is

$$0=\delta\int_{t_1}^{t_2}\sum_{i=1}^{N}L_i(q_k,\dot{q}_k)dt$$

$$=\delta\int_{t_1}^{t_2}\int_{\text{physical space}}\mathscr{L}\{Q_\alpha(\mathbf{x},t),$$

$$\dot{Q}_\alpha(\mathbf{x},t)\}d^4x;$$

$$d^4x=dx\,dy\,dz\,dt. \qquad (178)$$

Assuming that fields interact only with infinitesimal neighbors, the Lagrangian density should be a function of $Q_\alpha(\mathbf{x},t)$, $\dot{Q}_\alpha(\mathbf{x},t)$, and $\partial Q_\alpha(\mathbf{x},t)/\partial x_k$ or $Q_\alpha(x^\mu)$ and $\partial_\mu Q_\alpha$ in four-vector notation. By use of appropriate boundary conditions, the variation in Eq. (178) leads to the following set of equations of motion:

$$\frac{\partial\mathscr{L}}{\partial Q_\alpha}-\partial_\mu\left(\frac{\partial\mathscr{L}}{\partial(\partial_\mu Q_\alpha)}\right)=0,\quad \mu=0,1,2,3. \qquad (179)$$

The equations in Eq. (179) are the Lagrange's equations for classical fields.

5.6 Transitions to Quantum Mechanics

The laws of classical mechanics are not in general valid for the microworld, and new laws (quantum theory) that are appropriate for the microworld were developed during the period 1900–1927. In this section, the transition from classical mechanics to quantum mechanics in the Heisenberg picture, in the Schrödinger picture, and by use of the action functional (path integral) approach due to Dirac and Feynman will be made. For notational convenience, the discussion is restricted to the case of one nonrelativistic particle. The starting point in both the Heisenberg and Schrödinger pictures is Hamiltonian mechanics while the Feynman (Dirac–Feynman) approach begins with Lagrangian mechanics.

The postulates of quantum mechanics may be stated as follows.

1. Each state of a physical system corresponds to a normalized vector in Hilbert space called the state vector, Ψ or $|\Psi\rangle$.
2. Physical quantities are represented by linear Hermitian operators in Hilbert space.
3. If a system is in a state $|\Psi\rangle$, then the probability that a measurement (consistent with quantum theory) of the quantity corresponding to $\hat{A}$ will yield one of the eigenvalues a_k (where $\hat{A}|\Psi\rangle=a_k|\Psi\rangle$) is given by $|\langle a_k|\Psi\rangle|^2$. The system will change from state $|\Psi\rangle$ to $|a_k\rangle$ as a result of the measurement. The quantity $\langle a_k|\Psi\rangle$is the amplitude.

5.6.1 The Heisenberg Picture. In the Heisenberg approach, a system is quantized by letting q_k and p_k be Hermitian operators in a Hilbert space such that $q_k\to\hat{q}_k$ and $p_k\to-i\hbar\,\partial/\partial q_k$, and replacing Poisson brackets with commutators, $\{A,B\}\to[\hat{A},\hat{B}]/i\hbar$ where $[\hat{A},\hat{B}]=\hat{A}\hat{B}-\hat{B}\hat{A}$. If $[\hat{f},\hat{g}]=i\hbar$, the operators $\hat{f}$ and $\hat{g}$ are said to be canonically conjugate. The resulting Heisenberg equations of motion for a quantum mechanical system are

$$i\hbar\dot{p}_k=[p_k,H] \quad\text{and}\quad i\hbar\dot{q}_k=[q_k,H]. \qquad (180)$$

The equations in Eq. (180) are basic for Heisenberg (matrix) mechanics.

5.6.2 The Schrödinger Picture. From a classical mechanical point of view, the Hamiltonian of a particle subject to conservative forces equals the total energy of the particle, and one may write

$$H=E=\mathbf{p}^2/2m+V(x,y,z). \qquad (181)$$

The transition to quantum mechanics in the Schrödinger picture is achieved by use of the replacements $E\to i\hbar\,\partial/\partial t$ and $\mathbf{p}\to-i\hbar\nabla$; by use of these replacements, Eq. (182) is transformed into an operator equation. Operating on some function $\Psi(x,y,z,t)$ or $|\Psi\rangle$ in Hilbert space yields

$$i\hbar\frac{\partial\Psi}{\partial t}=-\frac{\hbar^2}{2m}\nabla^2\Psi+V\Psi \quad\text{or}\quad i\hbar\frac{\partial|\Psi\rangle}{\partial t}=\hat{H}|\Psi\rangle. \qquad (182)$$

Schrödinger's equation, Eq. (182), is the basic equation of motion of a particle in quantum mechanics in the Schrödinger picture.

5.6.3 The Feynman Path-Integral Approach to Quantum Mechanics. The special case of one particle with one degree of freedom is considered here to simplify the notation and make the explanations clear. Feynman's formulation of quantum mechanics was stimulated by some work of Dirac (1933) and is based on the following two postulates:

1. The amplitude $\langle q(t'')|q(t')\rangle$ for a particle to be found at $q(t'')$ at time t'' if its initial position is $q(t')$ at time t' equals a sum of complex contributions (amplitudes) for

each space-time path starting at $q(t')$ and ending at $q(t'')$.

2. All paths connecting $q(t')$ and $q(t'')$ contribute equally in magnitude, but the phase (weight) of their contribution is $\exp(iS/\hbar)$ where S is the classical action integral for the corresponding paths.

The measure on the functional space of paths $q(t)$ is denoted by $\mathscr{D}[q(t)]$, and appropriate normalization factors for the amplitude are contained in $\mathscr{D}[q(t)]$. Feynman's interpretation of the indicated functional integration is as follows: Divide the time interval $t''-t'$ into N equal parts, each with duration $\epsilon=t_{k+1}-t_k$; and in the limit $N\to\infty$ ($\epsilon\to 0$), it is assumed that the sequence of points $q(t_0),\ldots,q(t_n)$ approximates the path $q(t)$. The action functional associated with the classical path joining $q(t_k)=q_k$ and $q(t_{k+1}) = q_{k+1}$ is

$$S[q_{k+1},q_k]=\int_{t_k}^{t_{k+1}} L(q,\dot{q})dt.$$

Feynman's postulates thus assert that the amplitude $\langle q(t'')|q(t')\rangle$ is a sum of all amplitudes for all paths connecting $q(t'')$ and $q(t')$, and it may be written as (see Fig. 18)

$$\langle q(t'')|q(t')\rangle=\lim_{\substack{\epsilon\to 0\\ N\to\infty}}\int\cdots\int\prod_{k=0}^{N}\exp\left(\frac{i}{\hbar}S(q_{k+1},q_k)\right)\frac{dq_k}{A_k}=\int\cdots\int\exp\left(\frac{i}{\hbar}\int_{t'}^{t''}L(q,\dot{q})dt\right)\mathscr{D}[q(t)]. \tag{183}$$

The normalization factors A_k in Eq. (183) are independent of the path from q_k to q_{k+1} but depend on the mass of the particle and on the time interval ϵ. Equation (183) is a mathematical statement that the amplitude for a particle at $q(t')$ at time t' to move to $q(t'')$ at time t'' equals the sum of all possible paths between the two points times $\exp(iS/\hbar)$; the probability is the absolute square of the amplitude.

The path integral approach to quantum mechanics can be extended to include formulations of quantum field theory (a combination of quantum mechanics and special relativity), the partition function in statistical mechanics, and systems obeying Bose–Einstein and Fermi–Dirac statistics. The path integral method is the foundation for Feynman diagrams.

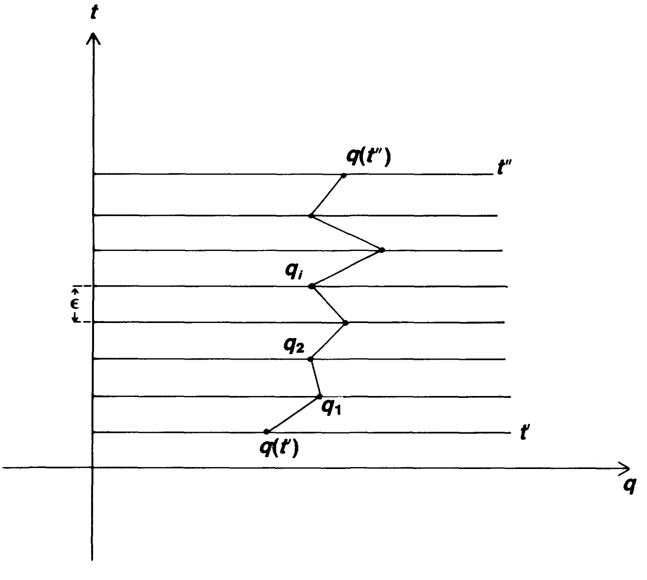

FIG. 18. A representative sequence of paths between $q(t')$ and $q(t'')$.

GLOSSARY

Complex Variable: An ordered pair of real variables ($z=x+iy$) with a real and an imaginary part.

Ordinary Differential Equation: An equation containing derivative(s) with respect to one independent variable.

Partial Differential Equation: An equation containing partial derivatives with respect to two or more independent variables.

Integral Equation: An equation where the unknown function appears in an integrand.

Functional: A function which depends on one or more functions.

INTRODUCTION

Traditionally, computers have performed data processing tasks but lacked the ability for reasoning, acquiring, and using knowledge; i.e., they were unable to solve problems. Artificial Intelligence (AI) goes beyond conventional data processing by focusing on the

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

development of programs that can solve problems. They do this, in part, by explicitly representing and using knowledge. Before discussing AI in more detail, we need to understand what is meant by the terms *computer, artificial,* and *intelligence.*

Computers belong to a class of objects known as physical symbol systems. A physical symbol system contains a set of symbols that it manipulates through creation and destruction (Simon, 1981). Copying symbols is considered to be a form of creation while changing an existing symbol into another symbol is considered to be destruction of the old symbol and creation of a new one. Thus, the symbol manipulation in a physical symbol system can be seen as analogous to the evolution of a particle system through allowable quantum states in time. Physical symbol systems consist of an architecture containing a storage area or memory, a processing unit, and input and output units for communicating with the outside world. Figure 1 shows a simple diagram of a physical symbol system.

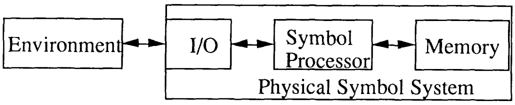

FIG. 1. The three components of a physical symbol system and its interactions with its environment.

Artificial refers to the human-made nature of computers and their programs. Although this term has a somewhat derogatory connotation with respect to food additives and the like, it is, in the context of this article, only descriptive. That is, "artificial" intelligence should be no less intelligent than "natural" intelligence.

Intelligent refers to the type of behavior that people exhibit when solving problems. Solving problems, then, is seen as the ability to achieve goals, where goals are defined as desired final states. Further, when people solve problems they are

1. often able to come up with an answer within a reasonable amount of time (even though it may not be the optimal one, just one that is good enough);
2. able to solve problems even when the data given to them are incomplete, inaccurate, or noisy; and
3. able to improve their performance at solving the task after repeated trials—in short, they learn.

Intelligence is also the ability to use knowledge to constrain a search through an enormous space of possibilities. In fact, one of the most important elements of AI is the study and use of heuristics, or techniques that constrain a search. Unlike traditional algorithmic search, heuristics involve a more exploratory type of search that is better suited towards problems that do not have an obvious algorithmic solution.

Hence, we define AI as the study of principles and methodologies for making intelligent computers. However, others have broadened the definition to include all forms of intelligent behavior, including human. The principles and methods of AI involve representation (of knowledge), control or strategy (of procedures), and search (through a problem space) directed towards solving problems (achieving goals), each of which will be discussed later.

Although computing engines, such as the abacus, have been around for hundreds of years, it was not until the development of computers in the 1950s that intelligence by machine became possible to study. Work in AI began after the development of the computer, so AI is still a young discipline, still in search of exactly what it is. However, just as intelligence is "practical," so too must be the results of AI.

AI at its lowest level is still just computer code, so what distinguishes it from conventional methods? Unlike conventional custom solutions to problems, AI is interested in problem solving in general. In fact, formalization of problem solving techniques that will have applicability across arbitrary domains is very difficult. On the other hand, AI differs from purely formal systems like logic and pure mathematics in that the emphasis is on problem solving which is verifiable through experimentation, which includes using imperfect data. AI methodology is better suited to problems where the structure is ill-defined than are conventional methods that depend on well-structured domains. Hence, the results of AI should be reusable across many domains. Thus, any field that desires automation in problem solving tasks is a candidate for an AI application.

In particular, AI should be a natural fit for science and engineering applications, since these two disciplines are most interested in solving problems in a systematic way. Scientists and engineers know all too well the difficulties with solving their problems—each one seems to have its own idiosyncrasies that demand custom techniques. AI's responses to these difficulties are its flexible problem solving techniques that are reusable in a variety of situations.

One goal of AI is to make science more automated. This may seem somewhat counterintuitive in that one usually thinks of science as something that is not routine, but requires gifted insight and clever experimentation to make progress. However, this is exactly one of the goals of AI, to bring such seemingly unfathomable qualities as creativity and discovery into the definable and programmable.

AI is important to people because it can free them from routine or mundane chores. Some of these monotonous chores include assembly line work, agriculture, and clerical tasks. In the context of science and engineering this means, for example, automatic monitoring and diagnosing of equipment or analysis of data.

The economic impact of computers is already pervasive and continues to have enormous impact on society. But this impact has been mostly in areas where human intelligence is weak—storage of large amounts of records (e.g., medical records) and complex mathematical computation (e.g., weather simulation). These types of applications make use of a computer's hardware capabilities of mass storage and the fast switching time of electronic components. So far the application of man-made systems to problems of reasoning has been small. The advent of intelligent computers will thus have even greater implications in all aspects of human society. The remainder of this article discusses how AI is realized and some of its applications.

1. PROBLEM SOLVING

1.1 Overview

Problem solving is defined as the performance of actions whose purpose is the attainment of some goal. A solution to a problem may be either the goal itself or the steps performed that led to the goal, depending on whether the goal is explicitly stated or not. Note that given an arbitrary problem, there is no guarantee of a solution, or even that the found solution be the optimal one.

What AI offers is a methodology for finding solutions to problems that are intractable because no formal mathematical technique exists, or are prohibitively expensive using brute force methods like exhaustive search. Methods that reduce search but do not guarantee solutions are called heuristic. The notion of heuristic methods is essential to the theme of AI. The tireless computer, through the use of heuristics, offers the possibility of exploring multiple, though not necessarily all, good enough solutions, whereas in human problem solving the solver often stops after finding the first good enough solution.

Problem solving involves several parts, some of which may overlap. The parts described in this article are referred to as representation, control, and search. An obvious implicit component in any problem solving system is the critic that evaluates a result and decides whether it is good enough, or modifies one or more of the components if it is not good enough.

1.2 Knowledge Representation

Knowledge may be implicit, as in procedures, or explicit, as in a database. Implicit knowledge is less easily understood, viewed, or manipulated than explicit knowledge. The behavior of the system depends on how the knowledge is represented. For example, a rule-based representation uses antecedent–consequent, or condition–action (IF–THEN), rules to test whether certain conditions have been met. The rules may chain together; i.e., the action of one rule is part of the condition of another rule so that they form a link of inferences. An advantage of this kind of representation is that the chain of inferences can be used as an explanation for why a particular final action was taken by the system.

1.3 Control

A problem-solving system needs a model in which to solve its problems. One popular paradigm is called generate-and-test. In the generate-and-test paradigm, a generator is used to create hypotheses that are then tested against the data and knowledge available to the system. Methods for constraining the generator, to search only the more plausible hypotheses, are provided through the search specification. A test program checks whether the generated hypothesis solves the problem. The system may return all the solutions or only some desired subset (e.g., the first solution).

Controlling a system also involves the detailed interactions of the data and procedures. This includes the order in which procedures are called and the data that are passed between them. Some systems operate under very predictable conditions, whereas others operate in a less predictable fashion. For example, the order in which data are received may be important because the actions of the system will vary according to the presentation of the data.

1.4 Search

In order to solve a problem, a program must search through a space of possibilities. These possibilities can be thought of as subproblems of the overall goal to be achieved. The difficulty in search is that the subproblems can interact so that what may seem like a good path to follow at one point may later turn into a dead end. Thus premature commitment to a path results in costly backtracking when the path is not the right one. In many real-world problems the potential search space is enormous and cannot be searched completely in any finite time by any physically realizable computer. Thus, there is not an explicit construction of the search space, but only an implicit one based on the parts of the space that are actually searched. Chess provides an example of a huge search space where humans have learned to solve the problem of playing the game in a finite amount of time. The way to avoid exhaustive search is to constrain it through knowledge of the problem domain. This is where AI's use of heuristics comes into play.

2. KNOWLEDGE REPRESENTATION

2.1 Overview

Knowledge in AI is not simply a set of statements, numbers, or facts stored in a database. It also refers to the data structures and the procedures used to manipulate and interpret the data as well. It includes the syntax and semantics of the objects in the knowledge base. In terms of problem solving, knowledge and search are related in an almost uncertainty principle–like way: the greater the amount of knowledge that can be brought to bear on a problem, the less search will be required, and the greater the amount of search, the smaller the amount of knowledge that is required to solve the problem (Berliner and Ebeling, 1986). However, unlike physics there is more than one value for Planck's constant, corresponding to the complexity of a given problem.

In AI, representation is the mapping between the symbol system and the environment; it is how the symbol system sees or describes the world. In physics and engineering the mapping between nature and nature's model, physics, is given by parameters such as mass, energy, charge, etc. Just as in physics problems, the correct representation can greatly facilitate problem solving. For example, in good representations, important things should be made explicit, including any constraints that may apply. A good representation contains all the things that are needed to solve the problem. Also, the grain size of the knowledge must be appropriate for the type of problem to be solved. Additionally, representations should present their knowledge in a clear and concise way. For instance, unnecessary information should be suppressed unless needed to solve the problem. The explicitness, clearness, and conciseness of the representation mean that understanding and modifying it will be much simpler, less time-consuming, and less error-prone. While all this may sound like standard practice in software engineering, the difference is that in AI what is being represented is the problem solving knowledge. However, unlike physics AI is not constrained to using numerical parameters, but may use symbolic data such as "big" and "heavy."

There are several types of knowledge that must be represented for a system to be capable of intelligent behavior. First, the system must have knowledge about objects—things that have properties (e.g., cars have wheels). Second, the system must have knowledge about events—happenings that occur to objects (e.g., the car got a flat tire). Also, an intelligent system must know about behavior—how objects interact with each other in events. Finally, an intelligent system should have metaknowledge—knowledge about knowledge (e.g., "knowing what you know").

As mentioned earlier, knowledge may be either explicit (declarative) or implicit (procedural). Most scientific programming hides knowledge in procedures. An example of the two representations is given by the problem of comparing musical notes. In a declarative representation the knowledge "F is higher than B" and "B is higher than A" are stored as facts in a knowledge base. In a procedural representation the sorting is done, say with numeric comparison of the sound frequencies, and the program itself has the explicit knowledge of how to do numerical comparisons. It should be pointed out that declarative representations still require procedures to manipulate them.

2.2 Schemes

Numerous schemes for representing knowledge have been developed throughout history. Some of these are useful for AI applications, as are ones developed as a direct result of AI research.

2.2.1 Logic. Logic offers a rigorous way of representing and proving things about situations (cf. LOGIC METHODS). However, there are also disadvantages to using "formal" logic, as will be discussed in sections on fuzzy and nonmonotonic logic.

2.2.1.1 Formal Logic. The formalism of logic has developed a language that provides a powerful means of knowledge presentation. Rules of inference (deductive rules) are used to derive facts that are true given other facts known to be true. This guarantee of truth is a powerful feature of formal logic. One useful application of formal logic is in its ability to prove theorems. Unfortunately, proof itself is subject to an exponential explosion in the number of nodes in the search space. Second, the search may not terminate unless there actually is a proof, which may not be known *a priori.*

2.2.1.2 Fuzzy Logic. Another one of the drawbacks of formal logic is the binary nature of its statements, either true or false. One way around the difficulties of the rigid constraints of formal logic is provided by fuzzy logic (Zadeh, 1979). In this logic, objects belong to a class with some range rather than being either in a set or not in a set; i.e., in a range 0 to 1. Fuzzy sets are useful in natural language applications, for instance, when describing a concept (e.g., "fast"). Fuzzy representation allows a gradual transition from fast to non-fast. Thus, if A is (FAST 0.9) and B is (FAST 0.6) then one can say A is "more fast" than B, whereas in formal logic both A and B may belong to the same class (either FAST or NON-FAST) or different classes.

2.2.1.3 Nonmonotonic Logic. When building a logic system, there is no guarantee that the axioms will be complete or noncontradictory. In nonmonotonic logic, one is able to get around the problem of conflicting conclusions drawn from the same set of axioms. Namely, if new assumptions have been made that may conflict with existing assumptions, then new inferences may be made. Thus, nonmonotonic logic does not assume that what was true at one time is necessarily true for all times. Nonmonotonic logic could be thought of as a time-dependent logic.

2.2.2 Semantic Networks. Semantic nets use a node and link graph structure to represent objects and their interrelations. Nodes represent concepts such as objects or events. The links between nodes represent interrelations between the objects. Figure 2 shows an example of a semantic net for a car. Unfortunately, there is some ambiguity in this representation. For instance, one may

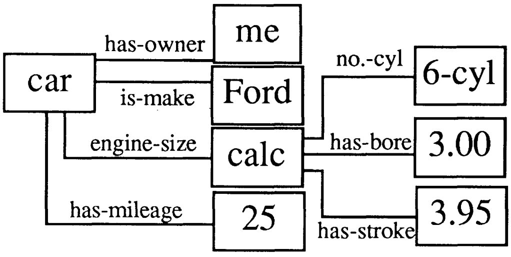

FIG. 2. A semantic network for a car.

conclude that all cars have these properties rather than just my car, or that all cars are owned by me. However, this problem can be eliminated by making a distinction between the car class and an instance of a particular car.

2.2.3 Frames and Scripts. In a frame representation declarative knowledge (facts) and procedural knowledge (programs) exist together in a predefined relationship to describe an object or event. Slots are used to hold values for attributes associated with a particular frame. An example of a frame for a particular car might be the following:

FRAME-NAME: CAR

OWNER: ME

MAKE: FORD

COST: 10,500$

MILES-PER-GALLON: 25

BORE: 3.00

STROKE: 3.95

NUMBER-OF-CYLINDERS: 6

DISPLACEMENT: PROCEDURE(CALC-DISP BORE STROKE NUMBER-OF-CYLINDERS)

Note that slot values need not be just numbers or symbols but, as in the *DISPLACEMENT* slot, can call out to procedures to obtain computed quantities as needed. Also, all objects belonging to the car class will have the same structure.

Scripts are frames that correspond to a particular situation or action (e.g., what happens when you go to a restaurant). The script includes slots for the low-level acts that can occur in a particular situation (e.g., waiting for a table or leaving a tip in the case of a restaurant script).

2.2.4 Production Systems. In a production system, knowledge takes the form of rules such as: IF condition exists, THEN perform action. An advantage of this representation is that the condition for its applicability is explicit. Additionally, rules are very modular and easy to modify and replace. Rule-based systems may be either antecedent-driven, that is, the system matches the condition parts of the rule and then takes the actions specified by the consequents, or consequent-driven, where the matching is done on the action parts of the rule, and the condition parts are performed.

However, when using a rule-based approach, several potential problems must be addressed. First, what should be done when multiple rules fire whose conclusions may conflict? In this case, the rules may be ranked by their previously determined accuracy in making correct classifications, or by their rate of misclassification, or by the ratio of correct classification rate to incorrect classification rate. Also, the rules could be ordered by the benefit of performing the recommended action, assuming it is correct, or by the inverse cost of performing the action if it is the wrong action. A second problem occurs when no rules match the current situation and the best that can be done is a partial match. One possibility, in this case, is to use the fraction of correct conjunctions matching to rank the rules.

3. CONTROL

3.1 Strategies

In order to perform a search, a strategy represented by some set of operators is needed to transform the problem from one state to another so that the goal can be satisfied. In logic, operators are the rules of inference, such as *modus ponens*. In game playing, the operators are the rules of the game.

A state-space search can be represented by its set of states, set of operators, and set of goal states. The state space itself is represented as a directed graph, or net, or tree, with the nodes representing the states and the links, or branches, between nodes representing the application of operators. A typical tree is shown is Fig. 3. A node with no parents is called the root node. Terminal nodes are the nodes with no children. Goal nodes are terminal nodes but not all terminal nodes are goal nodes. The difference between control paradigms is their different methods of traversing the search space to arrive at a solution.

More specifically, operators may employ forward, or data-driven, reasoning in which the object is to transform the current state forward toward the goal state. Another approach employs backward, or goal-directed,

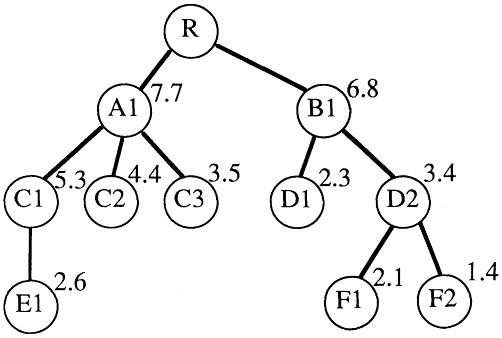

FIG. 3. The letters in the nodes identify the states. The numbers refer to the "distance" from the goal node. Distance is a metric used for measuring the cost in time or money, or whatever other parameter is relevant to solving the problem. When choosing a particular control strategy it is important to consider the cost of finding a path as well as the cost in actually traversing it. R is the root node and F2 is the only goal node. The goal of the search is to find a solution within some cost bound.

reasoning where the object is to work backward from the goal state by breaking the problem into smaller, more easily solvable subproblems. Finally, it is possible to combine forward and backward reasoning into a single strategy. One popular such method, means-ends analysis, finds the difference between the current goal state and the current state. The difference is used to fire a forward operator. If the most relevant forward operator does not decrease the difference then a backward operator is used to set up subgoals.

3.2 Control Methods

This section is intended mostly for multiprocessing systems where numerous procedures may be running concurrently, possibly on different machines. Control methods are how the procedures in a symbol system interact. All the procedures require certain input knowledge and resources in order to give an output. Control methods specify the architecture, resource allocations, and interaction among procedures. Three paradigms for control are discussed.

In the first control paradigm, each procedure has explicit knowledge of what other procedures to call so that it can complete its task. This is the method used in most scientific computing. Figure 4 shows an example of this kind of control.

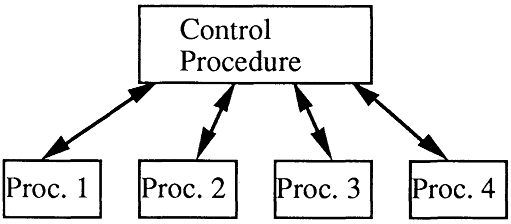

FIG. 4. A control paradigm where one procedure knows about all the other procedures.

In the second control paradigm, the entities in the symbol system belong to particular classes. In this case, it is possible to refer to a class of objects rather than to a particular procedure. The knowledge of which procedures are available and best suited for the particular problem is stored within a class object, as shown in Fig. 5.

In the third kind of control paradigm the procedures have no knowledge of other procedures, only that they can respond to certain requests from outside. Control occurs in response to statements posted on some centralized location, as depicted in Fig. 6. The centralized knowledge source, or blackboard, can be thought of as being analogous to a group of scientists brainstorming in front of a blackboard, each one writing his ideas down and drawing on the collective wisdom represented by the writings of the other contributors to solve the problem.

The problem of resource allocation may be handled in a number of ways. This problem arises when numerous procedures are all trying to solve some task using the same resources. One solution is simply to give each

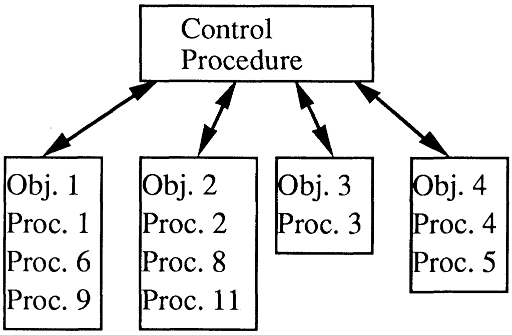

FIG. 5. Control between objects, showing links between procedure and objects.

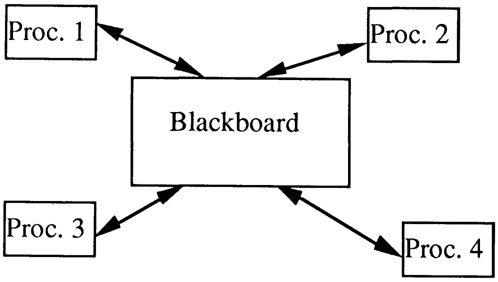

FIG. 6. Blackboard control, showing the links between the procedures and the centralized knowledge source (blackboard).

procedure an equal amount of the resource (processing time, memory, etc.). Another method allocates the most resource to the procedure that will have the highest "payoff" towards completing the task. Yet another scheme allocates on the basis of the inverse cost of performing the procedure, i.e., the more it costs to do it, the less resource it gets. More complicated resource "payoff" functions may be constructed that are combinations of the cost and benefit relevant to the problem solving activity. Further discussion of control methods can be found in Winston (1985).

4. SEARCH

4.1 Overview

Search is the engine that drives a system through a space of alternatives toward its goal. Thus, search is one of the most basic functions in any problem solving activity. It is the path through that choice of alternatives that the system follows on its way toward solving a problem. However, search must also address the problem of time and space limitations inherent in any physical system. Before discussing particular search algorithms we need to find a representation in which to conduct the search. The rest of this section presents several search techniques, each with different strengths and weaknesses. Further discussion of search methods can be found in Barr, Cohen, and Feigenbaum (1982) and Nilsson (1980).

4.2 Blind Search

Blind search is a class of search strategies wherein the search space is explored via the syntactic or structure of the space. In blind search there is no preference for one branch of the search over another. The search ends when the first path to the goal is found, which is not necessarily the best one. One of the problems with blind search is the combinatorial explosion of paths that occurs for all but the smallest of problems.

4.2.1 Breadth-First Search. In breadth-first search, the search path proceeds across nodes at a given level in the tree before going a level deeper. In Fig. 3 a breadth-first search would be: R, A1, B1, C1, C2, C3, D1, D2, E1, F1, F2. The disadvantage of this type of search occurs when multiple solutions exist roughly at the same level for many nodes.

4.2.2 Depth-First Search. In depth-first search the search proceeds by following the children of a particular node down the search tree before trying other paths at the same level. Thus, a depth-first search in Fig. 3 would proceed as follows: R, A1, C1, E1, C2, C3, B1, D1, D2, F1, F2. The disadvantage of this type of search is that, for very deep search trees, the system spends most of its time exploring fruitless paths that are far deeper than the solution to the problem. Depth-first tends to work best for problems where breadth-first is poorest and vice versa.

4.3 Heuristic Search

Recall the definition of the popular (in the AI world) and also controversial word "heuristic," to mean a strategy that enables a reduction in search through a space. The reduction in search means that the plausible part of the search space is reduced either by pruning unpromising nodes in the search tree or by focusing the search in a promising area. However, heuristic search does not guarantee a solution. Also, heuristic solutions are not necessarily optimal ones. Rules of thumb are heuristics as are other "tricks" used to solve problems. Heuristic search can be used to reduce the combinatorial explosion of possible search paths that exist by using purely blind search methods. However, in order to use heuristic methods there must be a reliable measure of cost or distance (e.g., from the current node to the goal node) so that the potential value of the heuristic can be determined. These distances are used to order the possible expansion nodes in the tree. The heuristic itself tells what the next node to expand should be and depends on the particular heuristic. Note that blind search methods can be modified so that the solutions can be found sooner.

4.3.1 Hill-Climbing. Hill-climbing search is basically parameter optimization and is the most familiar type of search used in optimization problems in physics. This is the type of search used by numerical optimization programs. Here, the hills in the search space are the relative extrema of the performance function. The profile of the surface depends on the performance function. The direction of the search path depends on the optimization method (e.g., gradient descent in numerical domains). Thus, the particular next node chosen would be the best of the children of the last node explored. Some of the problems with hill-climbing are that it is not exhaustive and that the complexity of the search surface increases with the dimensionality of the problem. This complexity leads to a greater prevalence of nonoptimal relative extrema such as foothills, plateaus, and ridges. In Fig. 3 a hill-climbing search would proceed as R, B1, D1. This example shows how hill-climbing can get stuck in local optima. To get around this problem requires costly backtracking.

4.3.2 Beam Search. Beam search is a modified version of breadth-first search where the path followed keeps active the "best" nodes at each level in the search, where "best" is based on the cost required to reach the goal. In Fig. 3 above, suppose that only the two best (lowest cost from the current node to the goal node) nodes are expanded to the next level. Then the beam search would be R, A1, B1, D1, D2, F1, F2. Note that in this case the C nodes were not expanded because they were "not good enough" according to the heuristic "expand best 2."

4.3.3 Best-First. Best-first search is similar to hill-climbing, except that in best-first the next node is chosen from the best of all the children of all the nodes explored so far, where "best" is as above. Best-first can often converge more quickly than hill-climbing at the expense of having to sort all the children at each expansion. In Fig. 3 the search would proceed as R, B1, D1, D2, F2. Note that unlike the hill-climbing example, the best-first search did not get caught in the local optimum, although, in general, for any heuristic search it is possible to get caught in a local minimum.

4.4 Game Search

Game search differs fundamentally from the above-mentioned techniques in that it involves the actions of two or more players whose actions affect the paths taken in the search.

Minimax search is a depth-first search where the depth is limited to a certain number of moves ahead. The path is then evaluated according to its value to the player. The idea is to maximize the evaluation function for the player and minimize it for the opponent. A maximizing evaluation function operates on alternating layers of the game move tree with a minimizing evaluation function. Both of the evaluation functions must be aware of the moves the other is likely to make. This search, like any heuristic technique, requires a measure of goodness to judge the moves.

5. MACHINE LEARNING

5.1 Overview

Learning is one of the most fundamental aspects of intelligent behavior. We define learning as the process by which a system is able to perform a given task more efficiently on subsequent trials. More efficiently means that either the accuracy (quality) of the solution is improved or the time to find a solution is decreased. The need for machines that learn is motivated by the desire to get away from the tedium involved in human learning and the difficulty in transferring human problem solving ability to a machine. While human learning is certainly an existence proof for intelligence, it should be kept in mind that it may be no more useful for the construction of learning machines than birds were for the construction of flying machines. Besides human learning, other examples of learning systems are species evolution, where the goal of learning is survivability; and the immune system of a living thing, where again the goal of learning is survivability.

Learning systems must create some representation, or model, for the world in which they will be learning. During learning, the model is refined to represent more closely the environment it is trying to learn. In some systems the model may take the form of differential equations in which learning takes place through the modification of coefficients. Adaptive control systems, neural networks, and pattern recognition systems fall into this category of learning system.

Learning can be divided into two categories. The first, knowledge acquisition, is the ability to construct new models and apply them in a variety of problem solving situations. The second, skill refinement, comes about from continued practice of some task with feedback on the performance.

Additionally, learning systems may be classified as to whether they perform their learning in a supervised or unsupervised mode. A supervised environment is akin to a stimulus–response system where the correct output for each input is available to the learner. In unsupervised learning there is no such teacher or oracle available. This latter situation leads to one of the most important issues in learning. That is, what component of the learning system receives credit or blame during training so that the system can avoid making the same mistake next time or can be more confident in getting it correct the next time? In other words, where does the feedback from the training example go? This credit-assignment problem remains one of the fundamental issues of learning.

Pattern recognition systems are learning programs used to do classification of some pattern or sequence of data. Many learning tasks can be viewed as pattern recognition or concept formation problems. A typical example of pattern recognition is recognizing written characters. There are also many tasks in experimental physics that require the classification of patterns, from oscilloscope tracings to energy depositions in large scale calorimeters.

More information about learning can be found in the *Machine Learning* books (Michalski, Carbonell, and Mitchell, 1983) and Vol. 3 of the *AI Handbook* (Barr, Cohen, and Feigenbaum, 1982).

5.2 Concept Learning

Learning systems in one important class, called concept formation systems, alter the symbolic structures in their representation of the environment, called the domain theory, in an attempt to form generalizations about classes of objects. A typical learning system contains the following components: environment, instance selector, learning element, domain theory, critic, and performance element.

Environment. This is where the training instances come from and where the ultimate feedback comes from.

Instance Selector. This element chooses the examples that the learning system is going to use. It may be as simple as accepting all examples given to it, or it may be intelligent itself and only choose "critical" examples that will be most efficient for learning.

Learning Element. This element is responsible for taking the recommendations of the performance element and suitably modifying the domain theory of the system. For example, based on the poor predictive power of a set of rules, the learning element will modify the rules in an attempt to improve performance to a level acceptable as specified in the domain theory.

Domain Theory. This element contains the current representation of the "world" or environment. It may be in the form of rules or parameters, for example. It also contains the semantics and syntax used in the domain representation as well as other constraints on the concept description language, such as the overall minimum performance level to be achieved during learning.

Critic. The role of the critic is to analyze the overall performance of the learning system and make recommendations about how and where changes should be made. This is where the credit-assignment problem is handled. The critic may be a local critic responsible only for one element of the learning system or a global critic responding to the overall performance of the system.

Performance Element. The purpose of this element is to test the current domain theory against examples given by the environment to see if the current theory is good enough. It also performs any actual manipulation to the environment requested by the theory in response to the environmental situation (e.g., robot movement).

5.3 Learning by Example

Learning by example is one of the most powerful methods of learning for people and machines. Presenting a system with preclassified examples (with respect to their class) allows the system to form generalizations based on the regularities it has seen in the individual examples of the training data. Of course, the utility of the generalizations depends on how well the training instances model the actual situation to be learned.

5.3.1 Induction. Inductive inference is one of the most effective tools in learning. Here, an inference is defined as a legal (with respect to a set of symbols and rules) translation from one statement to another. Induction is defined as an inferential process whose goal preserves truth and expands knowledge. Whereas deduction guarantees the truth of a conclusion given the truth of the premise, induction provides no such guarantee. Also, the inferences from induction are a function of the structure of the induction system and not purely a function of their premises as in deduction. In a learning system, there must be an amplification of the premise so that deduction alone cannot be used in a learning system; i.e., in deduction the premise and conclusion are equivalent so that no expansion of knowledge can occur. Below is an example of the algorithm for a rule-based induction program.

1. *Input Partial Domain Theory and Examples.*
2. *Recall previously saved rules.*
3. *Any untested rule? If no, then save "good enough" rules, done.*
4. *Evaluate next untested rule.*
5. *If rule too specific then go to 3.*
6. *If rule too general then add specializations and go to 3.*
7. *Add rule to "good enough" rules and go to 3.*

Further insight into induction can be found in Holland *et al.* (1986).

5.3.2 Analogical and Case-Based Reasoning. Analogy is one of the most powerful methods of human reasoning, but also one of the most difficult to codify. Analogy involves forming representations in one domain based on similarities with another domain. The difficulty lies in codifying what is meant by "similarities," particularly when non-numeric data are involved. Also, in making an analogy not all the features in the one domain will be mapped over to the other, and the problem is finding the correct ones. In the special case where the domains are the same the technique is called case-based reasoning.

5.3.3 Genetic Algorithms. Genetic algorithms are induction programs that learn, in analogy to biological evolution, through "mutation" of rules. Here, each gene in the population represents a string and each segment in the gene represents conditions and actions of rules. The basic idea is the "survival of the fittest" where, after a time, only the best rules will be active. The number of rules is fixed so that the poorly performing ones are eventually weeded out by better performing ones.

The program starts off by initializing a fixed population of genes, usually randomly in the absence of any prior knowledge. The current population is modified by operators to generate the next generation. There are several genetic operators that modify the population to produce offspring for the next generation. The modifiers are analogous to the "specialize" and "generalize" operators in the previous rules-based induction example. One of the most important operators is called crossover which takes portions of two genes and exchanges them between the two genes. Note that there is a random component not just in the mutation operator but in where the crossover operator crosses. Another operator causes random mutations in a gene. This operator functions at a much lower rate than the crossover operator. This is because, just as in biological systems, most mutations are not beneficial but they are necessary to insure that the entire search space can be covered. Operators are applied probabilistically to the strongest rules.

Once the new genes have been produced, a fitness evaluation function measures how well the output of the program agrees with the output produced by the training examples. The rules are ordered by fitness and only some number of the best are kept for the next generation. The survivors are then used as the parents for the offspring (i.e., the next generation of rules) so that the overall population is kept constant.

5.4 Connectionist Approaches

Connectionist approaches cover a class of learning programs commonly referred to as neural networks (*q.v.*), Boltzmann machines, simulated annealers, etc. The basic idea behind these programs is to employ the collective behavior of a large set of simple processing elements connected together in some way. It is through adjustments in the connectivity of the processors, reinforced positively or negatively with respect to training examples, that the system adapts and learns. The basic methods involve some sort of hill-climbing search through a performance space where the highest peak would theoretically be the one where the output of the program, given the training example inputs, was identical with the corresponding training outputs. Once the connection strengths have been learned, the network can be presented with cases it has not seen before and make predictions based on what it has seen before. Thus, the program behaves as a function interpolator. Like any induction-type learning system, the learner must be presented with a representative set of training examples. Changes in the network can be represented with differential equations (or, more accurately, as finite difference equations) which gives them a certain appeal for physicists.

The connectionist approach differs markedly from the traditional "computer science" type of approach in that the knowledge is represented implicitly in the connection strengths rather than explicitly in a knowledge base. Also, neural networks lack the modularity of design and flexibility of representation that is a hallmark of knowledge based systems. Additionally, neural networks only work with numeric inputs so that any symbolic inputs must be first converted to numerical form in an *ad hoc* fashion. This lack of explicitness also prevents neural networks from providing a reasoning traceback of how a particular answer was found. The analogic nature of neural networks permits a gradual shift in classification, more than is usually allowed in rule-based systems. However, rules can be given strengths or fitness and appear "fuzzy" just as the outputs of a neural network do.

One drawback to the neural network approach is the usually significant amount of computing time required. This is because prior knowledge of the domain (e.g., heuristics) cannot be explicitly codified (recall the relationship between knowledge and search mentioned in Sec. 3) so that learning even a trivial concept like exclusive-or (i.e., $00 \Rightarrow 0$, $01 \Rightarrow 1$, $10 \Rightarrow 1$ and $11 \Rightarrow 0$) can take hundreds of iterations through the example set. Another drawback is the possibility that the system performance will oscillate and never converge because the input parameters were not set correctly. The input parameters that must be chosen are the number of input units, output units, and "hidden" units (used to model higher order correlations), as well as their connectivity; i.e., not every unit needs to be influenced by all the other units. Also, the initial rate of change, or step, in the search space must be chosen—too small and learning will be agonizingly slow, too fast and the system may oscillate or behave chaotically. Choosing the correct parameters is based completely on intuition and experience. However, neural networks may be more suited to perceptual tasks such as image understanding than rule-based techniques. Such a system could be used to identify interesting events in a physics apparatus. A standard reference for neural networks is Rumelhart and McClelland (1986).

5.5 Other Methods

In explanation-based learning a concept can be learned from only one example (Mitchell *et al.*, 1986). This method has the advantage over induction which requires exponentially large numbers of examples before a conclusion can be drawn with some confidence. Developed in the 1980s, this method offers practical techniques for utilizing prior knowledge represented in a domain theory to reduce the training set size to a tractable value. Unfortunately, if the example is noisy then no concept, or the wrong concept, may be learned, although further research may alleviate this limitation.

In learning by discovery, the learner searches without the aid of a teacher. The learner must form its own clustering of concepts or classes based on the regularities it sees in the data (Langley *et al.*, 1983). In learning by instruction, a teacher or oracle explicitly tells the program what is to be learned. In this case, the teacher performs the role of an intelligent instance selector to give only the most relevant examples to the program. In rote learning there is explicit storage of the training examples. New examples are then compared against the training examples to find the closest match. The classification of the closest match then becomes the classification for the new example.

5.6 Current Issues

One area of current research in machine learning is aimed at improving the scaling of learning systems with respect to the number of examples and their complexity. Incremental learning is an approach to the problem of learning when not all of the training instances are processed at one time. Recent results from learning theory need to be broadened to increase the understanding of the relationship between the number of training examples, the tolerance for error, and the probability of successful learning.

6. IMPLEMENTATION ISSUES

Obviously one of the considerations in the development of intelligent systems is how to actually build one. Building includes the hardware and software to be used. While it may be true that "you can write anything in anything," meaning that an intelligent program could be written in any computer language, not all languages facilitate the construction of intelligent systems. The issues of implementation are those of facility, as in physics when choosing a coordinate system or gauge in which to solve a problem.

AI very often deals with symbol manipulation, rather than purely numerical manipulations as is usually the case in scientific programming. Thus, a language with extensive symbol manipulation capabilities would be desirable. Also a language supporting recursion, modular programming, and easy representation of formal logic would be useful (see COMPUTER PROGRAMMING LANGUAGES).

6.1 LISP

LISP (LISt Processing), first developed in the 1950s about the same time as FORTRAN, has found wide application in many areas of AI. Common LISP (all further references to LISP will refer to Common LISP) is the dialect that has become the standard that was long lacking. The basic data structure in LISP is a list which allows LISP to represent nearly any other data structure. In addition, LISP supports a large variety of data types such as integers, floating point numbers, complex numbers, ratios, characters, strings, symbols, arrays, vectors, bit-vectors, hash tables, etc. LISP also supports the full range of trigonometric, exponential, complex, and comparison operators found in "scientific languages" like FORTRAN. Functions are represented as lists where the first element in the list is the name of the function and the other elements in the list are the arguments and body of the function. Lists may contain lists of lists of lists, etc. The standard LISP reference is Steele (1984).

Originally, LISP was run interpreted and although this facilitates debugging, execution time is longer. However, there are LISP compilers that produce fast-running LISP code. Specialized hardware designed to run LISP code provides a high productivity environment with such features as a language-sensitive editor (checks syntax automatically, does indentation), incremental compilation (only compiles the lines of code that changed), and automatic linking, all of which act to reduce dramatically the edit–compile–link program development cycle.

Now consider a trivial example in LISP. In the example a database of facts will be stored and then inferences will be used to test hypotheses about the database using a rule. Suppose the property list in which the data will be stored is called JOHN. The function SETF is used to assign a value to the indicator TYPE to be the value PERSON, and so on.

```
(SETF (GET 'JOHN 'TYPE) 'PERSON)

(SETF (GET 'JOHN 'JOB) 'FUN)

(SETF (GET 'JOHN 'HEIGHT)' > 75)

(SETF (GET 'JOHN 'SMILE) 'ALOT)

(SETF (GET 'JOHN 'FROM) 'CALIFORNIA)
```

We can examine the resulting data structure with

```
(SYMBOL-PLIST 'JOHN)
```

which returns

```
(FROM CALIFORNIA SMILES ALOT HEIGHT >75
JOB FUN TYPE PERSON)
```

Now we can write a rule to see if a person is happy or not. Thus,

```
(DEFUN HAPPY-RULE (WHO?)
(COND ((AND (EQ 'PERSON(GET WHO? 'TYPE))
            (EQ 'FUN (GET WHO? 'JOB))
            (EQ 'ALOT (GET WHO? 'SMILES))
            (EQ   'CALIFORNIA   (GET   WHO?
            'FROM))
        )T)
       (T NIL)))
```

Now executing the function (possibly from inside another function),

```
(HAPPY-RULE 'JOHN)
```

returns T since all the conditions of the COND were true. In this example note how the data are separate from the rule procedure, and the mixture of numeric and symbolic data. Also note that the rules themselves are modular units that are easily modified.

6.2 PROLOG

Another popular "AI language" is PROLOG (PROgramming in LOGic), which is an implementation of first-order predicate calculus. Logic programming differs from conventional programming in that the programmer supplies facts in a database and lets the computer draw any conclusions, rather than explicitly writing a program that tells how to solve the problem. Put more simply, logic programming is more concerned with *what* a program computes rather than the details of *how* it computes. The standard PROLOG reference is Clocksin and Mellish (1981).

Given a question, PROLOG will do a depth-first search through its database of facts and rules in an attempt to resolve the question put to it. For example, we redo the previous LISP example in PROLOG.

Given the following database:

```
PERSON(JOHN).
JOB(JOHN, FUN).
HEIGHT(JOHN, >75).
SMILES (JOHN, ALOT).
FROM(JOHN, CALIFORNIA).
```

which translates to "John has a fun job, is over 75 inches tall, is from California, and smiles a lot." Now given the rule:

```
HAPPY_PERSON(X):-
    PERSON(X),
    JOB (X, J),
    SMILES(X, Y),
    FROM(X,California).
```

which translates to "X is a happy person if X is a person who has a job, smiles a lot, and is from California." Then inputting the question to PROLOG gives

```
?- HAPPY_PERSON(JOHN).
```

which yields the answer,

```
YES
```

This trivial example shows how PROLOG uses facts and rules to draw conclusions. Again note the modularity of the facts and rules.

7. EXPERT SYSTEMS

7.1 Overview

There is almost always a need for expert advice in any organization. Expertise, almost by definition, is a rare quantity (i.e., there is not enough of it or it is in the wrong place), and anyone able to make it more available could expect improvement in productivity. Expert systems are part of a proven technology that addresses the problem of making expert problem solving more available. Expert systems are programs that seek to achieve a high level of performance at some task through the use of codified knowledge of human experts. While there is no hard and fast criterion for defining what is and what is not an expert system there are numerous desiderata for what an expert system should contain. Several typical criteria for an expert system are listed below (Buchanan and Smith, 1988).

1. Able to reason with domain-specific knowledge that may include both symbolic and numeric data.
2. Able to use domain-specific techniques that may include both heuristic (plausible) and algorithmic (certain) methods.
3. Can perform comparably to experts in both accuracy and timeliness of response in its specific problem domain.
4. Can provide reasoning (backtraces) for how it arrived at a particular decision.
5. Has a flexible architecture that facilitates modification of domain knowledge and control structures.

Expert systems, by criterion 3, work well in their domains but their performance usually drops off sharply when the domain is changed or modified. Thus, although expert systems seek to embody general methods of reasoning and problem-solving, the task-specific nature of the knowledge base severely limits their applicability outside the domain for which they were originally designed. Recently, though, an attempt began to overcome this fragility so that knowledge bases would be reusable (Lenat, Prakash, and Shepherd, 1986). The standard references for expert systems are Hayes-Roth, Waterman, and Lenat (1983), Waterman (1986), and Buchanan and Shortliffe (1984).

An expert system contains several components: a knowledge base of facts, heuristics, rules, and procedures; an inference engine for applying the rules using the facts in the current situation; a knowledge acquisition system for incorporating knowledge into the knowledge base; and a unit for inputting and outputting data. A typical expert system architecture is shown in Fig. 7. Let us now discuss each component of an expert system in some detail.

First, there must be a way to get data from the environment and a way to manipulate the environment based on the response of the system. This input/output (I/O) module includes the human interface, since that is also often where the knowledge comes from. Also, a good interface is needed for debugging and other modifications that invariably occur over time. The man–machine interface also influences whether the system will be used by people, apart from how well the overall system solves problems.

Another feature (and shortcoming) of expert systems is knowledge acquisition. Traditionally, knowledge is acquired by a "knowledge engineer," a programmer with special training in building expert systems, who interviews the domain expert. Usually only one expert is chosen, which eliminates the problem of conflicting expert opinion but biases the expert system to one particular source of knowledge. Further, the knowledge engineer often has very little training in interview methodology, and the expert often has difficulty relating to the questions of a novice. Additionally, the expert's time is at a premium, so even obtaining the knowledge is quite laborious and time-consuming. However, this custom crafting has the virtue that it works.

The inference engine uses the knowledge (e.g., rules) in the knowledge base together with the data obtained from the environment to take actions and make conclusions. These actions may use other rules in the knowledge base, forming a chain of inferences before finally reaching some conclusion.

The knowledge base contains the facts, rules, etc., that the system uses to make its decisions. A key feature of expert systems is that the specialized problem knowledge is kept

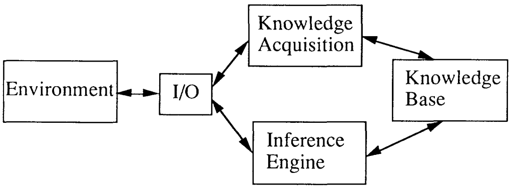

FIG. 7. Schematic diagram of an expert system showing the components and the links between them.

separate from the general reasoning methods in the inference engine.

A powerful feature of expert systems is their explanation capability which makes them much more believable to human users. When someone can explain his reasoning, we usually have much more confidence in his conclusion, because he seems to "know it" rather than our having to take it "on faith."

Not all problems are well suited to expert system methodology. For example, problems that are not well circumscribed are much more difficult to work with than ones that are clearly defined. Another problem encountered during expert system building occurs when the assumptions in the domain are not explicit. This can lead to poor performance when a situation occurs outside the assumptions. Debugging these assumptions can also be very difficult.

The organizations that successfully rode the first wave of AI are now clamoring for even more automated methods for problem solving. Clearly, overcoming the "knowledge acquisition bottleneck" is one area that is receiving great interest. This is the weakest link in the expert system chain. One of the most promising solutions comes from the area of machine learning; see Sec. 6.

Current research in expert systems includes development of more generally usable shells (an empty expert system where the knowledge base is filled in by the user) and less brittle systems that do not fail miserably when applied in a slightly different domain. Also, as expert systems become more pervasive there is a need to integrate their activities. Much of the work has to do with improving user interfaces (easier for nonexperts to use them), simplifying knowledge acquisition (learning), maintenance of knowledge bases (adding new knowledge without ruining the performance of the system and that is consistent with the old knowledge), and real-time monitoring (reasoning with time as a variable).

8. PROBLEM SOLVING APPLICATIONS OF AI

This section discusses some of the applications of AI. Although not meant to be exhaustive, it is intended to provide an idea of the areas where problems have been addressed by AI as well as the complexity of such problems. As indicated by the wide variety of applications, AI is indeed fulfilling its goal of wide applicability. In some domains, estimates of the search space (the number of possible answers) are given ranging typically from millions to $>10^{100}$. Again, this shows how AI can be used to reduce a search space from a size too large for blind search to one that can be heuristically examined to yield useful results.

8.1 Scientific Applications

Science provides a rich and challenging source of problems for AI. Indeed, science is an intelligent activity, so that AI has something to learn from the scientific method as well as being able to help scientists do science.

8.1.1 Physics. Although the physics community has been slow to incorporate AI techniques, there are nevertheless huge numbers of possible uses. For example, any large experiment in physics uses computers for data taking. As has been discussed above, expert systems provide a methodology for expert-level problem solving, such as automating the diagnosis of problems that occur with a detector or electronics. The Automated Beam Line Experiment (ABLE) (Clearwater and Lee, 1987) expert system has been used to locate and classify magnet and monitor errors in particle beam lines. Together with a knowledge-based induction system it has also been able to learn the diagnostic rules for classifying magnet and monitor errors in a beam line (Buchanan *et al.*, 1988) without the need for extensive knowledge engineering. Expert systems have also been used to diagnose problems in FASTBUS electronics (Booth and Carroll, 1987).

Other applications under way include learning rules ("cuts") for classifying events in high energy physics experiments. In this application the domain theory contains a list of parameters that are candidates for the cuts. As in any induction system, there is no *a priori* assumption that the domain theory contain all the relevant parameters or that it is free of irrelevant parameters. The training data for the learning program are preclassified examples (real or Monte Carlo) of the event type to be learned (signal events), as well as examples not belonging to the concept (background events). Because the data are noisy (e.g., misclassifications and finite resolution in the detector), the physicist sets the desired level of accuracy for the rules to be learned. The program then finds all the rules that satisfy the performance level given a domain theory. If certain parameters in the domain theory do not produce good enough rules, then those parameters may be left out of subsequent domain theories to reduce search. This procedure is similar to what physicists do anyway, except that now the process is formalized and the complicated hypothesis space is explored systematically rather than intuitively.

On a more down-to-earth level, the ISAAC program (Novack, 1977) uses a knowledge base of objects from elementary mechanics, such as masses and levers, to solve problems straight out of a college level physics text.

8.1.2 Biology. The recently begun Human Genome Project (National Research Council, 1988) and other related topics in molecular biology are excellent challenges for AI. The structures of biological molecules such as DNA are so complex that it may be necessary to use the techniques outlined in this article to learn the structure–functions relationship of sequences of amino acids in DNA. For example, properties of amino acids and the order in which they occur in proteins may be used to predict the location of three-dimensional structures such as helices in a protein, a precursor to predicting the overall properties of the protein. The utility of AI comes from the fact that at present it is very time-consuming to obtain these properties by conventional means.

8.1.3 Chemistry. The DENDRAL program (Lindsay *et al.*, 1980) was developed at Stanford University for interpreting mass spectrograph data from organic compounds. Meta-DENDRAL (Buchanan and Mitchell, 1978) was used to learn rules for determining the structure of organic compounds using the mass spectrograph as input and is one of the classic examples of an AI learning program. The input to both programs were properties of organic chemistry such as mass, valence, and stability, along with the mass spectrograph data. TQMSTUNE (Rauch-Hindin, 1986) was developed at Lawrence Livermore Laboratory to specify parameter settings for a triple quadrupole magnet spectrometer.

8.2 Technical Applications

AI has found great application in technical fields, particularly in the area of diagnosis. Diagnostic applications are relevant to physicists because diagnosis is a problem-solving activity that occurs over and over again when debugging experiments and in classifying processes in a detector. Several examples from different areas are given below. Additional and more detailed examples can be found in Feigenbaum, McCorduck, and Nii (1988).

8.2.1 Engineering and Industry. In the area of data interpretation, Schlumberger Inc. developed the Dipmeter Advisor System (Smith and Young, 1984) to interpret borehole data to aid oil prospecting. The program uses up to 650 geological categories in as many as 500 different depth intervals giving a search space of over 500^{650}.

Design systems, as exemplified by the following two examples, are relevant to scientists because today's experiments are so complicated that getting a good enough design is a huge task in itself that is still done largely by the "seat of the pants" approach. The XCON system (Rauch-Hindin, 1986) was developed to aid in the design of computer systems for VAX computers. The program had to select 50–150 items from a catalog of 20 000 parts giving a search space of over 10^{200}. Xerox Corporation developed the PRIDE (Mittal, Dym, and Morjaria, 1985) system which is used to design paper handling systems for copiers.

8.2.2 Medicine. Numerous systems have been developed to aid doctors in diagnosis of patient symptoms. The MYCIN (Buchanan and Shortliffe, 1984) system was developed to diagnose infectious blood diseases and has achieved expert diagnostician level performance during controlled tests. The INTERNIST (Schaffner, 1985) program was developed to aid in the diagnosis of internal disorders. Both MYCIN and INTERNIST reasoned in a space containing over a million possibilities.

8.3 Game-Playing

One of the earliest and still active areas of AI applications is in the realm of games. Very successful systems have been developed for many popular and complex games.

Recently, the Deep Thought (DT) system defeated an International Master at chess. DT consistently has a United States Chess Federation rating of 2500 in tournaments with humans. DT is currently (1990) the fastest chess machine and program and can analyze 700 000 moves per second. One of the classic results in AI and learning in particular comes from a checker playing program developed by Arthur Samuel in the late 1950s and 1960s (Samuel, 1963).

Waterman (1970) developed a poker playing program that learned how to play five-card draw poker. This program learned how to bet or fold depending on its hand, the amount of money in the pot, the last bet, and the bluffability and style of the opponent. The game of hearts has also been used as a test bed for learning by taking advice.

8.4 Defense

The U.S. Defense Department has long been a strong supporter of AI research. Recently this support has led to development of intelligent systems for use in military applications. Most of these applications are in the area of battle management, autonomous systems, intelligent analysis systems, etc. Some of the skills required for these applications include the ability to reason about scheduling, logistics, resource management, etc. Although many applications exist, only a small number are discussed here. Many military applications involve the same sort of pattern recognition skills needed in physics.

The Pilot's Associate (PA) is the U.S. Air Force's expert system for aiding fighter pilots. The purpose of PA is tactical planning during a combat situation. PA must take into account the threat environment, rules of engagement, currently available resources, etc., to allocate resources to provide overall tactics. All of these actions must occur in the real-time environment of combat.

The Force Requirements Expert System (FRESH) (Senator, Witte, and Kral, 1989) is currently in use by the Commander of the U.S. Pacific Fleet. FRESH is a knowledge-based system used to aid in the Navy's battle management decision making. Specifically, FRESH is used as an aid in resource and force employment allocation. The Navy reports higher readiness and higher accuracy of predictions with the use of FRESH.

The Autonomous Land Vehicle (ALV) is the U.S. Army's program to develop a vehicle that can perform tasks in the battlefield. Some of these tasks are smoke laying, deep reconnaissance, obstacle overwatch, mine laying, etc., all of which are performed without endangering soldiers and thus freeing them for other critical operations.

Part of the Strategic Defense Initiative (SDI) will require extensive use of AI for monitoring, targeting, and interpreting data from space-based devices as well as resource allocation.

8.5 Space Exploration

The National Aeronautics and Space Administration (NASA) is incorporating AI systems into its control rooms and future mission scenarios. As with the military systems, much of the work involves scheduling and resource allocation. One such space-based system is the Hubble Space Telescope whose limited viewing time must be optimally scheduled. Additionally, plans for a Mars Rover will involve many of the same problems of sensor interpretation and reasoning problems faced by the ALV.

8.6 Automatic Programming

Currently, computer programs must be laboriously developed by human programmers. This time-consuming and error-prone activity becomes even more critical as computer hardware leaps ahead in performance every few years. This "software gap" may be alleviated by the use of automated programming techniques.

Automatic programming tries to develop programs or systems that can automatically create computer-executable programs given some input of what to do, other than the code itself. Thus the goals of artificial intelligence may be thought of as some form of automatic programming. Automatic programming seeks to speed up the programming process by letting the programmer stylize and formulate the problem in a more abstract and natural way, unlike conventional programming languages that force the programmer to work within a rigid syntax and semantics in excruciating detail.

A familiar example of automatic programming comes from compilers, i.e., the source code of some programming language is converted into a form that is executable by a computer. More advanced automatic programming systems try to use natural-language input of a problem description that is then turned into executable code. Other methods use induction-like techniques of giving the automatic programming system examples of the desired input and output, as well as traces of the intermediate processing.

8.7 Mathematics

The AM program (Lenat, 1980) was designed to discover concepts in elementary finite-set theory. The program used empirical data and defined new concepts based on the regularities in the data. The data consisted of set theory concepts, operators, and heuristic rules for constructing plausible new concepts. While AM did not discover any new mathematics, it did find many well-known relationships such as DeMorgan's laws and led to the development of much shorter proofs for some laws of composite numbers.

The EURISKO program was an extension of the AM program and was designed to find useful heuristics and new representations in a variety of domains. EURISKO has been used in set theory, number theory, games, heuristics, device physics, etc. A couple of examples of the types of heuristics used by the program are these (Lenat, 1983):

If the results of performing f have not been useful, then lower the value of f.

If the results of performing f have sometimes been useful, then make new specializations of f.

8.8 Parallels with Human Perception and Language

8.8.1 Cognition. Much of the research in AI done by psychologists has been to model the human cognitive process. The idea is that information processing systems can thus be used to test cognitive models. This modeling includes models for knowledge representation and memory. Additional information on human problem solving can be found in Newell and Simon (1972).

8.8.2 Vision. Vision is included as an application of AI because it involves image interpretation, not just signal processing. Specifically, we define an image as a two-dimensional representation of an event in space. The image may be black and white, gray-scale, or color. Vision may be broken into three categories: signal processing—enhancing an image through a better signal-to-noise ratio with no regard to the content of the image; classification—where the classes are predetermined as in character recognition; and understanding—or scene analysis where the context of the entire image is important. One of the contributions of vision research has been the 2D sketch in which the surface knowledge is made explicit. Besides surface characteristics such as texture, reflectivity, etc., a vision system must be able to distinguish where one object stops and another begins, or where one side of an object changes to another side, i.e., edge detection.

AI vision systems might be useful in physics for interpreting spectra or event topologies in addition to being able to notice visible anomalies in a detector (e.g., a misalignment in an apparatus).

8.8.3 Language. Language is included as one of the applications of AI because it involves speech recognition and text understanding. Understanding language can be used to improve the performance of intelligent systems through better expression, recognition, and use of knowledge.

Understanding language means being able to interpret some language input and perform an action that is appropriate. For example, an appropriate response to "Where is your car?" might be "It's next to the big tree." Language understanding is difficult in part because of the complex interactions of the components of a sentence or group of sentences. For example, a mapping from a sentence may have many possible interpretations. Consider what must be known to understand a sentence. First, in understanding syntax, the order of the words must conform to the legal ordering specified by the language. Computer compilers are usually just syntax mappers; they do not know whether the program will work, only that there are no illegal statements. Second, the semantics of the sentence must have some meaning; that is, merely putting together a subject, verb, and object does not qualify a sentence as being semantically correct, such as "The car swims book." Finally, pragmatically the sentence must be interpreted; for example, "Did you drive to work today?" is usually interpreted to mean "Could I get a ride from you?" rather than as a yes/no question. Understanding not only includes individual words but sentences, paragraphs, etc.

An AI language system would provide a much more productive interface that could make programming and debugging much more efficient. As physics has become ever more dependent on extensive programming to run and analyze an experiment, a high-efficiency interface becomes even more critical.

8.8.4 Robotics. Robotics can be included as an AI application because it involves motion understanding. Robots must have both kinematic and dynamical knowledge which forms part of their spatial reasoning capability. Not only must a robot move through an environment, it must also have the ability to apply the correct amount of force, a tactile feedback. The robot must take into account the forces of motion such as centripetal and Coriolis forces as well as friction.

In science, an AI robot would be able to perform many mundane tasks around the experiment. In chemistry this could be mixing and performing actual experiments. In large physics experiments, the robot could go where people may not be able to because of high radiation and could possibly fix things without having to shut down a reactor or accelerator.

9. RELATION TO OTHER FIELDS

AI formalizes problem solving for a wide variety of domains. Intelligent systems such as evolutionary systems, where changes occur on a very long time scale, for example, species evolution (genetics), societal evolution, or national economies, are ill-structured and more difficult to parametrize and thus more suited to modeling using AI's methodology.

Operations research has made important strides in the last decade (Gill *et al.*, 1981), but these optimization programs work only with numbers and typically use some sort of hill-climbing search through the problem parameter space. They also make assumptions about the characteristics of the functions involved, such as invertibility, differentiability, continuity, etc., which in real life may be unknown or not applicable.

In statistics, Bayesian classification uses prior and posterior probabilities to represent less than certain data. The advantage of this technique is that it has a formal basis. The drawback is that it requires knowledge of distributions or other subjective estimates or requires a particular distribution to hold, which may not be the case in the real world. Recently, a nonparametric method of using trees, Classification and Regression Trees (CART) (Breiman, Olsen, and Stone, 1984), has been developed to do classification. These trees are similar in structure to the search trees discussed earlier and are constructed based on "best" partitioning the training data into two predefined classes. The nodes in the tree can be interpreted as antecedents of rules. The CART methodology removes the constraint of knowledge concerning the distributions in the data.

The areas of synergetics (Haken, 1983) and computational ecosystems (Huberman, 1988) have applications in almost any large complex dynamical system. These areas include the study of the behavior of such systems and their approach to stationary states, limit cycles, or chaos.

Cybernetics (*q.v.*) (Wiener, 1961) is the study of regulatory mechanisms. These systems are limited by their inability to take into account that the components of the system may have goals, nor do they require that the system be able to improve its performance (ability to achieve goals), only that it perform in an "optimal" way. In fact, closed feedback systems are subject to the second law of thermodynamics and therefore can only lose information and never gain. Although cybernetic systems may be adaptive, they are not so in a way that implies any understanding.

10. FUTURE DIRECTIONS INTO THE 21ST CENTURY

As has been discussed in this article, there are innumerable applications for AI. Almost any of them could be used as a grand challenge for AI—for example, the development of a machine and program that becomes the world champion chess player. Another example is a program that is able to help a handicapped person function more as a nonhandicapped person. Consider also machine systems that are able to self-organize and self-replicate, or to discover a new scientific result, or a truly natural language interface for communication between man and machine, or to write a poem.

By early in the next century, it can reasonably be expected that powerful computers will be readily available throughout the world. With the future advent of intelligent interfaces that can communicate through voice or handwritten character recognition, much of the knowledge of the world necessary for creating wealth can thus be made available to almost anyone who desires it (Reddy, 1988). Again this will have an enormous effect on global politics and the material well-being of all people.

Finally, we briefly summarize what AI has to offer to physics. On the one hand physics may seem like a straightforward approach to learning about nature because nature provides a ready test bed to test hypotheses. On the other hand, although the scientific method has been refined over the centuries it remains a hit or miss method whose progress relies on clever representations, heuristic search, and nonmonotonic reasoning, precisely the things that AI has to offer. Also, AI's emphasis on flexible programming methods facilitates construction of problem solving systems. In summary, the AI approach to problem solving offers a methodology for investigating situations where there is no known algorithmic solution by using heuristic knowledge to constrain the search for a solution.

11. APPENDIX: ADDITIONAL INFORMATION

11.1 Funding Sources

Traditionally, the Defense Advanced Research Projects Agency (DARPA) has been the largest funder of AI research over the years. Additionally, the Office of Naval Research (ONR), the National Aeronautics and Space Administration (NASA), the National Institutes of Health (NIH), and the National Science Foundation (NSF) are also large funders. Together these sources contribute over $100M/yr to research in artificial intelligence.

11.2 Centers of Research

Since the beginning of AI, three universities, Stanford, Carnegie–Mellon, and the Massachusetts Institute of Technology, have been at the forefront of AI research. These universities have faculty who were the founding fathers of the field as well as many of their disciples. Other schools with strong programs in AI include University of California at Irvine, University of California at San Diego, University of Illinois, University of Massachusetts at Amherst, University of Michigan, Rutgers University, University of Southern California, and University of Texas at Austin. Other centers include the industrial laboratories at AT&T Bell Laboratories, IBM Watson Laboratory, Schlumberger, Inc., and Xerox Palo Alto Research Center.

11.3 Selected Societies, Journals, Magazines, and Conferences

There are numerous societies involved in artificial intelligence and related areas. The most popular is the American Association for Artificial Intelligence (AAAI), which is open to anyone interested in AI.

Similarly, there are numerous publications available for those interested in the scientific and technical side of AI. *Artificial Intelligence, Machine Learning,* and *Neural Networks* are all scientific journals. The *AI Magazine* is a quarterly magazine which gives semitechnical accounts of recent work in AI, book reviews, announcements, etc. This a good source of information for AI products and upcoming AI events as well.

The annual meeting of the AAAI typically draws over 5000 people from universities, industry, and government from all over the world. The biennial International Joint Conference on Artificial Intelligence (IJCAI) is also a widely attended meeting and every fourth year cosponsors the AI conference with AAAI. The IEEE International Conference on Neural Networks and the International Conference on Genetic Algorithms are also offered. The AAAI and IEEE usually offer numerous other conferences, symposia, and workshops throughout the year catering to more specialized areas of interest.

GLOSSARY

AI: The abbreviation for Artifical Intelligence.

Computer: A machine that manipulates symbols.

Control Strategy: A strategy (set of rules) for directing the way a search will proceed.

Expert System: A program that is able to perform a task requiring human expertise.

Heuristic: A piece of knowledge that is used to reduce the amount of search in a problem, but is not guaranteed to work.

Knowledge: Facts about things, the way they interact with other things, etc.

Knowledge Base: Place where data structures and procedures used to manipulate and interpret knowledge are kept.

Learning System: A program that improves its ability to do some task without explicit programming.

Means-Ends Analysis: A control strategy that directs search in such a way as to minimize the difference between the current state in the search and the goal state.

Search: Exploration of a parameter space (also referred to as a hypothesis space or problem space) according to well-defined rules.

GENERAL INTRODUCTION

Astronautics deals with the design, engineering, science, and operation of vehicles intended for travel in space beyond Earth's atmosphere. As such, it provides the underlying technology that has led to many successful missions from Earth-orbiting satellites to lunar and planetary flybys, orbiters, landers, and rovers. Countries involved in exploring this exciting frontier include the United States, the Soviet Union, the European Space Agency consortium of member countries, Japan, Canada, and others.

The first three decades of space exploration came to a close with the epic Voyager Grand Tour mission, which dazzled the world with its flawless encounter with the remote Neptune kingdom in the late summer of 1989, but more ambitious missions were already under way or in their planning stages. These new missions will place great demands on the continuing evolution of performance improvements in the various technical disciplines comprising the astronautics field. The United States Space Exploration Initiative aspires to the landing of humans on Mars before another three decades have passed, but such an undertaking will depend upon available funding and may warrant that we first establish a Space Station, a Lunar Outpost, and a series of robotic precursor missions to the moon and Mars. In parallel with this challenging goal, a variety of other spacecraft will conduct more advanced explorations of the planets, their satellites, and the solar system's small bodies (asteroids and comets).

The 1990s will also usher in the era of the great Earth-orbiting observatories—the Hubble Space Telescope, the Gamma Ray Observatory, the Advanced X-Ray Astronomical Facility, and the Space Infra-Red Telescope. If successful, these sophisticated craft will enable astronomers to provide humankind with an unprecedented understanding of how the universe began, how it is unfolding, and how it might end. Where missions to the outer solar system will learn about worlds several billion kilometers away, the great observatories will probe the far reaches of the universe, billions of light years distant from Earth, gathering new knowledge about stars and galaxies, and about the physical and chemical nature of the stars and dust that pervade the cosmic sea.

All space missions require the same types of basic elements. In order to conduct the desired *science*, it is necessary to build a *spacecraft* capable of transporting the scientific payload to the destination, and provide the spacecraft with power, environmental protection, the proper instructions and orientation for performing measurements, and the necessary communications technology for transmitting the resulting data back to Earth. As the *launch vehicle* used to escape Earth's gravity well does not have an error-free guidance system, the process of *navigation* is necessary to deliver the spacecraft to a precise location at its destination, and to continue to control the flight path and accurately point the scientific sensors until the end of the mission. Until spacecraft have become entirely autonomous, a large complex of people, computers, communication lines, and tracking antennas at an *Earth base* must support the mission. Finally, for those nonrobotic missions involving the presence of a human crew, *life-support systems* are also required.

In the context of this article, the spacecraft and navigation elements will be described in some detail, with principal focus on the spacecraft design and the technical areas of power, propulsion, sensors, and attitude control. The Earth base, launch vehicle, science, and human crew elements will not be treated here.

1. SPACECRAFT DESIGN ARCHITECTURE AND PRINCIPLES

1.1 Spacecraft Systems and Architecture

A spacecraft is one part of a complex, highly interdependent set of systems that enable spaceflight, including the launch vehicle, launch facility, communications network, and control center. A spacecraft is defined by the mission-unique functions it performs, including

1. transporting the payload to a proper trajectory or orbit,
2. providing electrical power to the payload,
3. aligning and orienting the payload in space,
4. providing environmental protection and control to the payload and other supporting subsystems,
5. storing data, as necessary, from the instruments aboard, and
6. providing a communication link with Earth to receive instructions and to send back data.

Spacecraft can be categorized in terms of a number of different characteristics. The four most important characteristics are the following:

1. piloting (robotic or human),
2. mission type (e.g., orbiter, flyby, lander, rover),
3. attitude control (e.g., three-axis stabilized, spinning), and
4. propulsion (e.g., cold gas, chemical, electric).

Table 1 contains a selected listing of robotic and piloted spacecraft, mission descriptions, characteristics, masses, launch dates, and spacecraft-developing nations or agencies to illustrate the wide range and diversity of spacecraft designs that have been developed since the beginning of spaceflight in 1957.

The basic job of spacecraft system designers is to lay out the architecture of an electromechanical system that carries out the required mission objectives. This process requires that the spacecraft design include all the subsystems necessary to operate the spacecraft, taking into account all the interactions and constraints that are imposed by subsystems on one another. Such constraints include the fact that the communications antenna must be pointed toward Earth during periods of communication, the solar arrays must be pointed toward the sun, the radiators for heat rejection must be pointed toward space, and the payload must be aimed at its target and held steady. In general, the job of the spacecraft system designer involves integration of subsystems into a functional whole that minimizes launch mass and power consumption, both of which are almost always in high demand and short supply. The process of designing a spacecraft usually takes several years, during which time careful accounting of mass budgets and power budgets for every element of the spacecraft must be made, and great ingenuity used in optimizing the designs and interfaces.

1.2 Spacecraft Subsystems

To facilitate design and development, complex spacecraft are subdivided along specific functional lines into so-called subsystems. Some of the subsystems used in a typical robotic spacecraft developed by NASA's Jet Propulsion Laboratory (JPL) are as follows:

Attitude and articulation control. Maintains spacecraft and appendage stability and target pointing (see Sec. 5).

Adapter. The hardware interface between the spacecraft and the launch vehicle.

Cabling. The subsystem of wires, insulation, shielding, and connectors that interconnect the electronic subsystems. Cabling design is driven by such issues as electrical conductivity, grounding, electromagnetic interference shielding, and voltage drops.

Command and data handling. The command and data-handling subsystem provides the real-time or preprogrammed functions: decoding ground commands, distributing discrete and coded commands to subsystems, responding to interrupts generated on board; collecting, formatting, and managing science and engineering data (analog or digital); and the on-board clock. This subsystem consists mainly of electronic computers, memory, and input/output devices. Processor speed, quantity and access speed of memory, and fault-detection and -correction techniques are primary design considerations. For bulk data storage a magnetic tape recorder with various record and playback rates is the current state of the art.

Table 1. Selected spacecraft mission classes, masses, and launch dates (from Hart, 1987; Yenne, 1985).

Spacecraft	Mission	Characteristics	Mass (kg)	Date	Nation or agency
		Robotic Missions			
Mariner 4	First Mars flyby	Three-axis, cold gas	261	1964	U.S.
Luna 9	First Lunar landing	Three-axis, cold gas	1 538	1966	U.S.S.R.
Venera 4	First atmospheric probe	Three-axis, cold gas	1 106	1967	U.S.S.R.
Luna 17	First surface rover	Three-axis	5 700	1970	U.S.S.R.
Pioneer 10	First Jupiter flyby	Spin, chemical	258	1972	U.S.
Mariner 10	First gravity assist; first Mercury flyby	Three-axis, chemical	503	1973	U.S.
Viking	First Mars landing	Orbiter and lander, three-axis, chemical	2 991	1975	U.S.
Voyager 2	First Uranus and Neptune flyby	Three-axis, chemical	825	1977	U.S.
Ariane 1	Commercial launch vehicle	Three-axis, chemical	1 500 (ground to orbit)	1979–present	ESA[a]
Giotto	Halley's Comet flyby	Dual spin, chemical	575	1986	ESA
Galileo	First Jupiter orbiter and probe	Dual spin, chemical	2 700	1989	U.S.
Hubble Space Telescope	Visible observatory	Orbiter, three-axis, reaction wheels	11 400	1990	U.S.
		Piloted Missions			
Vostok	First piloted orbiter	Three-axis, chemical	4 713	1961	U.S.S.R.
Apollo L/M	First crewed lunar landing	Three-axis, chemical	43 900	1969	U.S.
Salyut	First space station	Three-axis, chemical	19 000	1971	U.S.S.R.
Space Shuttle	First reusable launch vehicle	Three-axis, chemical	100 000	1981–present	U.S.

---

[a] ESA = European Space Agency.

It is interesting to note that, due to contraints imposed by the environment (mainly radiation) and the need for reliability and limited available power, spaceflight computers lag far behind the terrestrial state of the art in speed and storage capacity (this is especially true for planetary missions). For example, each of the redundant processors launched on Galileo in 1989 was a 1975-vintage 8-bit machine rated at 0.015 million instructions per second (1 MIP=performance of a VAX 11/780) but only used 5 W of power and had 96 kbyte of RAM memory.

Contamination monitoring and control. A part of the design procedure that specifies appropriate materials, as well as venting and bakeout procedures to reduce the impact of outgassing of vacuum-condensible contaminating materials on critical surfaces and sensors. Contribution of propulsion modules to contamination is predicted by analysis of rocket-plume flow fields and calculating deposition rates. Plume shields are used to reduce this effect. Contamination sensors (usually quartz-crystal microbalances) are placed on board the spacecraft to record the buildup of contaminant layers on surfaces near sensitive areas in order to determine when and if it will be necessary to take action to mitigate contamination effects (including the use of heaters to drive off contaminant layers).

Electronic packaging. Electronic packaging is the technology by which the various digital and analog devices are packaged into high-surface-density, multilayer configurations. With present packaging techniques, the overall density is more limited by packaging of chips on boards than by packing of devices onto chips. For example, on the bus interface units for Mars Observer (to be launched in 1992), only 1.7% of the area of the circuit boards is covered with silicon devices; the remainder is used for chip housings, mountings, and connections. Such practices add greatly to the bulk and weight of spacecraft. In the case of highly optimized robotic spacecraft, packaged electronics represent on the average 30% of the dry spacecraft mass; however, the dry mass is often 20% to 50% of the total mass including stored propellants. Integrated-circuit technologies are changing rapidly toward smaller, higher-lead-count devices. Significant problems exist in mounting, attaching leads, inspecting, and flight qualifying these devices.

The combined spaceflight extremes of radiation, temperature, and vibration make the incorporation of state-of-the-art electronics a slow and difficult process. Soldered joints seem to lead to an endless series of problems for electronic packages on spacecraft. This is exacerbated by the practice of embedding electronics boards in plastic, which due to its coefficient of thermal expansion applies stresses to soldered joints. There are a number of new techniques being developed in industry that offer the promise of progressive increases in packaging density and higher speed. These new techniques offer great promise, but there are questions as to whether such boards are capable of being inspected, whether parts are replaceable, and ultimately how reliable they are.

Independent probe. Some planetary spacecraft carry an independent probe, penetrator, or lander that is released from the spacecraft and directed at a target (atmosphere or surface) for *in situ* measurements.

Power. The power subsystem deals with the processing, control, and distribution of power on board the spacecraft. Energy sources may include solar-cell arrays, radioisotope thermoelectric generators (RTGs), or batteries (see Sec. 3).

Propulsion system. The propulsion subsystem provides propellants and engines for mass-expulsion methods of trajectory changes and attitude control (see Sec. 4).

Mechanisms and pyrotechnics. Mechanical and pyrotechnic devices satisfy such open-loop functions as separation, latching and unlatching, deployment, scanning, etc. The nature of these devices generally makes them all candidates for single-point failures. For example, on Galileo, if a single pyrotechnic separation bolt or boom deployment pin puller had failed to actuate, the entire mission would have been lost at that instant. Design practices emphasize large strength or force margins, redundancy where practical (e.g., bearings within bearings), vacuum-compatible materials and lubricants, and special attention to thermal expansion and contraction effects. All mechanical devices are extensively tested to verify margins and lifetime, and intentional "fouling" tests are often conducted to gain extra confidence in their "bulletproof" performance.

Science payload. Scientific payloads perform both remote sensing and *in situ* measurements of planets and the interplanetary medium. Remote sensing requires precision pointing of optical instruments and antennas to do imaging, spectroscopy, and/or radiometry in the visible, UV, IR, and radio wavelengths. As a minimum, space missions usually include visible-wavelength cameras and often ultraviolet and infrared instruments. *In situ* instruments perform measurements on various magnetic fields, charged particles, and plasmas, including their distribution, charge, and energy. In the case of reentry probes (e.g., Venera 4) or surface missions (e.g., Viking, Lunakhod), direct measurements are made of atmospheric properties (e.g., pressure, temperature, humidity, particulates) and surface characteristics (e.g., elemental composition, chemistry, mineralogy). These instruments are usually developed separately from the development of the spacecraft itself, but they must be integrated into the spacecraft and the spacecraft designed to provide the instruments with the required articulation and pointing capabilities, appropriate power, proper thermal environment, and adequate data storage and processing.

Structure. The structure provides support and alignment of all flight subsystems and equipment during launch and flight. It also provides protection from natural and induced environments such as vibration, meteoroids, radiation, and electromagnetic interference. As can be seen from Table 2, the structure on a spacecraft tends to account for about 30% of the total dry mass. It should be pointed out, however, that for recent planetary and cometary orbiting spacecraft, the dry mass is typically less than that of the stored propellant aboard the spacecraft.

The primary requirement for the structure is to withstand the launch loads. For typical launch vehicles, there is a spectrum of force versus frequency with specific peaks in the low frequencies of 1–50 Hz. Generally, structural elements are designed to meet one of two criteria: strength or stiffness. A stiffness (frequency tuning) criterion is often used to minimize loads on individual resonant subsystems or instrument structures by shifting resonances away from regions of high input energy. For example, the Galileo RTG boom designer chose to shift primary modes to around 22 Hz. This reduced RTG vibration response to levels that the RTGs could withstand without internal damage.

Table 2. Typical distribution of mass on dry spacecraft (excluding liquid propellants) for solar system exploration.

Mechanical systems	Percentage of dry spacecraft mass
Structure	32
Electronics packages	32
Devices, sensors, and optics	14
Cabling	7
RTG, battery, and solar arrays	10
Propulsion (dry)	5

Because of the criticality of mass, materials with high specific stiffness (elastic modulus divided by the density) and high specific strength (yield strength divided by the density) are very important. With use of aluminum 6061-T6 as a reference standard, the following list shows the characteristics of some common and advanced aerospace structural materials.

Material	Specific stiffness	Specific strength
Al 6061-T6	1	1
Titanium	1	2.4
Beryllium	6	1.4
Graphite-epoxy composite	5	4.7
Metal-matrix composite	5.3	3

As the structural design of a spacecraft proceeds over its multiple-year developmental stage, a detailed finite-element model is maintained. For complex spacecraft, these models may have many thousands of mass degrees of freedom. To verify model accuracy, a full-scale *dynamic test model* of the spacecraft is built that has all the dynamic attributes of the real spacecraft but does not contain real electronic subsystems or instruments. This test model is extensively tested on the ground to verify the predictions of the computer model.

For new astronomical missions involving large telescopes, the issues regarding the structure may be very different. Such structures may weigh thousands of kilograms and deform significantly in a 1g field, necessitating special ground measurement and testing techniques. For deployable telescopes with large reflectors, the principal issue may be stiffness and thermal distortion when deployed in space, rather than stiffness and strength when stowed for launch. Techniques are being developed that use passive and/or active control techniques to maintain tolerances in the deployed state.

Telecommunications. The telecommunications subsystem provides communication to and from Earth for the purpose of vehicle tracking, range measurement, commanding, and telemetry. The telecommunications subsystem is comprised of antennas, transmitters, receivers, modulators/demodulators, and amplifiers. A key parameter that determines the capability of the communications subsystem is the number of bits per second (bps) that can be transmitted. The performance of a telecommunications subsystem is proportional to the transmitter power, the area of the transmitting and receiving antennas, and the square of the transmitting frequency. Over the past 25 years, there has been a trend toward higher frequencies for spacecraft telecommunications. The present state of the art is undergoing a transition from X band (8.4 GHz) to Ka band (32 GHz). Researchers are now developing much-higher-frequency optical communication systems with vastly increased capacity. The telecommunications subsystem involves data formatting and coding, data compression, modulation of the carrier signal, radio-frequency transmission, and similar steps in receiving. Spacecraft transmitters for planetary spacecraft have been limited to power levels of about 20 W. The current state of the art for long-distance data transmission rate is about 10^5 bps, from Jupiter range [5 astronomical units (AU)]. For new Earth-observing spacecraft planned for the Global Change Initiative of the late 1990s, NASA will require much higher data rates (up to 300 Mbit/s), and the telecommunications subsystems will be very challenging. (See TELECOMMUNICATIONS.)

Temperature control. The temperature-control subsystem maintains mechanical and electrical elements of the spacecraft within allowable operating and nonoperating temperatures. This includes meeting the special temperature requirements of components and subsystems such as batteries and cryogenic instruments. Temperature control of spacecraft must be effective throughout the prelaunch, launch, cruise, and operational phases of the mission. For hazardous conditions such as carrying propellants in the Shuttle, temperatures must be maintained within safe limits even in the event of a sudden mission termination.

The basic strategy for planetary spacecraft thermal design is the following:

1. minimize temperature sensitivity due to external and internal heat fluctuations,
2. emphasize passive (e.g., blankets, radiators, coatings) over active techniques (e.g., heat pipes, fluid loops, thermostatically controlled heaters), and
3. keep the design simple for ease of analytical modeling and ground testing.

The process of thermal control begins with the conceptual design of the spacecraft. A sophisticated thermal model including solar inputs, planetary infrared and visible heat loads, heat sources and sinks, conductances, capacitances, and radiation view factors is used for steady-state and transient analyses.

Temperature-control design tools include selection of absorption and emissivity properties of surfaces and coatings, thermostatically actuated low-emittance louvers that can open to expose a high-emittance heat-rejection surface, multilayer (typically 5–20 layers of aluminized Mylar separated by a Dacron net) insulation blankets, electrical heaters, radioisotope heater units (RHUs), heat pipes, radiators, shades, stored cryogens, and active refrigerators.

In recent years, greater emphasis is being placed on instruments making infrared wavelength measurements. Such instruments require cryogenically ($\sim$55–80 K) cooled sensors and optics. In low Earth orbit, radiators can only cool to about 150 K. For lower temperatures, cryostats have been developed that can store 80–200 L of liquid helium for as long as a year [e.g., IRAS (Infra-Red Astronomical Satellite) and COBE (Cosmic Background Explorer) missions], and much larger cryostats are now being planned. A number of mechanical coolers using split Stirling cycles are under development for longer life missions. By 1995 they are expected to be able to provide about 1 W of cooling in the 50–80-K temperature range for <30 W of electrical power.

Some missions have very severe requirements for temperature-control technology. For example, the Galileo mission involves three gravity assists, one by Venus and two by the Earth. In the Venus gravity assist, the spacecraft approached within $\sim$0.7 AU of the sun, and achieves its final orbit around Jupiter at ~5 AU. The solar input varies by a factor of ~50 during this extended journey. Despite the huge changes in solar heating, most of the sensitive electronics and instruments had to be kept near room temperature throughout the mission.

1.3 Design Requirements and Constraints

Space-vehicle design is set apart from the design of other electromechanical systems by simultaneous application of the following extreme conditions:

1. the demanding performance requirements and constraints of space missions,
2. the severe environments of space and the launch vehicle,
3. the general permanent inaccessibility for repair, and
4. the extreme lack of political tolerance for *any* failure.

Item 4 drives the entire spacecraft design attitude and creates a factor of 100 or more higher cost than would be required to produce equally complex terrestrial systems.

Spacecraft functional requirements and constraints evolve through an iterative process involving mission and science objectives, performance objectives, and resource tradeoffs. The subsystem-level functional requirements include specific statements about the following: performance, configuration, interfaces, lifetime, safety for personnel and hardware, alignments, compatibility, accuracies, etc. In order to meet the functional requirements, a number of key parameters must be controlled and managed as part of the functional design of a spacecraft: mass, power, volume, schedule, on-board data rates, spacecraft-to-ground data rates, computer memory, computer processor speed, propellant, design margins, surface area, inertia properties, operating and nonoperating temperature ranges, and cost.

Design environments for spacecraft are specified for particular mission phases such as prelaunch ground operations, launch, flight, and, for some missions, operations in and on the atmosphere or surface of another body. Natural environmental hazards include ionizing radiation, heavy ions, nuclear radiation, magnetic fields, charged particles, meteoroids, atmosphere, planetary ring particles, temperature, and pressure. For example, the Galileo spacecraft electronics were designed (with a factor of safety of 2) to survive an integrated mission dose of 75 krad from Jupiter's radiation belts. Most interplanetary electronics need only be designed to 7.5 krad. Induced environments are associated with manufactured or vehicle-related phenomena such as structural vibration, random vibration, acoustic noise, pyrotechnic shock, electrostatic discharge, space debris, and radiofrequency radiation. Launch vibration is typically the driving structural design consideration.

Once a spacecraft leaves the launch pad, there is no opportunity to repair it (a notable exception is the unique capability of the Space Shuttle to capture and repair some vehicles from low Earth orbit, as was done in 1984 with the Solar Maximum Mission). Conservative design practices, quality control, and preflight testing are the primary tools to avoid flight failures. Reliability is also enhanced by utilizing block, functional, and alternate-mode redundancy such that individual element failures, called single-point failures, cannot cause significant loss of data or of the mission. However, reliability can only be enhanced at the cost of other resources: time, money, mass, memory, power, and performance.

Advanced technology plays a critical role in spacecraft design and performance. Advances in materials, electronics, and sensors have enabled giant steps forward in subsystem and component technologies, which have, in turn, enabled more and more sophisticated missions. However, due to the demands of space reliability and qualification, the technology level in space missions generally lags the terrestrial state of the art by many years. Space-radiation environment effects severely restrict the selection of acceptable electronic components. For example, the processor being proposed for the Comet Rendezvous Asteroid Flyby (CRAF) mission (development started in 1989) has an effective speed of only 0.25 MIPS, a factor of 10 or more below the state of the art for desktop computers on Earth. However, it is radiation resistant and immune to single-event upsets.

1.4 System Design Principles

The design of spacecraft is an evolutionary process, paced by the inflexible demands of a fixed launch date for solar system exploration missions. Project development is an iterative cycle rather than sequential. The design proceeds not in an unbroken flow from functional requirement to design requirement, to design to finished product, but as a series of design cycles as both requirements and interfaces evolve.

Principles of spacecraft system design can be enumerated, but the reality imposed by parallel requirements and design evolution results in many exceptions to these principles. The following items are guiding principles in each cycle of the recursive design–requirements iteration loop:

1. Define the mission and subsystem requirements and constraints as early as possible, preferably before starting design.
2. Establish and manage margins of critical resources (mass, power, memory, etc.), and make the design robust to accommodate uncertainties and last-minute changes.
3. Identify major problems early and search for designs that avoid them instead of using brute-force solutions.
4. Maximize performance, quality, reliability, adaptability, and precision within the constraints.
5. Utilize proven technology.

Optimum performance is obtained by tightly integrating many functional elements. In a highly optimized design, there are no "clean" interfaces between elements, and changes made by one element tend to strongly affect others. For example, to achieve minimum mass of electronics and structure, JPL utilizes an electronics subchassis to stabilize the primary bus structure. In contrast, the separation of elements such as electronics units into discrete, stand-alone components can lead to lower cost, easier modification late in the design cycle, and shorter development schedules, but all at the cost of performance, especially mass. For example, mounting "black boxes" of electronics on a structural plate and cabling them together may be simpler from an interface point of view, but it is not mass efficient. The key to a good system design is optimization in selected areas where performance is crucial and only a few elements are integrated or interactive.

When subsystem development must occur in parallel, many subsystem design parameters must be simultaneously managed at the system level to assure meeting overall system requirements. This process generally requires establishing budgets for critical resources and making allocations to the various subsystems. The two most difficult resources to manage are mass and power. Very early in the design process, the total mass is established by the trajectory requirements and the estimated launch vehicle performance. Mass allocations are made with an adequate contingency and reserve to accommodate inevitable growth and possible shortfalls in launch-vehicle performance. Invariably, problems arise, changes occur, trade-offs are made, and the total allocated mass rises from the initial estimate, while the contingency and reserve diminishes.

1.5 System Configuration Drivers

The spacecraft configuration provides the primary constraints on the design of subsystems that integrate the spacecraft, such as the structure, thermal control, electronics packaging, cabling, and mechanisms. Because the configuration defines all the basic geometric relationships and many of the physical relationships between the various subsystems and the payload, it is driven by a number of competing functional requirements and interfaces. The basic configuration requirements of the Voyager and Galileo spacecraft provide a good illustration because even though they were essentially the same, different emphases between them resulted in vastly different configurations for the two spacecraft. The configuration drivers for both missions are summarized below:

- stable platform for imaging;
- maximum field of view for field and particle instruments;
- large high-gain antenna integration and pointing;
- radioisotope power source;
- propulsion tankage and location of attitude control thrusters;
- instrument shielding from thruster plumes,

stray light, and RTG heat and radiation;
- compatibility with launch-vehicle envelope and dynamic loads;
- inertia properties balancing;
- spacecraft fabricability, maintainability, and transportability.

Figures 1 and 2 show the configurations of the Voyager and Galileo spacecraft, respectively, in free flight.

The Voyager spacecraft was designed as a flyby mission of Jupiter and Saturn by two spacecraft, but the extended mission of one

spacecraft was to achieve a "Grand Tour" including Uranus and Neptune. The configuration was dominated by a 10-bay electronics bus, a science boom, an RTG boom, a payloadof 10 science instruments, and a 3.7-m-diam fixed high-gain antenna capable of transmitting 115 kbit/s to Earth from Jupiter (Anonymous, 1979).

Like all of JPL's previous spacecraft, Voyager was a three-axis stabilized design. Thrusters were located to provide fully redundant torques about three orthogonal axes. A small propulsion module (104 kg of hydrazine) was located in the middle of a 10-bay electronics bus for attitude-control and small trajectory-correction maneuvers.

Voyager's mission deep into the solar system required the use of three RTGs. Each RTG utilized a 2500-thermal-watt PuO_2 heat source and silicon germanium thermoelectric devices to produce 150 W electrical power (4 W/kg) at launch (Anonymous, 1979). Because of the health risks associated with plutonium, significant efforts were made to ensure that, in the event of a launch-vehicle or spacecraft failure, each of the PuO_2-carrying heat sources would return safely to Earth.

A few failures occurred on the Voyager spacecraft. Voyager 2 lost one of its two telecommunications receivers (possibly due to a blown fuse), and the other receiver required special control procedures to maintain 0.25 °C temperature stability. This stability requirement was needed to enable ground controllers to predict the uplink frequency at which Voyager 2 could be commanded. Voyager 2 also had its scan platform actuator temporarily stall after passing through the Saturn ring plane (the failure was not related to the ring crossing). Thorough analysis and ground simulation indicated that the azimuth actuator probably lost lubricant. Procedures were implemented that limited operations ($\frac{1}{12}$-deg/s slew rate and only a few total rotations of the actuator output), and no additional stalling occurred.

The Galileo spacecraft is in reality two spacecraft: an orbiter and a Jupiter atmospheric probe. The configuration is dominated by an 8-bay electronics bus, two RTG booms, a 9.5-m science and magnetometer boom, a 4.8-m-diam unfurlable high-gain antenna, a probe (with atmospheric science instruments), a 935-kg (wet) propulsion module, a scan platform, four bays of electronics opposite the scan platform, and nine science instruments (Anonymous, 1988).

The fundamental distinction between the designs of the Galileo and Voyager spacecraft was in the choice of Galileo's approach to satisfy field and particle science viewing requirements, by spinning part of the spacecraft. In this dual-spin concept, part of the Galileo spacecraft spins, allowing nearly a full 4π-sr field of view for its field and particle instruments, while the remainder of the spacecraft maintains an inertial pointing platform for remote sensing instruments on the despun section. In order to provide vehicle stability and to meet antenna and scan platform pointing requirements, the spinning section was designed to have a polar moment of inertia 1.16 times greater than the maximum transverse moment of inertia of the entire spacecraft. This resulted in using long booms for the RTGs, actively positioning the RTGs in flight to adjust products of inertia, adding 31 kg of ballast, and adding a tuned nutation damping mechanism to the magnetometer support (making it the largest nutation damper ever built). By contrast, Voyager, with its three-axis stabilized design, was simpler to design and build, but it did not provide as good a field of view for field and particle instruments as did Galileo. These two very different spacecraft provide insight into the conflict between the desire for better performance (more science) and the engineering design complexity that it produces.

1.6 Future Missions

Space telescopes are spacecraft in which the optical system, particularly the primary reflector, tends to dominate the design requirements. During the decade of the 1990s, NASA's Astrophysics Division is planning to launch four "Great Observatories." The first of these is the Hubble Space Telescope (HST), a reflecting telescope with a 2.4-m aperture and an extremely high-quality surface mirror. The limitations of the envelope of the Space Shuttle cargo bay (4.5×18 m^2), the light baffle forward of the secondary mirror, and the space required by instruments behind the primary mirror dictated a very compact Cassegranian optical system for the telescope itself. The primary mirror is mounted on a graphite-epoxy truss structure that acts as the main optical bench. The remainder of the spacecraft provides the normal spacecraft functions including large solar arrays that generate about 4 kW of power. The instruments of the HST are designed for periodic changeout and refurbishment.

Another of the Great Observatories is the Space Infra-Red Telescope Facility (SIRTF), scheduled for launch in the late 1990s. This 0.9-m-diam telescope will operate in the infrared region and will be cooled to an internal temperature of 1.7 K by immersing the optics and detectors in a toroidal cryostat filled with superfluid helium. The spacecraft will be deployed in high Earth orbit at an altitude of about 100 000 km to reduce the Earth thermal input to the cryostat and to improve the viewing efficiency of the telescope. The cryostat will hold about 4000 L (vs 200 L for IRAS, its predecessor) of superfluid helium and is to be designed for a five-year life. Two of the major design challenges are to develop a structure that will maintain its dimensional stability and to develop mechanisms that will allow active mirror pointing at these very cold temperatures.

The two other Great Observatories are the Gamma Ray Observatory and the Advanced X-Ray Astronomical Facility.

Toward the end of the century, it is hoped that construction will begin on a far-IR and submillimeter observatory of about 20 m diameter, called the Large Deployable Reflector (LDR). The reflector on this telescope will be shaded and will reach a passive temperature in the range 100–150 K in high Earth orbit. Unlike other space telescopes, which are small enough to be designed to be rigidly assembled on the ground and launched as a unit, the LDR is inherently much larger than any current launch vehicle cargo bay. One of the major challenges is to develop the capability to either deploy or construct the telescope reflector in space. In addition, the design must include active and passive figure control techniques to maintain dimensional stability within a few microns in the face of thermal gradients produced by the nonuniform solar inputs.

A Mars rover and sample return mission has been under study by NASA for a number of years. Early concepts include a moderately autonomous surface rover (rolling and walking designs are being studied), collecting about 5 kg of samples for *in situ* analysis, and return to Earth. This mission requires some unique techniques such as "aerobraking" in the Martian atmosphere to slow the spacecraft down and achieve orbit. This technique requires an "aeroshell" to protect and control the spacecraft's flight through the atmosphere but saves thousands of kilograms of propellant. Such a mission requires many elements, including a communications orbiter, the aeroshell system, the rendezvous vehicle, the lander, the ascent vehicle, and the Earth return vehicle.

2. SPACECRAFT POWER SYSTEMS

2.1 Functions of Spacecraft Power Systems

Spacecraft power systems (SPS) provide electrical power for the operation of a spacecraft. A SPS consists of an energy source (or sources), a system for conversion of energy to electrical power, energy storage (if necessary), and a system for management and distribution of electrical power on the spacecraft. The electrical power must be conditioned for particular end users, distributed to users (loads), made stable, and safely controlled to protect the entire space system from power failure. These capabilities must be arranged in an architecture allowing inclusion of the SPS within a limited volume, while supplying the required electrical power at the user load. In addition, the "noise" or electromagnetic signals carried on the power lines must be controlled to minimize impact on and disruption of sensitive scientific sensors. This entire "orchestra" of component players must then be directed. This is accomplished by a set of computer instructions, or programs, resident either in the spacecraft command computer or a special computer embedded in, and thus part of, the SPS.

2.2 Energy Sources

There are really only two major sources of energy on spacecraft, solar radiation and nuclear energy. Batteries can be used to augment these power sources for temporary periods. However, batteries do not have the capacity to supply the long-term power needs of spacecraft.

At a distance of 1 AU from the sun, the solar intensity is 1368 W/m^2. Solar radiation energy is readily available as long as a spacecraft stays within about 2 AU of the sun. The solar intensity, however, falls off as the square of the distance from the sun, $E \sim 1/R^2$, and at distances from the sun of more than a few AU, use of solar energy becomes impractical. In most cases, it is difficult to avoid having the spacecraft periodically "shadowed" or eclipsed by a planet or moon. This makes it necessary to include an energy storage device, such as a battery, or to include a nuclear energy source in those missions that must place the spacecraft in shadow or in regions of the solar system where the sunlight is very dim.

Nuclear sources take two primary forms, based either on fission or on radioactive decay of unstable isotopes. In either instance the energy is provided as heat. Energy is released by the fission reaction in the form of heat, electromagnetic radiation (e.g., γ rays), and other energetic particles. The γ rays are extremely energetic and can cause damaging ionization to materials in their surroundings. Because fission reactors generate large amounts of ionizing radiation, the shields to protect sensitive components or humans will tend to be massive.

Another alternative involves radioactive decay of unstable isotopes. In early applications on Earth, strontium-90 (^{90}Sr) and cesium-137 (^{137}Cs) were attractive because of their long half-lives and their ready availability as fission products from nuclear reactors. However, both ^{90}Sr and ^{137}Cs are strong γ-ray emitters and therefore require heavy shielding, which detracts from their value as energy sources on spacecraft. However, plutonium-238 (^{238}Pu) is an emitter of lower-energy α particles (stopped by a sheet of paper) and emits very little γ radiation. This, coupled with its relatively long half-life and high melting point ($\sim$2300 K), makes it the isotope of choice, even though it is expensive and has a much lower power density (4 W/g) than isotopes of cesium, cobalt, and polonium. Polonium-210 (^{210}Po) was used by the U.S.S.R. to power their moon-sampling Lunakhod. It has a very high power density (140 W/g) and a low radiation field, making it an ideal energy source for short missions. However, the half-life is only 138 days, making it unsuitable for long, deep-space missions.

Since the beginning of space exploration, nuclear SPS have included both radioisotope and fission reactor options. A series of navigational satellites were the first to employ nuclear power in space, beginning in 1961. They used an RTG in which some of the heat released by a radioactive material was converted to electricity by thermoelectric converters. These early RTGs provided 2.2 W of electrical power and weighed 2.3 kg each. Although their capability was modest, they performed well and raised confidence that RTGs could meet future mission lifetime requirements.

A spacecraft carrying an experimental fission reactor was successfully launched into orbit in 1965. After 43 days of producing 600 W of power, a spacecraft malfunction (having nothing to do with the reactor) caused the reactor to shut down automatically. A twin of this reactor accumulated 10 000 hours at power in a ground test, until it was shut down in 1966. The U.S. continued development of reactors at higher power levels (30 to 60 kW) for use in space, until all space reactor programs were terminated in 1973. In the mid-1980s a new U.S. space reactor program was begun, called the SP-100.

Beginning with their first publicly identified launch of nuclear power in 1965, the Soviet space program has actively developed small space reactors. They have launched about 35 reactors into low Earth orbit, primarily for military reconnaissance spacecraft. Several of these have accidentally reentered the Earth's atmosphere, the most notable being the reentry over Canada of the Radar Ocean Reconnaissance Satellite (RORSAT) known as Cosmos 954. This reentry in January 1978 focused world attention on the environmental consequences of the use of nuclear power in space. Although the Soviets have used nuclear power more extensively than the U.S., the U.S. continues to use RTGs for deep-space missions.

2.3 Energy Conversion

As shown previously, the sources of energy available for SPS are nuclear-generated heat and solar radiation. As with all energy sources these two forms must be converted to the form that is most useful on a spacecraft, namely electricity. (See ENERGY CONVERSION.)

2.3.1 Photovoltaic Conversion. For spacecraft that operate within about 2 AU of the sun, the most common SPS use arrays of photovoltaic cells to directly convert sunlight to electrical power (see PHOTOVOLTAIC DEVICES). In some ways, photovoltaic conversion of solar luminosity to electrical current is analogous to the photoelectric effect, which produces ejection of electrons from metal surfaces by photon impact. In semiconductor materials such as silicon, the impact of photons releases electrons that flow in opposite direction to "holes" (electron vacancies) within the material, creating an electric potential. Small wafers of such semiconductor materials, or "cells," are used in photovoltaic-space-power systems to convert incoming light energy into electrical power, *W*, with

$$W = I\eta,$$

where *I* is the incident solar-radiation intensity and η is the efficiency of the photovoltaic conversion cell. Typical conversion efficiencies in the range 10%–15% are now routine. This means that one can obtain roughly 150 W of electrical power for each square meter of solar cells at 1 AU from the sun.

To supply power to a spacecraft, arrays of large numbers of solar photovoltaic cells are integrated on lightweight structures called "substrates." The design of the substrates must be such that the entire mechanism can be stored in a small volume and withstand the launch loads imposed by the launch vehicle. After launch, the solar array is deployed and oriented toward the sun to begin producing electricity. The electrical power generated by hundreds or thousands of solar cells on an array must be collected and conducted to the electrical power bus, and usually to a storage-battery system. Each solar cell has an interconnect grid to connect its voltage to the next cell and, at the end of a series string, to a terminal or tie point. Most arrays include some isolation devices (diodes) for circuit fault isolation and to prevent nonilluminated cells from dissipating power.

The primary issues in solar-cell-array development are the conversion efficiency, the areal density, the degradation resulting from exposure to natural radiation in space, and methods for stowing and deploying arrays. These combine to provide the main figure of merit for array performance, specific power, typically given in W/kg. Typical performance of current solar arrays with rigid substrates is in the range 33 to 46 W/kg. A large experimental 12.5-kW flexible substrate "wing" was tested in space with a specific power of about

66 W/kg (see Fig. 3). The Advanced Photovoltaic Solar Array (APSA) now under development has advanced cells ($\eta \approx 13\%$) and composite, low-mass structures, with an estimated potential specific power of $\sim$ 130 W/kg.

2.3.2 Thermal-to-Electric Conversion. Primary energy sources that produce heat, such as nuclear fission reactors or radioisotopes, require a system to convert the heat into electricity. There are basically two techniques available, one being dynamic and the other being static.

Systems for dynamic conversion of heat to electricity in space build on our terrestrial experience in electric power generation using thermal power cycles. On Earth, boilers are heated by fossil-fueled or nuclear heat sources to produce steam, which is passed through a turbine to drive an electric generator in a *Rankine cycle*. The theoretical conversion efficiency of this cycle is determined by the temperature at which heat is absorbed by the working fluid in the boiler, and the temperature at which excess heat is rejected in the condenser. The actual efficiency is degraded below the theoretical efficiency by inevitable losses in the converting machinery. On Earth, excess heat unable to be converted is simply dumped into the atmosphere or ocean.

Proposed dynamic space-power-conversion techniques use variants of this technique in a variety of possible thermodynamic cycles, including the organic Rankine, Brayton, and Stirling cycles. Such cycles have the potential for conversion efficiencies of over 20%. A SPS must include radiative heat rejection (no air or water heat sinks) and redundancy to increase reliability. Such dynamic power-conversion systems have not been actually used in space for several reasons. One reason is that they tend to be complex and involve mechanical systems with moving parts, which are considered to be problematical for systems that require ex-

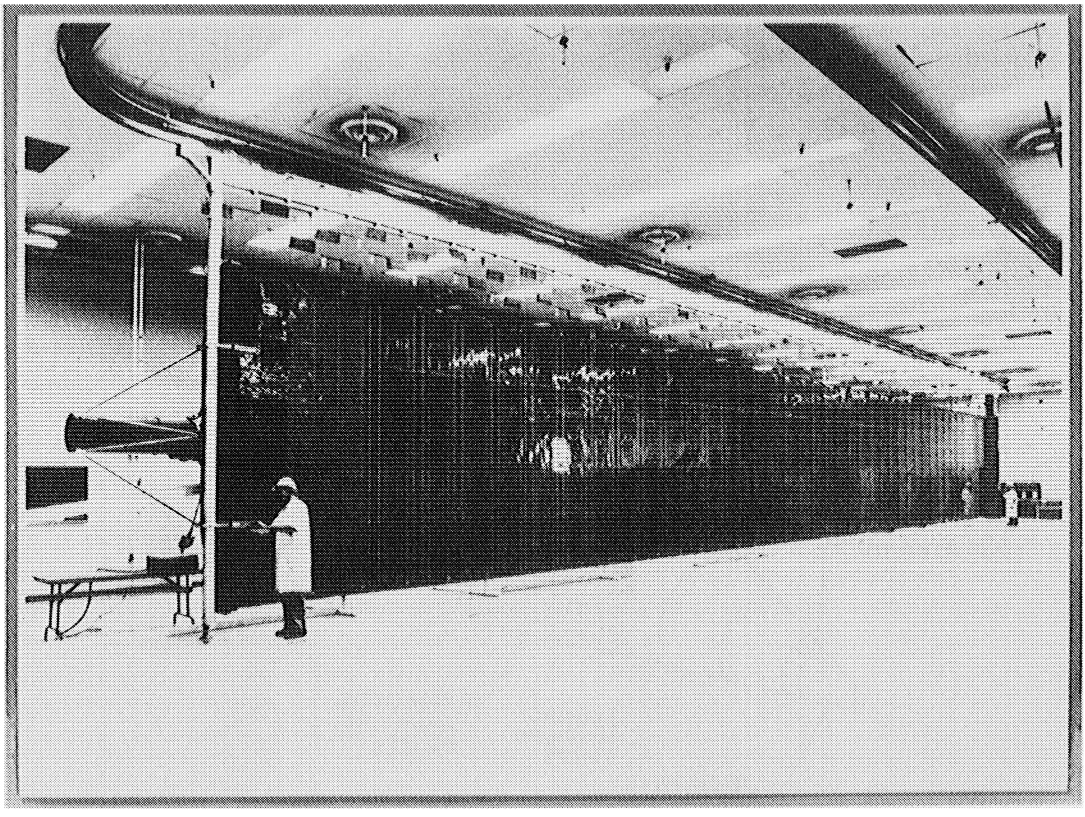

FIG. 3. NASA 12.5-kW SEP array wing.

tremely high reliability. A second reason is that the bulky and heavy nature of the components used in these systems (turbines, pumps, compressors, heat pipes, radiators, etc.) results in a poor specific power for systems that produce less than a few kW. For such low power levels, thermoelectric converters are the preferred choice because of their high reliability and low mass, despite their low conversion efficiency.

The second conversion technique does not employ moving machinery components, but instead, uses the phenomenon of temperature-induced current flow in materials (Seebeck effect) (see THERMOELECTRIC DEVICES). In this system, a pair of dissimilar semiconductor materials in contact, with each end at different temperatures, is joined in a closed circuit to produce a voltage. This type of system is called a thermoelectric converter. Unfortunately, their conversion efficiency is quite low (typically 5%–8%) and therefore the amount of power they produce is limited for a given thermal input. For thermoelectric SPS that must produce more than several kW of electrical power, such as SP-100, this leads to a requirement for large radiators that dominate the configuration of SPS because the large amount of excess heat not converted to electricity must be radiated into space (see Fig. 4 for the SP-100 reactor that uses this technology). It should be noted that the Seebeck effect is also used with metals, e.g., as thermocouples for temperature sensing.

For relatively low-power SPS (<1 kW of electrical power) the radiator penalty can be tolerated. For example, the RTG used to power today's crewless planetary spacecraft uses thermoelectric converters to provide about 285 W of electric power from heat released by radioactive isotopes. Galileo (the U.S. planetary exploration mission now in flight on its way to Jupiter) uses two such RTGs. RTGs utilizing thermoelectric converters are the standard power source for spacecraft that travel beyond Mars in the solar system. A cutaway drawing of an RTG is shown in Fig. 5. This RTG is a slightly modernized version of those that powered the successful Voyager spacecraft during its decade-plus tour of the solar system. RTGs were used on Ulysses and are planned for use on the CRAF Cassini spacecraft.

The focus of most U.S. space missions has been on applications that require typically less than about 1 kW. As a result, the energy sources have typically been RTGs and solar-

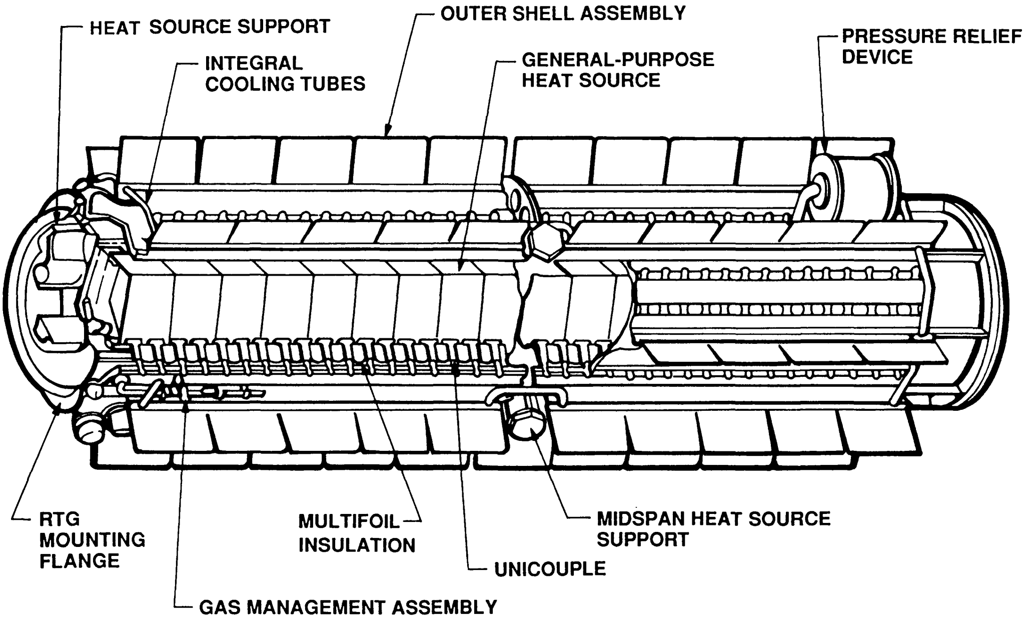

FIG. 5. ~250 We Radioisotope Thermoelectric Generator (RTG).

cell arrays. However, for more ambitious missions such as establishing human habitats on the moon and Mars, the power requirements will increase dramatically. In this forward-looking context, the SP-100 Program seeks to develop and demonstrate the technology for a nominal 100-kW reactor that can be easily scaled to higher power levels, using either static or dynamic conversion, depending on their state of readiness. A spacecraft powered by an SP-100 would have the form shown in Fig. 4, consisting of two major elements separated by a deployable boom structure. The forward main body, or power-generation unit, contains the reactor, shielding, the auxiliary cooling loop, static thermoelectric converters, radiators, and other equipment. The large radiator consists of 12 panels that fold forward and overlap when stowed for launch. When deployed, they form the "shuttlecock" configuration shown in Fig. 4.

Several new technologies for static conversion of heat to electricity that may be viable for space application are now under development in laboratories. One of the most attractive approaches is the alkali-metal thermoelectric converter (AMTEC) that uses liquid sodium as a working fluid and porous β-alumina to convert sodium atoms to ions, thus directly producing electricity from a pumped sodium circulation system. The pumping of sodium is done with an electromagnetic pump, which avoids dynamic machinery, a major source of vibration and unreliability in dynamic conversion systems.

2.4 Energy Storage

Rechargeable batteries contain cells that can be discharged and recharged (cycled) hundreds or thousands of times. They are used primarily to store energy when an Earth-orbiting spacecraft passes in the Earth's shadow. The most common battery for space applications uses nickel-cadmium (Ni-Cd) electrochemistry. Because of its favorable recharge characteristics and high cycle life, it has been used in the majority of Earth orbiting spacecraft. The cycle life is defined as the number of charge-discharge cycles that a battery will tolerate before failure. The cycle life, in turn, depends on the depth of discharge (DOD), which is the percentage of rated capacity removed from a cell during discharge. Ni-Cd batteries undergo a sharp drop in cycle life at high depths of discharge, so the DOD must be constrained in order to lengthen mission life. However, with this technique, the Solar Max spacecraft (orbiting the earth every 90 min) achieved eight years (~40 000 cycles) with three Ni-Cd batteries. Batteries are also characterized by their specific energy (energy stored per unit mass) and energy density (energy stored per unit volume). Table 3 displays these parameters for a selection of available batteries and a few batteries under development. (See also ENERGY STORAGE.)

2.5 Management and Distribution

The integration and interfacing of the energy source with a SPS to operate various spacecraft loads are accomplished with a power management and distribution system (PMAD). The PMAD

1. connects the energy source to the power grid or bus,
2. manages and regulates the bus current and voltage,
3. switches user loads on and off line,
4. monitors the status of the SPS, and
5. detects and manages faults in the system.

Almost all SPS employ direct current (dc) at around 28 to 30 V. A generalized PMAD architecture is given in Fig. 6. This example employs a photovoltaic solar array and a RTG as the power sources. The power control section of the SPS includes a microprocessor (computer) to direct the power. It does this by commanding various switches and components in accordance with its internal fault-detection and protection algorithms and instructions received from the ground.

Redundant batteries are included to provide power during short periods when the spacecraft requirements exceed the available combined RTG and solar-array power. When requirements are below the available power, a shunt-regulator unit regulates the bus by shunting the excess power to a radiator.

A "control" voltage (CV), in proportion to the variation of the 30-V bus, is developed by the shunt regulator and is used to control the switching of the solar array and the bidirectional converter (BDC). The latter handles charging and discharging of the batteries in response to the CV by providing appropriate voltage levels and charge rates. When the RTG and solar-array power is insufficient, the BDC provides supplemental battery power. When excess power is available, the BDC ensures that the batteries are charged.

The spacecraft engineering and science loads are connected to the power bus by the power distribution assembly of switches (relays). These switches must be designed to handle faults and protect the load.

3. SPACECRAFT PROPULSION

3.1 Introduction

The propulsion system provides thrust that is used

1. to accelerate or decelerate the spacecraft,
2. to counter the effects of atmospheric drag and other perturbations, or
3. to change or control the attitude of the spacecraft.

There are many different types of propulsion systems, and the selection of a propulsion system for a particular application depends on a number of considerations. Launch- or lander-vehicle propulsion systems must provide high thrust to escape or counter the pull

of gravity. Thrust is less important for other applications, and for these spacecraft the choice of propulsion system is driven by other considerations. High-energy missions such as unmanned outer-planet orbiter missions or fast manned missions to Mars must have propulsion systems that provide very high performance. For some missions, science objectives drive the choice of propulsion system. Sensitive optical surfaces, cryocooled sensors, and low-temperature thermal radiators are vulnerable to contamination produced by the propulsion system. Spacecraft using such devices require propulsion systems that do not exhaust condensable species that can accumulate on these sensitive surfaces. In some cases, a propulsion option is eliminated because a spacecraft instrument is designed to detect the very same chemical species that are present in the exhaust of the propulsion system.

All propulsion systems consist of

1. a source of energy,
2. a supply of propellant, and
3. a device for accelerating the propellant to high exhaust velocity.

In the chemical rocket, the propellant is both the source of energy and the expellant; in the electric propulsion system, nuclear rocket, or laser propulsion system the energy source is independent of the propellant. It is not even necessary that the source of energy be on board the spacecraft; it may be the sun, or a remote laser or microwave transmitter. Most rockets use a thermodynamic expansion process to accelerate the propellant to high velocities, but electric propulsion systems employ electrostatic or electromagnetic fields for this purpose. All propulsion systems must provide for the storage and transfer of the propellant to the rocket engine. For solid-propellant rockets, this is conceptually straightforward. Liquid-propulsion systems can be as simple as a system that stores a single propellant at room temperature and transfers this propellant to the engine by fluid pressure, or as complex as a system that applies sophisticated thermal control technology to store cryogenic propellants and turbine-driven pumps to transfer the propellant to the engine.

The preceding has been a general discussion of rocket propulsion. After a brief discussion of the basic physics of rocket propulsion, the characteristics of several representative propulsion systems will be addressed.

3.2 Physics of Rocket Propulsion

The propulsion system produces thrust (F) by expelling mass, i.e., propellant, at rate $\dot{m}$, at high velocity (v):

$$F=\dot{m}v.$$

The power (P) required to produce thrust is given by

$$P=\tfrac{1}{2}Fv.$$

This power can be supplied by energy stored on board the spacecraft in a chemical or nuclear fuel or by a source remote from the spacecraft such as the sun or a laser or microwave transmitter.

The power required by a launch-vehicle propulsion system is truly formidable. For example, the combined power of the main engines and solid rocket motors of the Space Shuttle at liftoff is 43 GW, which is equal to the output of 43 terrestrial electrical power plants. The combined thrust of these engines and motors is 29 MN. At the other end of the spectrum are small attitude control thrusters that produce a few millinewtons of thrust.

An important figure of merit for propulsion systems is specific impulse, which is a measure of the efficiency with which the system uses the expelled mass. Specific impulse (I) is defined as

$$I=F\frac{dt}{dm}=\frac{F}{\dot{m}}$$

and is equivalent to the exhaust velocity (v). By convention, specific impulse is often quoted in units of lbf s/lbm or "seconds," which is equivalent to the exhaust velocity in m/s divided by the gravitational constant (g). The specific impulse provided by different propulsion systems varies greatly. For chemical or nuclear systems, the maximum theoretical performance is limited by the energy release per unit mass of the fuel. The specific impulse that is really available, however, is often much lower than this theoretical value because of temperature constraints imposed by combustion chamber or reactor materials. Values of specific impulse for different propulsion systems are presented in Table 4.

The change in spacecraft velocity (V) that results from expelling propellant mass (m) is

$$V=v\ln[M/(M-m)],$$

where M is the mass of the spacecraft before the propulsive event. The mass M includes the payload as well as the "dry" mass of the propulsion system (i.e., the engine, tanks, and the power supply for nonchemical systems). Maximum performance requires that the mass of the nonpayload hardware be kept to a minimum. This equation illustrates the significance of specific impulse; the amount of propellant that must be expended to achieve a given velocity is less for a high-specific-impulse (i.e., high exhaust velocity) propulsion system.

The spacecraft velocity increases as the fraction of the vehicle mass devoted to propellant increases. As shown in Fig. 7, the maximum velocity achievable by a single-stage vehicle is 3 to 4 times the exhaust velocity of the propulsion system. Velocity requirements for typical spacecraft missions are given in Table 5.

3.3 Cold-Gas Propulsion Systems

The cold-gas system is the simplest propulsion system. This system requires no chemical reaction, but relies on the expulsion of a high-pressure gas such as nitrogen or helium to produce thrust. The performance of this system is low and the mass of the high-pressure tanks is high. Such systems are used for spacecraft with minimum propulsion requirements and for applications that require a very clean expellant.

3.4 Chemical Propulsion Systems

Almost all operational rocket propulsion systems are either solid or liquid chemical systems. These systems use a wide variety of propellants, some of which were identified in Table 4. Modern solid rocket propellants consist of an oxidizer, typically a perchlorate, and a metal fuel in an organic binder. Solid

rockets are simple, reliable, and easily stored. The principal disadvantage of the solid rocket is poor controllability; once ignited these motors cannot be throttled or shut down easily. The Magellan spacecraft used the PAM D/Star 48D solid rocket motor shown in Fig. 8 to insert the spacecraft into orbit about Venus. This motor produces a thrust of 68.4 kN.

Liquid-propellant rockets use a wide range of propellants from single-component monopropellants such as hydrazine (N_2H_4) to two-component bipropellants such as nitrogen tetroxide–monomethylhydrazine (NTO-MMH) and cryogenic bipropellants such as oxygen–hydrogen. Liquid-propulsion systems can be relatively simple systems in which the propellant is fed to the engine by the propellant tank pressure or more complex systems in which propellant is fed to the combustion chamber by turbopumps that are driven by combustion gases or vaporized propellant.

Monopropellant propulsion systems are often used on planetary flyby spacecraft with modest propulsion requirements and for attitude control and precision trajectory adjustment requirements on spacecraft that use a solid rocket motor or a bipropellant system for large maneuvers. A monopropellant thruster uses a catalyst to decompose exothermically a propellant like hydrazine, and ex-

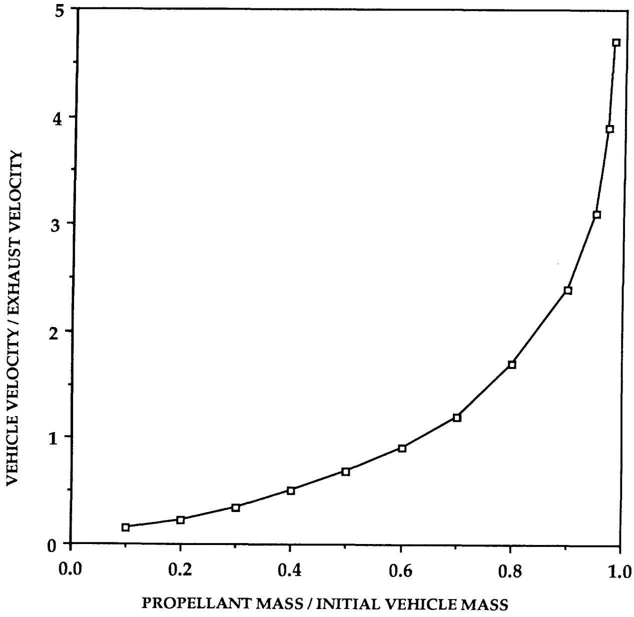

FIG. 7. Spacecraft velocity increase provided by a single-stage rocket.

hausts the high-temperature decomposition products through the thruster nozzle. A 0.9-N hydrazine thruster like that used on the Voyager spacecraft is shown in Fig. 9.

Propulsion requirements for planetary orbiter spacecraft are larger and more complex, and require a higher-performance propulsion system. For example, the Mars Observer propulsion system is composed of bipropellant and monopropellant subsystems. The bipropellant system is pressure regulated with four 490-N thrusters and four 22-N thrusters and contains 1360 kg of NTO-MMH propellant. The monopropellant system consists of eight 4.45-N and four 0.9-N thrusters and contains 84 kg of N_2H_4 propellant. Both of these systems consist of propellant storage tanks, con-

trol valves, pressure transducers, filters, and other components.

The Space Shuttle Main Engine (SSME), shown in Fig. 10, is an example of a state-of-the-art high-performance liquid rocket booster engine. This oxygen–hydrogen engine produces 2.1 MN of thrust under vacuum conditions and can be throttled between 65% and 109% of rated power. The turbopumps of this engine are driven by high-temperature hydrogen supplied from the propellant tank and heated by the combustion chamber. The SSME is designed for repeated reuse, up to 55 flights, before requiring a major overhaul. The engine is controlled by a pair of computers that monitor its operation and respond to commands from the Shuttle guidance and navigation computers.

3.5 Electric Propulsion Systems

Electric propulsion systems rely on a source of energy other than that contained in the propellant to accelerate the propellant. Such systems can achieve very high performance, but require a solar or nuclear power supply to provide the required electrical energy. The mass of the power supply can be large, and its effect on the performance of these propulsion systems can be significant. Space-power technology is discussed in Sec. 3 of this article. Electric propulsion devices have been under development for many years and are finding increasing application in operational systems.

The hydrazine resistojet is a device that uses a resistive element to heat the hydrazine decomposition products and thereby to increase performance. The 0.2-N thruster, shown in Fig. 11, provides a specific impulse of approximately 300 lbf s/lbm, equivalent to bipropellant performance, at a power level of 500 W. This type of thruster is currently being flown on the INTELSAT, SATCOM, G-Star, and Spacenet communication satellites.

The arcjet uses an electrical arc rather than a resistive element to heat a propellant that is then expanded through a conventional nozzle. These devices have been successfully operated in the laboratory at power levels

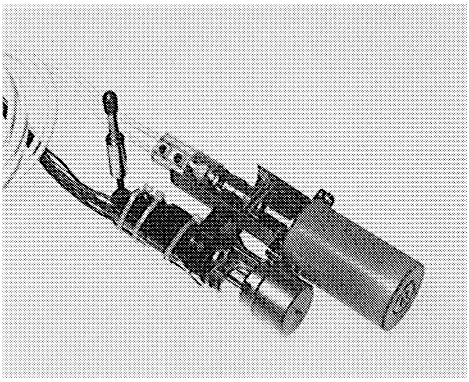

FIG. 11. 0.2-N hydrazine resistojet. (Photograph courtesy of Rocket Research Company.)

from 1 to 200 kW with a variety of propellants. The Telstar 4 communications satellite, to be launched in the late 1990s, will use two 1.8-kW arcjets for station keeping.

The magnetoplasma dynamic (MPD) thruster and the pulsed plasma thruster (PPT) accelerate a highly ionized propellant with an electromagnetic force. Micronewton-class PPTs are operational on the U.S. Navy Nova satellites, and MPD thrusters are operational in the laboratory at steady-state power levels of up to 500 kW. High-power MPD thrusters may be an attractive option for multimegawatt electric propulsion vehicles of the future.

The ion thruster employs an electrostatic field to accelerate propellant ions to high exhaust velocities. Because of its potential for providing very high exhaust velocity and high efficiency, it is well suited to meet the primary propulsion requirements of high-energy planetary missions. Mercury-ion thrusters were flown as experiments on U.S. spacecraft during the 1960s and 1970s. More recently, 5-cm ion thrusters were flown on ETS-III, a Japanese satellite. Ongoing U.S. research is directed toward improving thruster life and efficiency with inert-gas propellants such as xenon. A 25-cm-diam xenon thruster is shown in Fig. 12. This engine produces a thrust of 0.06 N at a specific impulse of 2900 lbf s/lbm and requires 1.3 kW of electrical power.

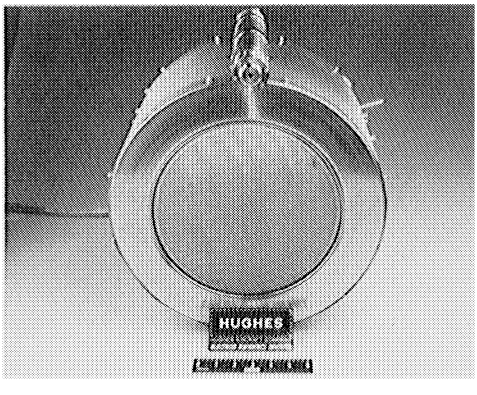

FIG. 12. 0.06-N xenon ion thruster. (Photograph courtesy of Hughes Corporation.)

3.6 Advanced Propulsion Systems

The energy released by nuclear fission is more than 100 times greater than that released by the most energetic chemical reaction. As previously stated, nuclear fission is a very mass-efficient source of energy for generating the electrical power required by electric propulsion systems. Nuclear energy may also be used to directly heat the propellant, which is then accelerated by a thermodynamic expansion process. In the solid-core nuclear rocket, heat is generated in nuclear fuel assemblies and transferred to a propellant such as hydrogen, which flows through the core. The maximum specific impulse, 800–900 lbf s/lbm, is limited by the maximum operating temperature of the fuel assembly materials. This performance is a factor of 2 greater than the best chemical systems. Solid-core nuclear rockets were developed and tested in the U.S. during the 1960s at thrust levels up to 0.9 MN, but this work stopped short of full-scale development when the U.S. plans for Mars exploration were put on hold. Even higher performance is theoretically possible with the gas-core reactor that bypasses the limitations of the solid-core rocket by using a fissioning plasma to heat the propellant. Fusion and antimatter-annihilation processes are even more energetic sources of power that may someday be harnessed for space propulsion.

4. ATTITUDE CONTROL

4.1 Introduction

Attitude control involves the control of the orientation of a spacecraft with respect to an inertial reference coordinate frame or with respect to a local relative coordinate frame, such as that defined by the direction to a nearby body. This includes the orientation of the spacecraft body structure, articulated appendages, and sensors and instruments attached to the various parts of the spacecraft. Maneuvers, turns, and articulations required to achieve desired orientations are part of attitude control.

The purposes of attitude control are varied. For example, orientation with respect to the sun may be for thermal control of the spacecraft, for power generation with solar-cell arrays, or because the sun is an easily detected attitude-reference body in our solar system. High-gain antennas need to be oriented to establish and optimize communication between the spacecraft and the Earth. Scientific instruments in the payload of the spacecraft require orientation toward the phenomena to be observed. Articulated masses on the spacecraft are used to control the mass properties (center of gravity and moments of inertia), particularly on spinning spacecraft. Propulsion system thrusters must be oriented inertially in order to perform trajectory-correction maneuvers.

Attitude-control systems are concerned with stabilization of the motions of the spacecraft, and with pointing and orienting the spacecraft or parts of the spacecraft. Because of the various forces that act on a spacecraft (gravity gradients, torques due to propulsion systems and mechanical mechanisms, solar pressure, micrometeorite impact, etc.), a spacecraft that is not stabilized will tend to acquire rotational motion and will tumble and move in a chaotic fashion if it is not explicitly stabilized by some technique. There are two general types of stabilization: three-axis and spin stabilization. Spin stabilization works on the same principle as a child's top. If a rigid body is spun to moderate rotational speed about its axis of maximum moment of inertia, the angular momentum vector and the spin axis will stay fixed in inertial space, stabilizing two rotational degrees of freedom. The third degree of freedom, about the spin axis, may have only rate control and not position control. Now, if any modest torques are applied to the spinning body, the net resultant angular momentum vector will be a vector sum of the large initial angular momentum plus the small perturbation, and will lie very close to the original vector. Thus the spacecraft becomes stabilized by virtue of its high initial angular momentum. The three-axis-stabilized spacecraft controls the position and rate in all three rotational degrees of freedom, and the usual state is holding a fixed orientation with respect to its reference coordinate frame. If perturbations tend to move it away from its preset orientation, forces are automatically applied by the spacecraft to compensate and keep it oriented as desired. Turns from one orientation to another are controlled but are considered a temporary or transient state. A hybrid of the two general types is the dual-spin spacecraft, which is predominantly spin stabilized but has a part that has a rotational degree of freedom about the spin axis. This part can be despun to allow position control about this third degree of freedom so that it has three-axis-like stabilization and allows inertially fixed pointing for instruments and sensors on the despun part. Any of these types can carry articulated appendages.

An attitude-control system has three basic components:

1. a complement of sensors to determine or measure the attitude in three degrees of freedom;
2. information processing to compare the sensor data to the commanded or desired attitude and to transform the error into the action necessary to correct the attitude; and
3. an actuation system to apply the required corrective torques to the spacecraft.

The control of articulated parts requires the equivalent three components but with probably fewer degrees of freedom.

4.2 Attitude Sensing

To measure the attitude of a spacecraft it is necessary to measure the direction, in a spacecraft fixed-coordinate frame, of an external body whose direction is known in an external reference coordinate frame. Each measured direction provides two degrees of freedom of attitude knowledge. Full attitude knowledge involves three degrees of freedom and thus requires observing two different directions, though some particular tasks, e.g., high-gain antenna pointing, require only two components of attitude knowledge.

Some of the external entities that can be used as references include light from stars, the sun or solar-system bodies, radio-frequency beacons, or directional fields like the Earth's magnetic field. Sun sensors are most commonly used because of the sun's highly visible presence in our solar system and its high luminosity. Even if totally disoriented, a spacecraft can rely on the sun as an unmistakable beacon. Its great brightness and relatively compact size (0.5° at Earth) provide an excellent attitude reference. A sensor staring at the sun, or scanning over its disk periodically from a spinning spacecraft, can provide two of the three axes of information needed to fully determine inertial orientation. A solar reference is also the first external reference sought in recovering from a serious spacecraft anomaly. After the solar reference is acquired, the spacecraft can position itself in a known orientation, where the solar power and thermal input are maintained at acceptable levels. A two-axis sun sensor usually consists of two single-axis channels providing measures of the sun direction offset from each of two orthogonal null planes. Both photovoltaic and photoconductive detectors have been used for sun sensors.

While sun sensors usually play a key role in establishing an initial two-axis attitude reference for both nominal operations and recovery from anomalies, star trackers often play an equally important role by either filling in the missing axis of information (as was done with the Mariner and Voyager Canopus tracker), or providing more accurate three-axis references once a safe orientation is established. The latter approach is used for the Galileo spacecraft in which the sun sensor keeps the spin axis pointed roughly at the sun (or the Earth for some phases of the mission), while the star scanner provides accurate three-axis data into the attitude-estimation process. Sensing the direction to distant objects like stars or bodies in our solar system requires the signal enhancement of a telescope and a sensitive detector. A single-axis star tracker, measuring the offset from a null plane, is sufficient to provide the third knowledge component to augment a two-axis sun sensor. A star tracker with a two-degree-of-freedom focal plane detector, e.g., a vidicon or charge-coupled device (CCD), can provide a complete star-direction measurement of one or more stars. Two or more stars in the field of view can thus provide full three-axis attitude knowledge. However, to be usable, the stars observed must be positively identified, since observation of an unknown star provides no information.

For a spinning spacecraft, a star scanner with two nonparallel (V) slit fields of view, approximately orthogonal to the spin axis, provides a series of timed events when the slit fields of view pass stars. The times of the pulse pair arising from the two slits crossing an identified star provides two pieces of information, and observation of two stars is sufficient to determine the spacecraft attitude. (A similar V-slit sun sensor provides only the angle between the spin axis and the sun direction, since there is only one sun.)

For an orbiting spacecraft maintaining an axis along the local vertical, a horizon scanner, measuring the angles from the spacecraft axis to the horizon in several (at least two) different planes, provides two axes of information on the offset of the spacecraft axis from the local vertical. By continuously or periodically measuring the vector to a planet's limb, this device provides horizon information that can be used to maintain a desired spacecraft orientation, or to point instruments, antennas, etc. For highest accuracy, corrections must be made for orbit altitude and inclination, planet oblateness, and sensed horizon altitude, including diurnal and seasonal variations. The sensed horizon altitude depends on the part of the electromagnetic spectrum used, usually the infrared.

While optical trackers are required for providing known references to celestial or "absolute" coordinates, inertial sensors, which measure vehicle motion without reference to any external body, are also required when the spacecraft attitude is changing. *Accelerometers* measure changes in linear motion that generally cannot be measured by optical means. *Gyroscopes*, measuring angular motion, are often required to supplement optical sensors to

1. provide high-bandwidth data when needed, particularly during critical mission phases such as propulsive maneuvers;
2. operate when normal optical references are unavailable, such as during eclipse;
3. instantly take over control should optical references be lost or some other anomaly occur.

Measurement of the deviation of the attitude from that determined by optical sensors is accomplished with gyroscopes, which measure the inertial attitude rate of the spacecraft and integrate this to compute the current attitude. Occasional optical measurements are used to correct for accumulated gyroscope and integration errors.

The position of movable joints, whether rotational or translational, must be measured if they are to be controlled. A number of sensors, such as potentiometers, resolvers, or digital encoders, are available. It may also be desirable to measure the joint velocity and the force (or torque) being applied. Actual selection depends on requirements such as accuracy, power consumption, mass, volume, and analog versus digital compatibility with the system design.

4.3 Attitude Determination

The attitude sensors described in the previous section provide measurements of quantities that are dependent on attitude, but not the attitude itself. The processing of these sensor measurements to obtain the attitude is called *attitude determination.*

The simple spacecraft, with no on-board attitude determination, is controlled to keep the sensor outputs at null or a specified biased value. In this case the attitude is known to the ground control but the spacecraft only knows about deviations from this unknown target attitude. The equivalent, using gyroscopes for turns, is to try to null each gyroscope axis error signal while the gyroscopes are biased by rate commands. This ignores the noncommutativity of the angular variations.

With on-board processing capability now available, on-board, autonomous attitude determination can be done. The sensor measurements, the knowledge of the directions to the objects seen, and the geometric relationships between attitude and measurements are combined to derive an estimate of the spacecraft attitude. This is only an estimate of the attitude since it is based on noisy data and can be improved with the processing of more measurements. The complexity of the estimator can range from simple, fixed-gain suboptimal to a full multistate Kalman filter.

If the measurements are not simultaneous but distributed in time, an attitude state model is required to propagate between measurements and must be updated with each new measurement.

Autonomous attitude determination has many advantages, from enhancing spacecraft fault tolerance to reducing the workload in ground control by being able to respond to high-level commands, working out the details on board.

4.4 Actuators

To effect a change in the spacecraft attitude it is necessary to apply a torque. This torque may be generated by mass expulsion, reaction against an external field, or momentum transfer to an internal component of the spacecraft.

Mass expulsion through small thrusters oriented such that the line of thrust does not pass through the spacecraft center of mass will provide a torque. Thruster locations and orientations are usually chosen so that the torques from various thrusters are aligned with the spacecraft principal axes. To provide torque without a translation force, they are usually mounted in opposing pairs (couples) to cancel the forces and combine the torques. To conserve the mass available, attitude maintenance using thrusters will have a very low duty cycle, with occasional small pulses to reverse the spacecraft angular rate as it is allowed to drift between specified limits (dead band). Higher duty cycles are used when a larger torque impulse is needed as for control during the firing of a larger thruster. For such a larger thruster, two axes of control torque can be provided by a two-degree-of-freedom gimballed nozzle that moves the line of thrust with respect to the spacecraft center of mass. A low duty cycle is not suitable for high-precision attitude control. For a spinning spacecraft, torque normal to the spin axis changes the direction of the angular momentum vector, and thus the spin axis, in inertial coordinates.

Solar-radiation pressure on the spacecraft causes a torque that can be controlled by changing the configuration, e.g., with movable vanes, to move the center of pressure. A configuration with the center of pressure behind the center of mass provides passive, stable control of two spacecraft axes. The third-axis torque can be controlled by changing the "windmill" component of the configuration but does not provide passive, stable control.

An orbiting spacecraft with its axis of least moment of inertia vertical is inherently stable due to torques from the gravity field gradient.

A spacecraft in a magnetic field can create torque by activating magnetic dipoles on board. However, only two axes of torque are possible at any one time with no torque about the field direction, so it is not suitable for continuous three-axis control, but can be used for "momentum dumping", described later.

A spacecraft can be made to turn about an axis by torquing against an internal reaction wheel that rotates about that axis. Momentum is transferred between the wheel and the spacecraft body. To stop, the momentum is transferred in the other direction. Control moment gyroscopes are also used for this momentum transfer. This type of actuation is well suited for high-precision, high-bandwidth control. If an external torque acts on a spacecraft that is to be held still, the momentum accumulates in the wheel and occasionally must be "dumped" by applying an external torque.

Actuators (torquers) for rotary joints are usually electric motors. They may be direct drive with the rotor and stator attached to opposite sides of the joint, or they may be geared to increase torque and positioning precision. Bearings must be designed to have low friction and still carry the appropriate loads. A common translational actuator is a ball screw that converts rotary motion of a screw to translation of a nut with ball-bearings. When high precision is required within limited ranges of movement, piezoelectric or magnetostrictive devices can be used.

4.5 Controller

We now have the attitude from the sensors and attitude determination to compute the error with respect to the desired attitude, as well as a means to torque the spacecraft, but we must still close the control loop. The control law is the computation of the torque command required to null the error, in a stable manner, given the attitude error. If attitude rate error is not available, it may need to be derived in order to provide stable control.

For low-duty-cycle systems using thrusters, the analysis and design of the control law is most easily done using piecewise-linear phase-plane techniques. For continuous control, the classical control theory of Bode and Nyquist or root locus is needed for design of a stable controller. Discrete digital control systems have sampling, quantization, and delays to consider as destabilizing factors and require other techniques such as *Z* transforms in lieu of the continuous Laplace transform.

Spacecraft evolution has made its own contribution to the difficulty of control law design. A small compact spacecraft is easily modeled as a rigid body. Flexible appendages, e.g., solar panels and science booms, complicate the model and the control law required to stabilize the spacecraft without unduly exciting appendage motion. As the spacecraft gets larger, it may no longer be considered a rigid body, but it has structural resonance modes of its own that must not be excited. On a large spacecraft the attitude sensors and the actuators may be separated by flexible structure (noncollocated). All these factors contribute to the increasingly difficult task of designing stable control laws for increasingly more complex spacecraft.

5. SENSORS FOR SPACECRAFT CONTROL

5.1 Introduction

An extensive range of sensors is needed for controlling all but the most simple spacecraft. This is true whether the vehicle is in orbit about the Earth or some other planet, or far from all other objects in interplanetary space. These sensors support a number of critical spacecraft functions:

1. control of attitude (and spin) with respect to inertial coordinates,
2. control of orbital motion (propulsive maneuvers), and
3. control of instrument pointing.

Although there may be much overlap in the sensors supporting these functions (e.g., a gyroscope can be important to all three) it is often helpful to keep these functional differences clearly in mind. Many of these same systems will play an important role as crewless exploration moves to surface vehicles for exploration of other planets and satellites. Other unique sensors, such as a three-dimensional mapper to aide in robot navigation, are still in early phases of development.

5.2 Optical Sensors

Optical tracking instruments, sensitive to visible or infrared wavelengths, are used for all but the most rudimentary spacecraft (e.g., simple spinners). Several types of instruments usually work together with inertial sensors to fully control the spacecraft.

5.2.1 Sun Sensors. Relatively simple sun-sensor configurations can provide full sky coverage for acquisition, or higher accuracy tracking over a more limited field. Figure 13 shows the layout and typical response curve for the fine sun sensor that was used on Mariner and Viking missions to Mars. More recent off-the-shelf designs incorporating digital signal processing electronics typically achieve 1.0 arcmin accuracy over a 64×64 deg^2 field, and 15 arcmin over 4π sr in scanning (spinning vehicle) applications.

One challenge for outer-planet missions has been the wide range of solar illumination. The intensity of sunlight at Saturn is roughly $\frac{1}{100}$ of that at Earth, dropping to $\frac{1}{900}$ at Neptune and Pluto. Most sensors designed for operation at 1 AU will not operate satisfactorily at these low intensity levels. As a result, a special high-dynamic-range detector was needed for Voyager. Substitution of linear CCDs for the monolithic detectors previously used is an approach to solving this problem. In addition, by precisely measuring the position of the solar limb this approach leads to significantly improved measurement accuracy.

5.2.2 Star Trackers. Early star-tracker designs (through Galileo) employed image dissectors or photomultiplier tubes for starlight detection. Both devices use electron multipliers for low-noise amplification, and in many cases achieve quantum-limited performance. For spinning spacecraft, a simple V-slit scanner using a photomultiplier to detect star pulses can provide excellent results. Each star crossing produces two pulses, their arrival time giving clock information (around the spin axis) and their separation providing cone data (angle from the spin axis). Complete (three-axis) knowledge of the spacecraft orientation is derived by tracking several known stars on each rotation.

Image dissectors develop two-axis data by electronically scanning a small sensitive aperture over the field of view. This enables star coordinates to be measured for an inertially fixed spacecraft. Image dissector tubes were used throughout the 1970s and 1980s in both "fixed-head" and "focal-plane" star trackers. A fixed-head tracker includes all elements (optics, stray-light baffle, detector, and electronics) needed to provide a stand-alone capability ready to mount at any appropriate orientation on the spacecraft. In contrast, a focal-plane tracker examines a portion of the image formed by an external optical system, tracking stars or other objects in that field. The Hubble Space Telescope's fine guidance sensor is an example of a focal-plane tracker, part of which uses image dissectors to develop "coarse" error signals. A dissector was also used for the NASA standard fixed-head tracker, which generates two-axis measurements of a star position by rapidly scanning the dissector's sensitive aperture over the star image. Multiple stars could also be tracked by time-sharing of the aperture over several images.

While the image dissector has many strengths for star tracking, it also suffers from a number of drawbacks that substantially limit its usefulness. First, by sensing only one point at any instant, the tracker is very susceptible to image motion. This is particularly true when attempting to track more than one star in the field. Another serious limitation to

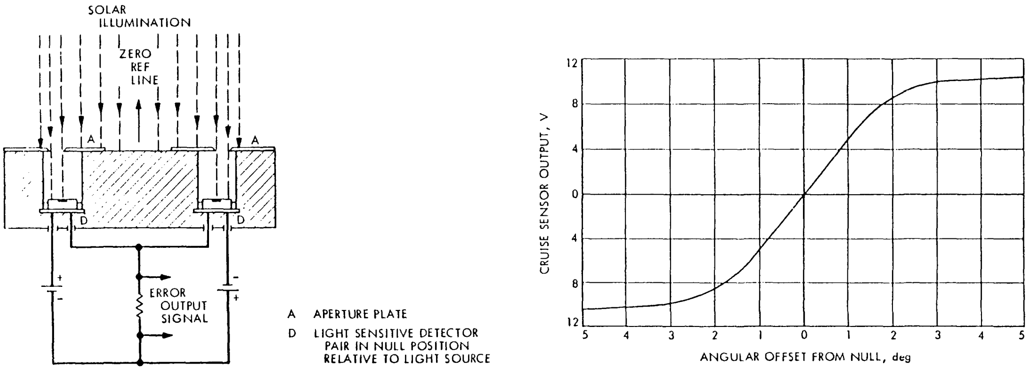

FIG. 13. Fine sun sensor used on Mariner and Viking missions to Mars.

accuracy is the positional distortion and nonlinearity associated with the electromagnetic deflection of the sensing aperture. Although these effects can be calibrated to some extent, significant errors remain ($>1/10^3$ of the field), which can be further exacerbated by variation in external magnetic and electrostatic fields.

These limitations have been removed to a remarkable degree by the advent of area-array CCDs [see CCDs (CHARGE-COUPLED DEVICES)] in the star-tracking arena. Instead of relying on variable electromagnetic deflection to derive positional information, the precise photolithography of the CCD provides a geometric reference frame accurate to substantially better than one part in 10^4 over the field. Much of this resolution is achieved by measuring the centroid of each star image to an accuracy much finer than the pitch of an individual pixel. Also, by integrating all image pixels simultaneously, a CCD can track much fainter stars and avoid the nonsimultaneity problem associated with image dissectors. Other advantages, such as insensitivity to magnetic fields, avoidance of high voltages, insensitivity to damage by overexposure, etc., have helped make CCD-based trackers the new *de facto* standard. Many of these advantages can be appreciated in comparing the specifications of a typical CCD tracker, flown on the Astro-1 shuttle-based observatory, to the earlier NASA standard (see Table 6). A schematic of the Astro-1 tracker is shown in Fig. 14.

5.2.3 Horizon Sensors. Horizon sensors, like sun and star trackers, can be divided into scanning and staring types. Staring sensors usually employ an array of detectors that locate the limb by radiance-balancing techniques. Many Earth satellites, at both low and geosynchronous altitudes, employ scanning horizon sensors, where the scanning motion is provided either by the spacecraft itself or by rotating mirrors, optical wedges, etc.

Infrared wavelengths are used to avoid significant day-night differences in the appearance of the limb, as well as to minimize the effects of clouds. For the Earth, bolometers operating in the 14–16-μm carbon dioxide band have proven most effective. At these wavelengths, the effective limb appears roughly 40 km above the surface, well above the weather in the troposphere. There are still season- and latitude-dependent errors, but these can be largely removed analytically. As one moves to other planets, detectors covering the mid- to long-wavelength infrared region are still required. The weather on Mars is substantially less dramatic than Earth's, but it can produce substantial albedo variations and horizon errors in optical wavelengths. Mars's atmosphere of mostly carbon dioxide dictates wavelengths similar to those used on the Earth.

5.2.4 Optical Target Trackers. The advent of the CCD has also provided the opportunity to track accurately targets that are much more complex than simple star fields. A capability to locate and track extended targets, limb points, or particular surface fea-

tures can all be derived from the information in a CCD image. By using two cameras, or a succession of frames with a single camera, three-dimensional maps can be generated for rover navigation, sample acquisition, or other functions required for robotic exploration of planet surfaces.

5.3 Inertial Sensors

As is the case with optical sensors, a new generation of inertial instruments is being developed that could be vital to the more challenging, extended life missions envisioned for the future.

5.3.1 Accelerometers. Typical spacecraft accelerometers provide single-axis information by measuring the force a small mass exerts on its surroundings, generally providing sensitivities in the micro-*g* range (10^{-5} m/s^2). Substantially more sensitive devices have been reported (10^{-8} m/s^2), for special "quiet" environments such as a "drag-free" spacecraft.

New-technology microaccelerometers have been recently demonstrated using a variety of micromachining techniques in silicon. A promising development uses the detection of a tunneling current to detect very minute motion of the proof mass (on the order of nanometers). Since these devices draw little power and can be made extremely small (see Fig. 15), their use in a wide variety of applications measuring vibration and rotations, as well as linear acceleration, can be envisioned.

5.3.2 Gyroscopes. *Spun Mass Gyroscopes.* To date, conventional floated and tuned rotor ball-bearing gyroscopes have been widely used in spacecraft applications due to their advanced state of development and adequate performance. Operating lifetimes of more than three years have been demonstrated, but wear-out mechanisms eventually lead to failure. Electrostatic suspension has been thoroughly investigated as one technique for limiting wear-out mechanisms and improving accuracy. However, high cost and difficulty in making them sufficiently rugged for the launch environment have kept this approach from being adopted.

A very successful conventional design, incorporating dual-axis gyroscopes in a redundant three-axis configuration, has been the NASA Standard Dry Rotor Inertial Reference Unit (DRIRU II). The characteristics of this instrument are listed in Table 7. It has been

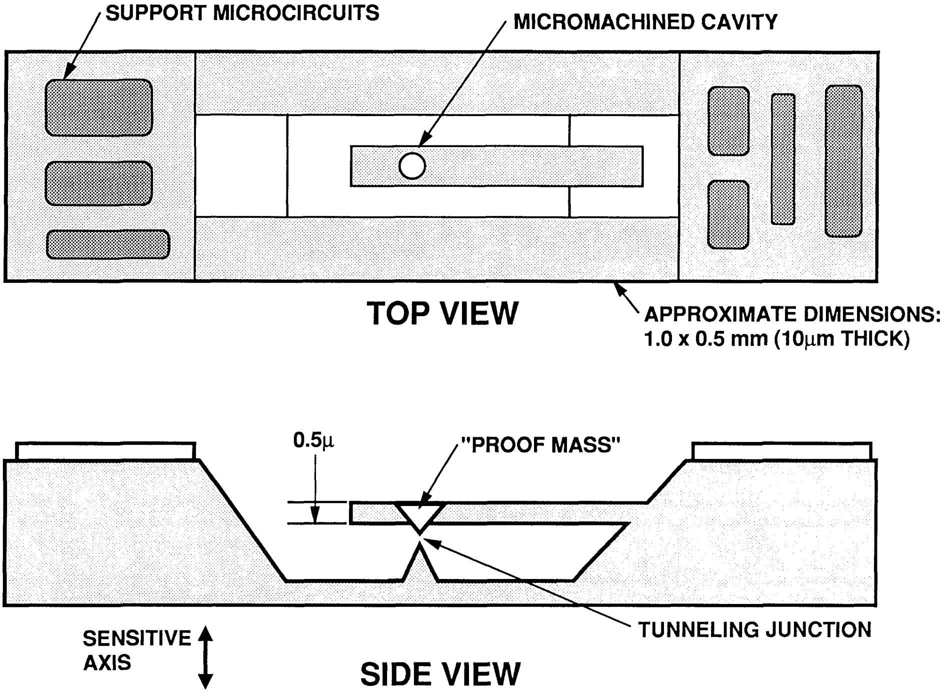

FIG. 15. Micromachined tunneling accelerometer.

incorporated into a number of NASA spacecraft including the Solar Maximum Mission, Hubble Space Telescope, and the Astro Ultraviolet Spacelab observatory.

Optical Gyroscopes. A substantial development effort has been undertaken in recent years to replace spun mass gyroscopes with optical devices. Although the main advantage for many spacecraft applications is expected to be the reduction in failure rate associated with the elimination of mechanical wear-out, other advantages, such as lower mass or power consumption, may also be substantial.

Both *laser gyroscopes* and *fiber-optic gyroscopes* are based on the principle discovered by G. H. Sagnac in 1913. The Sagnac effect states that, when two counterrotating beams of light are subjected to a rotation in their planes, a phase shift is generated between the two beams that is proportional to the rotation rate. By measuring this phase shift, it is possible to infer the rotation rate, usually over a range much larger than can be achieved with mechanical devices.

The fiber-optic approach (Fig. 16) is generally believed to offer the most promise for long-life applications. Laser gyroscopes require maintenance of a helium-neon gas laser operating within a precisely machined quartz block. In contrast, fiber-optic gyroscopes can

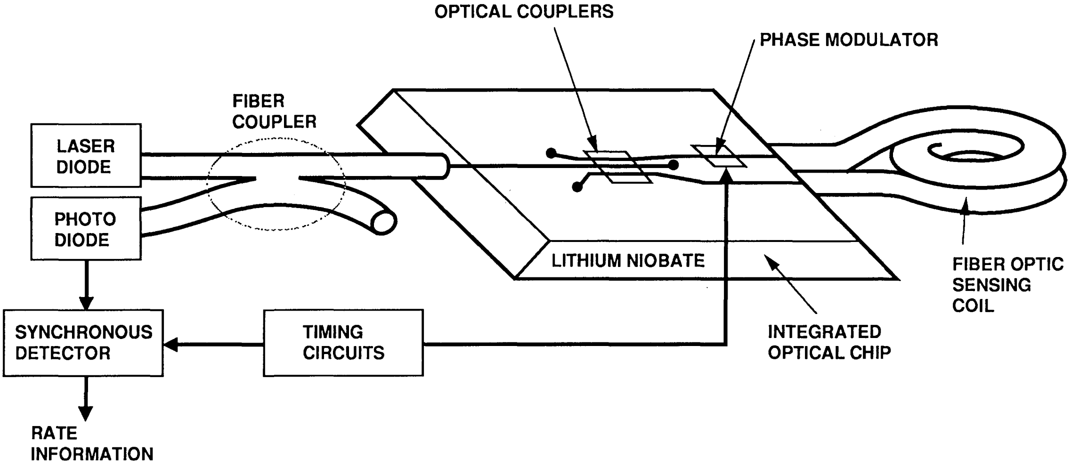

FIG. 16. Fiber-optic gyroscope.

use solid-state lasers with a length of fiber (meters to kilometers) commensurate with the accuracy needed. The use of redundant lasers for each gyroscope axis can be made to increase lifetime potential.

At present, many development challenges, such as the ability to manufacture reliable electro-optical switching and modulation chips, and the temperature sensitivity of the optical fiber, are being worked on, along with other problems. Progress in these and other developments is pointing the way to the realization of a new generation of completely solid-state control system combining CCD star and sun sensors with fiber-optic gyroscopes and micromachined accelerometers.

6. NAVIGATION AND GUIDANCE

6.1 Introduction

Navigation of an aerospace vehicle has traditionally been defined as the process of determining the current position and the predicted path of the vehicle and correcting that path so that it stays within acceptable limits of some desired trajectory. The latter portion of the navigation function is referred to as guidance. (Sometimes, though, navigation and guidance are defined as two distinct functions, with navigation comprising only flight-path determination.)

Navigation of a space vehicle is a complex process involving the collection of data containing information about the position and velocity of the vehicle (and other pertinent quantities as well), followed by the processing of these data to yield estimates of the vehicle's position and velocity as functions of time. Further computation is then needed to plan corrections for the trajectory dispersions away from the desired flight path that inevitably occur. The computational process requires accurate modeling of the motions of the vehicle and various planets and natural satellites and accurate modeling of the observational data. The following sections describe the dynamic modeling of a spacecraft's orbital motion, the various observational data that may be available for navigational purposes, and the processing of these data to estimate the spacecraft's position and velocity and to compute trajectory-correction maneuvers.

6.2 Modeling of Spacecraft Orbital Motion

The acceleration experienced by an orbiting spacecraft can be attributed to a number of effects. The dominant effect is usually gravitational, with one celestial body at a time typically exerting the dominant gravitational influence. The orbital motion of a spacecraft (or a natural body) subject to the influence of a single massive object with a spherically symmetric mass distribution can be described by simple geometric shapes such as ellipses and hyperbolas, as described several centuries ago by Kepler, Newton, and others. Most other forces, gravitational and nongravitational, are small in relative terms and perturb the orbit slightly from these simple geometric shapes. Accurate propagation of predicted spacecraft orbits generally requires numerical integration.

Additional gravitational effects that must be taken into account for the accurate description of spacecraft motion include the gravitational influence of nondominant bodies (such as the moon and the sun for an Earth-orbiting spacecraft), asymmetries in the gravitational field of the dominant body, and (in very high-precision applications) general relativistic effects. For example, the oblateness of the Earth, induced by its spinning motion, causes significant changes in the orbit of a low-altitude spacecraft over a period of time. This effect may be used to advantage to make the orbit plane of the spacecraft precess in synchronism with the Earth's orbital motion about the sun, so that the ground track of the spacecraft is always illuminated in the same way. The Earth and other terrestrial bodies in the solar system possess inhomogeneous mass distributions; hence they have complex gravitational fields, which are often described by spherical harmonic expansions. Coefficients in these expansions are often estimated as part of the navigation process. General relativity causes subtle differences in the motion of a spacecraft and in the propagation of radio signals relative to what would be expected on the basis of classical physics. Today's measurement systems are sufficiently sensitive to detect some of these small effects and consequently can be used to test predictions of general relativity.

From time to time, the rocket engines on board a spacecraft must be fired to modify the trajectory of the vehicle. In addition, the motion of a spacecraft is affected by mass expulsion that cannot be precisely modeled or predicted in advance. The attitude of a planetary spacecraft is typically maintained by firing small rocket engines or gas jets. Although these firings are intended to change the orientation of the vehicle, they also change its trajectory. In addition, gas leaks unrelated to commanded attitude-control maneuvers can cause deviations in the trajectory. All of these propulsive effects, whether intended or unintended, are often estimated as part of the navigation process.

Spacecraft in low orbits about atmosphere-bearing bodies are subject to aerodynamic drag perturbations. The resulting accelerations are relatively small except in launch and reentry applications and can be estimated as part of the navigation process.

Solar-radiation pressure exerts a small perturbing influence on orbiting spacecraft. The resulting acceleration can be modeled, to the extent that the absorptivity and reflectivity properties of the vehicle are known in advance, or can be estimated from navigational data.

6.3 Types of Navigational Data

The data that are collected and processed for navigating a spacecraft may be broadly classified as radiometric, optical, or inertial. The relative values of these classes of data and the specific forms taken on by each vary considerably from application to application. Missions to other planets in the solar system impose some of the most stringent navigational challenges yet encountered in space exploration. Consequently, representative navigational data types will be discussed first in the context of NASA's unmanned planetary program. Differences associated with Earth-orbiting missions will then be addressed.

Some of the measurements used to navigate planetary spacecraft are derived from the radio link between the spacecraft and the Earth. The Earth-based part of the telecommunications system is a network of large radio telescopes, or tracking stations, located geographically so that virtually any distant spacecraft is continuously in view. There are three principal tracking station sites, located in California, Spain, and Australia. Each site is equipped with several antennas that are 34 or 70 m in diameter. The tracking stations maintain a radio-communication link with the Space Flight Operations Facility at the Jet Propulsion Laboratory in Pasadena, California. The facility originates commands to the spacecraft and receives data from the spacecraft by way of the tracking stations.

The traditional radio-navigation measurements for planetary missions consist of two-way Doppler and range, acquired at S- and X-band frequencies by the Deep Space Network. The simplest form of Doppler measurement employs a downlink, or one-way mode, in which the frequency of the signal received by the tracking station is compared with the best estimate of the frequency of the signal that was sent by the spacecraft. Since the clocks on board the spacecraft and at the tracking station do not run at precisely the same rate (with the latter much more accurate than the former), the accuracy of one-way Doppler data is limited. Instead, a two-way coherent transmission mode is normally used, in which the tracking station continuously transmits and receives. The signal transmitted from the Earth is received by the spacecraft's radio system, which increases its frequency by some multiple (to avoid interference between the outgoing and incoming signals) and coherently transmits it back to the Earth (by means of a phase-locked loop). If the distance between the spacecraft and the tracking station is increasing (decreasing), the spacecraft radio system receives and subsequently retransmits a signal whose frequency is shifted to a slightly lower (higher) value by the Doppler effect. On the downlink trip from the spacecraft to the Earth, the frequency of the signal received by the tracking station is again modified by the Doppler effect. The difference between the frequency received by the tracking station (compensated for the deliberate downlink-uplink frequency multiplication in the on-board transponder) and the frequency transmitted at a time corresponding to one round-trip earlier is a measure of the rate of change in the distance between the spacecraft and the tracking station. (In practice, the frequency of the received signal is compared with the frequency of the signal currently being transmitted instead of the signal transmitted one round-trip time earlier. The error introduced by this approximation is negligible because the stability of the transmitting frequency, better than one part in 10^{13}, prevents any significant buildup of frequency error during a time interval of one round trip.) The Doppler shift can be measured in 1-min counts to an accuracy of about 0.1 mm/s.

The other conventional radio-navigation measurement, range, is obtained by determining the round-trip time of the radio signal. The current ranging accuracy is about 10 ns in round-trip time, which is equivalent to 1–2 m in one-way range.

In recent years the technique of very long-baseline interferometry (VLBI) has been developed for use as a navigation data source. VLBI measures the difference in signal reception times at two widely separated ground stations to an accuracy of several nanoseconds. When compared with the signal reception time difference from a background extragalactic radio source (or quasar), these measurements allow the spacecraft direction to be determined to an accuracy of 50 nrad with respect to the direction to the background quasars.

The discussion above has concentrated on the use of radio navigation in deep-space missions. Range and Doppler data, in various forms, are also used in navigating Earth-orbiting missions. The radio links can be one way or two way and can be from a spacecraft to a ground tracking station or from one vehicle to another. Interferometric data types are being considered for use in certain high-precision Earth-orbiting applications. Spacecraft in relatively low orbits can be tracked by ground-based radar.

In many planetary missions, optical measurements can be obtained from the imaging system on board the spacecraft. These instruments, although originally designed to meet the stringent high-resolution and dynamic-range specifications required for scientific imaging of the planets, have also proved to be excellent for optical navigation. Images of the target planets and their natural satellites against stellar backgrounds yield valuable navigational data on approach to these planets. Spacecraft angular position fixes to accuracies of 5 μrad relative to the target body can be obtained.

Optical observations are sometimes used to track Earth-orbiting spacecraft also. Telescopes on the Earth can be used to track satellite motions relative to background stars.

Inertial navigation sensors include gyroscopes and accelerometers. Of these, only accelerometers measure the translational motion of a vehicle. They detect all forces acting on a spacecraft that are not gravitational in nature. They are essential in launch and reentry applications, where aerodynamic forces are quite large. They are also useful for measuring (and sometimes controlling) vehicle thrusting. In most cases, they are not sufficiently accurate to measure the nongravitational forces experienced by a nonthrusting spacecraft far from a planetary atmosphere.

6.4 Computation of Spacecraft Orbits

For most spacecraft, navigational computations are performed on the Earth. In some applications, though, particularly where short reaction times or on-board autonomy may be required, the computations are performed on board. As in the previous section, the techniques used in NASA's planetary missions will be described. The computational procedures used in connection with Earth-orbiting spacecraft are generally similar.

Figure 17 illustrates the elements of measurement, communications, computation, and propulsion that comprise the overall navigation system that is employed for NASA's deep-space missions. The left side of the diagram shows a spacecraft acquiring optical images of a target body. Optical data are encoded at the spacecraft and telemetered to Earth. Radio data (Doppler, range, and VLBI) are extracted from the incoming radio signal at the tracking stations. Also shown on the left is the capability for spacecraft propulsion. The right side of the diagram depicts the ground processing system used to compute the spacecraft orbit and trajectory-correction parameters.

Several major functions must be performed as part of the orbit determination process. The first is the accurate numerical integration of the trajectory from assumed initial conditions, along with partial derivatives of the position and velocity components with respect to parameters on which their evolution depends. Next, simulated measurements are computed corresponding to each actual observation, based on the modeled trajectory. Partial derivatives of the measurements with respect to trajectory initial conditions, and parameters affecting the motion of the spacecraft and the observations, are computed. The estimates of the initial conditions and other parameters are then adjusted until the differences between the actual measurements and the expected measurements, based on the values assumed for the parameters, are minimized in some sense. The estimation algorithm may be a straightforward least-squares procedure, or it may be sequential in time, with stochastic accelerations of the spacecraft modeled as piecewise-constant functions. The estimation process can be performed iteratively until convergence is obtained. The final

product of the estimation process is a numerically integrated trajectory that best fits the observations.

The high accuracy required for deep-space navigation is achieved with

1. precise observational measurements and precise knowledge of the timing of the measurements,
2. numerically accurate computational algorithms, and
3. a precise modeling knowledge of all physical phenomena that affect the values of the observational measurements.

These phenomena include those that affect the values of the measurements directly and those that affect the values of the measurements through their influence on the motion of the spacecraft. Examples of these phenomena that require highly accurate knowledge include the locations of the tracking stations on the Earth, the Earth's rotational motion, the motions of the Earth, moon, planets, and their natural satellites through the solar system, the gravity-field structure of the Earth and other solar system bodies, and the effects of the transmission media on the radio signal. All of these phenomena are modeled in the orbit determination software.

6.5 Trajectory-Correction Maneuvers

The best-estimate trajectory, derived from navigational data, serves as the basis for computation of velocity-correction parameters. A stylized interplanetary flight path is depicted in Fig. 18, in which several propulsive maneuvers that may be required to navigate a typical deep-space mission are indicated. Launch injection errors are usually corrected in the first month of travel. Often, during the transit from Earth to the distant target, an orbit-plane adjustment is required to redirect the spacecraft flight path to intersect the path of the moving planetary target. As the spacecraft approaches its distant target, one or two maneuvers are required to guide the spacecraft to the desired encounter geometry. If the spacecraft is to orbit the encountered planet (or other celestial body), a large retromaneuver is required near the point of closest approach. Subsequent orbit maintenance is usually required throughout the useful lifetime of a planetary orbiter.

In all space missions, the timing of trajectory correction maneuvers is governed by the desire to control the trajectory as accurately as possible, while minimizing the expenditure of propellant. Precise determination of the orbit of the spacecraft is essential prior to the computation of each maneuver. The error in this determined orbit usually dominates the flight-path error after the maneuver.

GLOSSARY

Astronomical Unit (AU): The average distance of the Earth from the sun (1.5×10^8 km).

BDC: Bidirectional converter. A power converter that operates in two directions to control a spacecraft power bus automatically by shunting excess power (e.g., from a solar array) to a battery, or supplying power from the battery to the bus, to maintain bus voltage.

Bipropellants: A pair of substances that are reacted in a rocket with the release energy in the reaction products.

Bus: Spacecraft central module containing subsystem electronics; typically excludes the scientific payload.

Charge-Coupled Device (CCD): Linear or area array of photosensitive elements that transfers the image charge from element to element during readout.

Doppler Shift: Change in the frequency with which electromagnetic (or sound) waves from a given source reach an observer when the source and observer are in motion with respect to each other.

Image Dissector (ID): Photomultiplier tube incorporating an electrostatically scanned internal aperture that permits an image to be scanned one point at a time.

Monopropellant: A single substance that decomposes in a rocket with the release of energy in the decomposition products.

Photomultiplier: Vacuum tube incorporating a photosensitive cathode and electron-multiplying stage that can detect extremely low light levels (some detect individual photons).

RTG: Radioisotope thermoelectric generator, employing thermal-to-electric converters to produce electric power from heat released by radioactive isotopes.

Specific Impulse: The impulse produced by a rocket per mass of propellant expelled (a measure of propellant efficiency).

Vacuum Specific Impulse: Specific impulse for a rocket operating in a vacuum.

INTRODUCTION

The goal of astronomy is to understand the nature, origin, and evolution of the physical universe. Astronomy is a physical science, relying on physical measurements for its data and on physical theories for their interpretation. It is also a historical science, because, as in biology, questions of origin and evolution occupy central positions.

In modern astronomical research, theory and observation interact closely. Data are given meaning and coherence by the theories used to interpret them. Observational evidence guides the construction and revision of theory. Without theory, observation is blind; without observation, theory degenerates into story-telling.

An internally consistent theoretical story is likely to be true to the extent that it meets two criteria: it must be consistent with strongly confirmed physical and astronomical theories, and it must be consistent with relevant observational data. As observations provide increasingly precise and increasingly varied data, they progressively narrow the range of viable hypotheses. At the same time, these hypotheses become increasingly secure. Our knowledge of the astronomical universe may be likened to a ball whose core is made up of strongly corroborated theories and whose ever-expanding surface, the interface between knowledge and ignorance, is made up of weakly corroborated hypotheses and empirical generalizations. The hypotheses and empirical generalizations at the surface come and go, but a few of them survive to become part of the growing core.

This article is divided into three parts. The first part describes the various sources of astronomical data and discusses the way in which astronomers analyze these data to derive information about the distribution in space and the physical properties of astronomical systems and the intervening medium. The second part discusses in general terms how gravitational attraction shapes the astronomical universe. The third part discusses specific astronomical systems, with particular attention to the solar system and excluding galaxies and systems of galaxies, which are discussed in GALAXIES AND COSMOLOGY. Stars and stellar evolution are discussed in greater detail in ASTROPHYSICS.

Astronomy has undergone an information explosion during the past 40 years. The present article, however, stresses the most basic methods and ideas, and their evolution, rather than results.

1. ASTRONOMICAL DATA

1.1 Sources of Astronomical Data

Astronomical observation is largely a matter of collecting, measuring, and analyzing light incident on the Earth. Until the middle of the twentieth century, astronomers relied almost entirely on ground-based visual and photographic observations. Photography extends the wavelength range of detectable light beyond the range of the human visual system, but only slightly. Nowadays astronomers collect light over a range of wavelengths extending from less than a millionth of a micron (1 micron$=10^{-6}$ m) to more than a hundred meters; the accessible spectral range has been expanded from a single octave (a factor of 2 in wavelength or frequency) to well over 14 decades (powers of ten). Differences in the information obtained at different wavelengths are exemplified in Fig. 1. Gamma rays, x rays, ultraviolet light, visible light, infrared light, millimeter and microwave radiation, and radio radiation are collected and analyzed not only by ground-based instruments but also by instruments based on balloons, rockets, and satellites.

There are three other important carriers of astronomical data: meteorites, cosmic rays, and neutrinos.

Chemical analyses of meteorites yield estimates of the age of the solar system and provide clues to its origin.

Cosmic rays consist of highly energetic protons, heavier nuclei, and electrons. They contain information about the processes that accelerate charged particles in the Sun, in supernovae, in interstellar space, and (possibly) in external galaxies.

Neutrinos are emitted in the nuclear reactions that burn hydrogen to helium in the cores of the Sun and other stars. Because neutrinos interact so weakly with matter, nearly all of them escape into interstellar space; but for the same reason they are exceedingly difficult to detect. Experiments to detect neutrinos from the Sun have, however, been successful. The results of these experiments have not been in accord with theoretical expectations. Their interpretation is still controversial. Theories of stellar evolution predict that neutrinos are also copiously produced in supernova explosions. This prediction was confirmed by successful detections of neutrinos emitted by Supernova 1987a (see, e.g., Abell *et al.*, 1991).

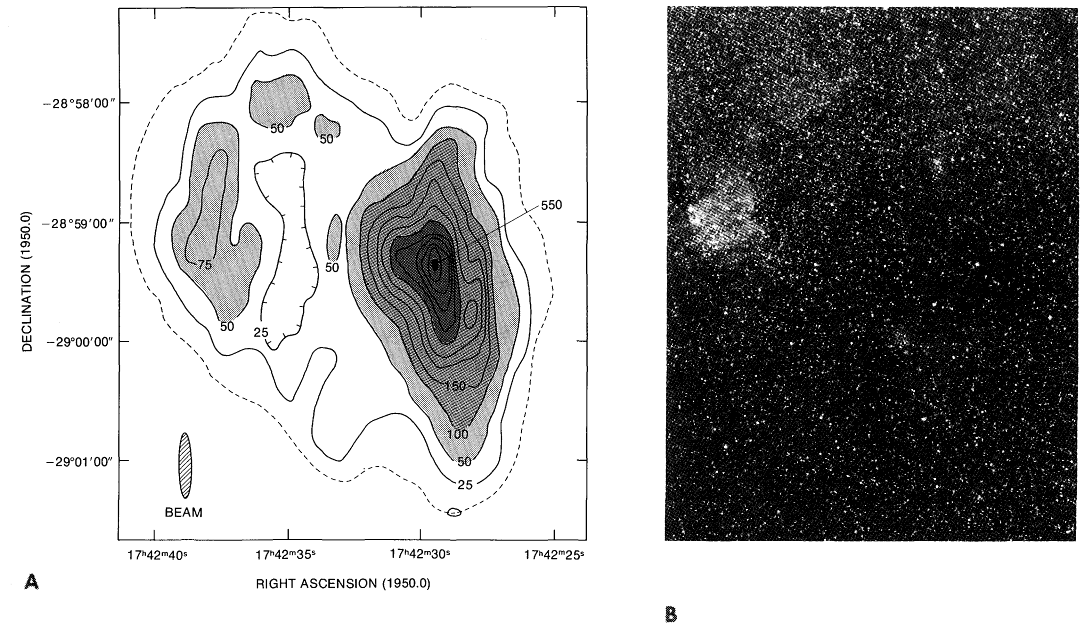
Gravitational radiation is another potential source of astronomical data. Einstein's theory of gravitation (general relativity) predicts that certain objects, including binary stars and asymmetrically imploding and exploding objects, emit gravitation waves. These waves interact very weakly with matter. Since the early 1960s, progressively more sensitive gravitational-wave detectors have been developed, but until now (1991) no confirmed detection has been reported.

Finally, space probes have been able to explore and send back (or, in the case of the Moon, bring back) new and valuable information about the planets, their satellites, and the contents of interplanetary space.

1.2 From 2D to 3D

The earliest astronomers mapped the sky, noting the position and brightness of stars on the spinning celestial sphere and the motions (angular displacements) of the Sun, Moon, and planets among the stars. To this map of naked-eye stars and planets astronomers have added objects up to a million or more times as faint as the faintest naked-eye star—new planets and satellites, stars, multiple stars, star clusters, galaxies, galaxy clusters, and clouds of gas and dust. They have measured the brightness of discrete objects and made continuous brightness maps in broad and narrow spectral bands over 14 decades of the electromagnetic spectrum. They have measured angular displacements of thousands of relatively nearby stars. They have categorized, counted, and cataloged stars, star clusters, galaxies, and galaxy clusters in untold numbers. Most important of all, they have succeeded in translating these varied two-dimensional maps into three-dimensional models of the astronomical universe and the systems that compose it.

Aristarchus, in the third century B.C., and later Copernicus, in the 16th century A.D., used observations of planetary motions to construct a tolerably accurate scale model of the planetary system. Not until 1672 did astronomers succeed in estimating the scale of the model. In that year French astronomers measured the distance between Earth and Mars by triangulating Mars from Paris and



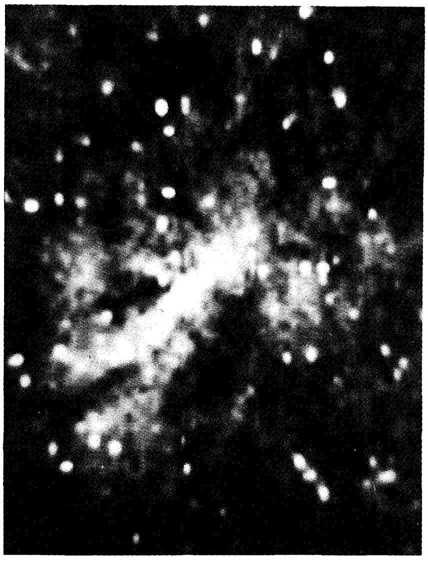


FIG. 1. Views of the center of the Milky Way galaxy at three different wavelengths: (A) 6 cm, (B) visible light, (C) 2.2 μm. The scale of (C) is somewhat different from that of (A) and (B). [Pasachoff and Kutner (1978), Fig. 25-4 and unnumbered.]

Cayenne (in French Guiana). At about the same time, Christiaan Huygens and James Gregory made independent estimates of the distance of the star Sirius, using the optical law that relates an object's apparent brightness to its distance (the inverse-square law) and making the qualitatively correct but quantitatively unreliable assumption that Sirius is intrinsically as bright as the Sun. (Many modern procedures for estimating distances rely on the same law, but use more reliable estimates of the distant object's intrinsic brightness.) The first successful triangulations of stars were accomplished in 1838 by Friedrich Bessel (61 Cygni), Thomas Henderson (Alpha Centauri) and Friedrich Struve

(Vega). These measurements created the first rung of the astronomical distance ladder.

Knowing the distances and hence the intrinsic brightnesses of nearby stars, astronomers sought indicators of intrinsic brightness that could be used to estimate distances (via the inverse-square law relating true and apparent brightness) of stars beyond the range of triangulation. They discovered that a star's color, which is a direct indicator of its *effective temperature,* the temperature of the layers from which we receive light, is also a reliable indicator of intrinsic brightness, provided it is combined with subtle spectral features that serve to distinguish bright stars with distended envelopes (giants) from faint stars (dwarfs) with the same effective temperature. (A plot of apparent brightness against color or effective temperature is known as a Hertzsprung-Russell diagram, after Ejnar Hertzsprung and Henry Norris Russell, who demonstrated its utility early in the twentieth century.)

The next, and in some ways most crucial, rung of the distance ladder was added in 1912–1913. Henrietta Swan Leavitt (1912), a research assistant at the Harvard College Observatory, measured the periods of light variation of certain variable stars, called Cepheids, in the Small Magellanic Cloud, an irregularly shaped object in the southern sky containing stars, star clusters, and bright gas clouds. She found that the measured periods were tightly correlated with apparent brightness, and hence, because all the stars in the Cloud could be assumed to be at nearly the same distance, with intrinsic brightness. The following year Hertzsprung (1914) succeeded in calibrating Leavitt's period-brightness relation by estimating the distances of 13 relatively nearby Cepheids in the Milky Way. The period-brightness relation for Cepheids played the key role in establishing the truth of a hypothesis put forward by Immanuel Kant in 1755: that the "spiral nebulae," fuzzy, often S-shaped patches of light, are distant stellar systems comparable in size to our own stellar system, whose central plane is defined by the Milky Way. An example is shown in Fig. 2. (Such stellar systems are now called galaxies.) With greatly improved calibration, the period-brightness relation (see Fig. 3) is an important rung in the modern distance ladder.

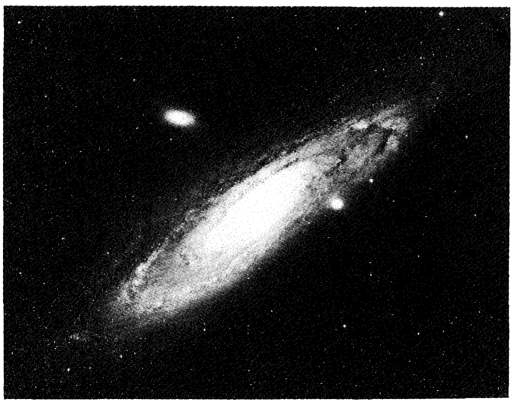

FIG. 2. M31, the Great Galaxy in the constellation Andromeda, a type Sb spiral, with its accompanying elliptical galaxies NGC 205 (upper left) and M32 (lower right). [Pasachoff and Kutner (1978), Fig. 26-3.]

Individual stars can be resolved—even with modern telescopes—only in relatively nearby stellar systems. In the 1920s Edwin Hubble began to use characteristics of whole galaxies as indicators of their intrinsic brightness (Hubble, 1936). The most reliable characteristic of this kind was discovered by R. Brent Tully and J. Richard Fisher (1977). They found that the width of a certain spectral line is a precise indicator of a spiral galaxy's intrinsic brightness. This line, at a wavelength of 21 cm in the radio region of the electromagnetic spectrum, is emitted by clouds of neutral atomic hydrogen concentrated toward the central planes of spiral galaxies.

Many other kinds of objects have been used as distance indicators, including novae and supernovae. Novae are now known to be close binary stars whose interaction gives rise to the characteristic brightenings of the system. Supernovae are exploding, massive single stars. Theoretical calculations show that stars whose masses lie between 10 and 70 solar masses explode when the supply of nuclear fuel in their core has been exhausted. These stars become so-called type-II supernovae; they are found in the disks of spiral galaxies. Type-I supernovae, which are found in the spheroidal halos of spiral galaxies and in elliptical galaxies, are less well understood. They are thought by some workers to result from explosions of stars with masses between 4 and 8 solar masses.

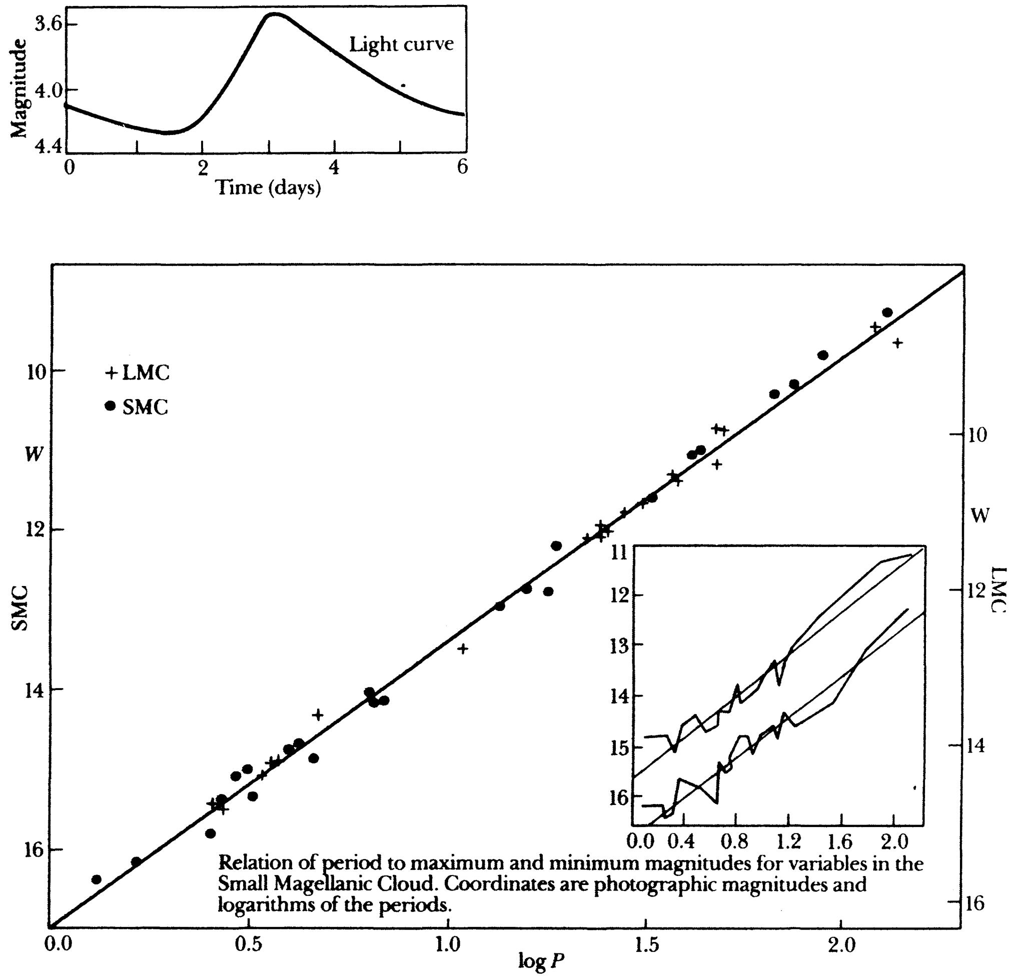

FIG. 3. Top, light curve of the star δ Cephei. Bottom, Leavitt's original plot of brightness vs period for Cepheids in the Small Magellanic Cloud (inset), and a modern plot for Cepheids in the Large and Small Magellanic Clouds (LMC and SMC, respectively). The ordinate is W, a linear combination of blue and apparent visual magnitudes that is insensitive to reddening by interstellar matter. [Layzer (1984).]

1.3 Stellar Spectra

A prism or diffraction grating spreads light into a spectrum, separating rays of different colors or frequencies. The spectra of astronomical objects are rich sources of information about their physical characteristics.

Stars, like incandescent solids, emit continuous spectra whose shape (which defines the distribution of radiant energy in frequency or wavelength) is completely determined by the temperature of the emitting surface. Physical theory predicts that the peak wavelength, which defines the color of the light, is inversely proportional to the (Kelvin or absolute) temperature. The temperature of sunlight is around 6000 K.

By contrast, a hot, transparent gas, like the gas in a fluorescent lamp, emits light only in very narrow, well separated bands of frequency or wavelength. (These narrow bands are called spectral lines. See ATOMIC SPECTROSCOPY.) For example, heated sodium vapor emits two closely spaced, narrow bands of yellow light. During the 19th century astronomers discovered that "spiral nebulae" have continuous spectra like stars (see Fig. 4), thereby confirming Kant's 100-year-old hypothesis that they are stellar systems. Other nebulae, which have bright-line spectra, are

true gas clouds, excited by embedded hot blue stars. Most of these gaseous nebulae belong to our own stellar system, but some are bright enough to be seen in neighboring galaxies. There are also dust clouds that, like the planets, shine by light reflected from nearby (or embedded) stars.

In 1823 Joseph Fraunhofer discovered that the spectra of the Sun and bright stars are crossed by very narrow dark lines. These lines represent light absorbed and scattered by the tenuous outer layers of a star. Every chemical element and every molecule produces its own characteristic pattern of spectral lines. In the spectrum of a hot transparent gas cloud these lines appear bright. If the gas lies between an incandescent source and the observer, it produces dark lines at exactly the same frequencies or wavelengths. The relative strengths of the lines, and hence the appearance of the spectrum, is determined by the temperature of the layers where the spectrum is formed. Conversely, from the appearance of the spectrum one can infer the temperature of the layers where the spectrum is formed. The temperature deduced in this way coincides with the temperature deduced from the continuous spectrum (the "color temperature")—provided the characteristics of the light have not been altered by its passage through an intervening medium. In fact, as discussed below, interstellar space is populated by clouds of dust and gas, which leave their imprint on starlight. Dust particles of sizes comparable with the wavelength of visible light (around a tenth of a micron) scatter blue light more effectively than red light. Hence light that has traversed a transparent dust cloud appears reddened. The relative strengths of the dark spectral lines, however, are not altered, and from them the true temperature of the emitting layers can be inferred. By relating the amount of reddening, as measured by the difference between the true and the apparent color of a distant object, to the amount of dimming, astronomers have been able to allow for the attenuation of light in its passage from source to observer.

Although the appearance of the line spectrum depends primarily on the temperature of the layers where the spectrum is formed, it also depends, though much more weakly, on the pressure or density. As mentioned above, by paying attention to subtle pressure-sensitive spectral features, astronomers have been able to distinguish bright stars with distended envelopes (giants) from faint stars (dwarfs) with the same surface temperature.

The appearance of a stellar spectrum depends not only on the temperature and pressure of the layers where the spectrum is formed but also on the relative abundances of the chemical elements and their isotopes in those layers. By subjecting careful and detailed spectral measurements to elaborate theoretical analyses, astrophysicists have been able to carry out quantitative chemical analyses of stellar atmospheres, interstellar gas clouds, and quasars. The results of such analyses have important implications for theories of cosmic evolution and for theories of the origin of the chemical elements.

1.4 Dimming and Reddening of Starlight

Long before the true nature of "spiral nebulae" had been definitely established, astronomers noticed a peculiarity in their distribution on the celestial sphere. Spiral nebulae are found everywhere except in the Milky Way itself, a narrow, irregular, bright band of stars and diffuse starlight centered on a great circle of the celestial sphere. In short, the spiral nebulae avoid the region of the sky where stars are most strongly concentrated. To those who accepted Kant's interpretation of the Milky Way as a great disk-like stellar system viewed from the perspective of an observer in a peripheral region, and his hypothesis that the spiral nebulae are distant stellar systems comparable to our own and lying well beyond its limits, the interpretation of this state of affairs was obvious: external stellar systems that lie in the direction of the Milky Way must be hidden from view by a layer of dust strongly concentrated toward our system's central plane, the plane of the Milky Way. Spiral nebulae seen edge on do indeed have conspicuous dark central lanes. Nevertheless, until the 1920s most astronomers preferred to believe that we have a clear, unimpeded view of the heavens—that the light we receive from stars and galaxies is dimmed by distance alone.

In the late 1920s, Edwin Hubble, armed with data from photographs made with the world's largest telescope, the 100-in.-diam reflector on Mt. Wilson in California, showed that the hypothesis of a thin, uniform obscuring layer centered on the central plane of our galaxy could explain not only the absence of external galaxies along lines of sight that make small angles with this plane but also the rate at which the density of galaxy images on the plane of the sky decreases with decreasing elevation of the line of sight relative to the plane. Around the same time, Robert J. Trumpler (1925) found clear evidence of dimming by a thin layer of galactic dust in the linear diameters of star clusters that lie close to the plane of the Milky Way. Trumpler deduced the linear diameters of these clusters from their angular diameters and estimated distances. He found that diameters estimated in this way increased systematically with estimated distance in all directions from the observer, an effect that could most plausibly be attributed to a systematic error in the distance estimates, arising from the dimming of starlight by intervening dust.

Finally, Joel Stebbins (1933), using the newly developed technique of photoelectric photometry, found that globular star clusters become systematically redder with decreasing elevation of their line of sight relative to the central plane of the Milky Way. The reddening of starlight indicated that a substantial fraction by mass of the solid particles responsible for dimming the light have dimensions comparable with the wavelengths of visible light. Because reddening and dimming are related in a known manner, measurements of reddening allow one to predict how much the light from a star or stellar system is dimmed in any given direction and thus to correct distance estimates for the effects of dimming. In this way Stebbins was able to deduce that the globular clusters form a spherical system strongly concentrated toward its center. The Sun lies on the central plane of this system, roughly 30 000 light years from the center.

1.5 Measuring the Velocities of Astronomical Objects

The frequency of monochromatic (single-frequency) light, or of any other periodic signal, is shifted by relative motion along the line joining source and observer. The fractional change in frequency or wavelength is equal to the ratio between the line-of-sight velocity and the speed of light. The shift is toward the red for recession (increasing separation), toward the blue for approach. This effect is a simple consequence of the finite speed of propagation of light. Although it is named after Christian Doppler, who demonstrated it for sound waves early in the 19th century, it was discovered in 1675 by Ole Roemer, who attributed systematic variations in the period of Io's eclipses by Jupiter to the Earth's orbital motion and the finite speed of light. Roemer's analysis established for the first time that light signals travel with finite speed, and yielded a remarkably accurate estimate of this speed. The Doppler effect has continued to play an important part in astronomy. Astronomers deduce the line-of-sight velocities of stars, galaxies, quasars, and other astronomical objects by measuring the displacements in the frequencies or wavelengths of their spectral lines from the standard laboratory frequencies or wavelengths (see Fig. 4). Theory predicts and observation confirms that the fractional shift is the same at every frequency.

As discussed below, estimated line-of-sight velocities, interpreted in the light of Newton's theory of gravitation, form the basis for estimates of the masses of stars, galaxies, and galaxy clusters. Systematic redshifts in the spectra of distant galaxies led to, and continue to support, our present picture of an expanding universe. (See GALAXIES AND COSMOLOGY.)

2. GRAVITY AND THE HIERARCHY OF SELF-GRAVITATING SYSTEMS

2.1 Newtonian Gravity

The domain of astronomy coincides with the domain of gravity. Astronomical systems, from planets and their satellites to clusters and superclusters of galaxies, are held together by the mutual gravitation of their parts. Moreover, the cosmic expansion—the expansion of the universe as a whole—is a gravitational phenomenon (see GALAXIES AND COSMOLOGY).

Unlike the electrostatic forces that hold together atoms, molecules, liquids, and solids, and the strong forces that hold together atomic nuclei and their constituent protons and neutrons, gravity has no preferred scale. The scale-free character of gravity is a consequence of two properties enunciated by Newton. First, every particle attracts and is attracted by every other particle in the universe. The strength of attraction is proportional to the product of the masses. Second, the force of attraction diminishes slowly with increasing separation (as the inverse square of the separation). As a consequence of these two properties, the cohesive energy per unit mass of a stable self-gravitating system—a system that is neither expanding nor collapsing—is proportional to its average mass density (mass divided by volume) and to the square of its diameter. So a system of low average density can have a large gravitational cohesive energy per unit mass if it is large enough.

In principle, the average mass density of a self-gravitating system can have any value at all. The actual range of observed and inferred average mass densities is indeed very large. The most diffuse (and largest) self-gravitating systems have average mass densities around 10^{-28} g cm^{-3}. The most compact astronomical objects have mass densities ranging from around 1 g cm^{-3} for ordinary stars to around 10^{14} g cm^{-3} for neutron stars. So the mass densities of stable self-gravitating systems span a range of 42 decades. By contrast, the mass densities of ordinary solids and liquids span a range of about two decades. The average densities of atomic nuclei and nucleons span an even narrower (but higher) range.

2.2 Mass, Size, and Motion

Newton's theory of gravitation relates the motions within a self-gravitating system to the distribution of mass in the system and its size. For example, with the help of Newton's theory we can deduce the Sun's mass (2×10^{30} kg) from the orbital period and the major diameter of a single planetary orbit. (Newton's theory predicts and observation confirms that the calculated mass is the same for each orbit.) Similarly, we can infer the mass of a planet from the orbital period and orbital diameter of one of its satellites. (For example, the Moon's period and orbital diameter give us the Earth's mass.) The same relation has allowed astronomers to infer the masses of stars in binaries (mutually gravitating pairs of stars).

Applied to more complex self-gravitating systems, Newton's theory yields a relation between the average squared velocity of the "particles" (molecules, stars, galaxies) that make up the system and the system's mass and diameter: The mean squared velocity is approximately equal to Newton's gravitational constant multiplied by the mass of the system and divided by its diameter. This relation is the basis of astronomical estimates of the masses of stellar systems. The diameter of a distant object can be inferred from its angular diameter which is directly measurable, and an estimate of its distance. The internal velocity dispersion can be inferred from the object's spectrum. The spectrum of a self-gravitating system is a composite of the spectra of its components. Each component contributes a line spectrum shifted to the red or violet according to that component's line-of-sight velocity. The composite spectrum has broadened lines, whose widths are simply related to the velocity dispersion of the components. Lines in the spectrum of a single star are broadened by the thermal motions of the atoms and molecules that give rise to the lines. Lines in the spectrum of a galaxy are further broadened by the line-of-sight motions of individual stars relative to the galaxy's center of mass. The 21-cm line of neutral hydrogen in a spiral galaxy is broadened by the rotational motion of hydrogen clouds in the galaxy's central plane. Hence its width—the criterion for intrinsic brightness proposed by Tully and Fisher (see above)—is an index of the galaxy's mass.

2.3 Tidal Effects

A major triumph of Newton's theory of gravitation was its explanation of ocean tides. The lunar tide-raising force at a given point on the Earth's surface is the difference between the gravitational pull of the Moon at that point and the gravitational pull at the Earth's center of mass. The Sun also exerts a tide-raising force, defined in exactly the same way. But because the tide-raising force turns out to be inversely proportional to the cube of the distance, the lunar contribution to the total tide-raising force dominates the solar contribution. The lunar tide-raising force is directed toward the Moon on the side of the Earth facing the Moon and away from the Moon on the opposite side. This accounts for the observation that high tides are separated by half a lunar day. The tides are highest when the lunar and solar contributions reinforce one another, lowest when they tend to cancel. Thus the highest tides occur when the Moon lies between the Sun and the Earth (at new Moon), while the lowest tides occur when the Earth lies between the Sun and the Moon (full Moon).

Tidal forces, defined more generally as the spatially varying part of an external gravitational force, are ubiquitous in astronomy. Their effect is always disruptive. The small objects that make up the rings of Saturn, Jupiter, and Uranus (see below) are prevented from coalescing into larger self-gravitating bodies by the tide-raising forces exerted by the respective planets. In 1850 Eduard Roche showed that a self-gravitating liquid satellite whose density is equal to the planet's mean density can resist tidal disruption only if its distance from the center of the planet exceeds

2.44 planetary radii. Satellites and ring particles that lie inside the "Roche limit," as this critical distance is called, are held together primarily by chemical cohesion, not gravity. Star clusters in the plane of the Milky Way are continually disrupted by the tide-raising force exerted by mass interior to their galactic orbits. Tide-raising forces limit the sizes of globular star clusters. Tide-raising forces also limit the sizes of galaxies in clusters and tend to disrupt subclusters within large galaxy clusters.

2.4 Self-Gravitating Clusters

The distribution of mass in the astronomical universe is strongly clustered on a wide range of levels. Self-gravitating systems tend to belong to larger self-gravitating systems and to have smaller self-gravitating systems within them. Because tidal forces tend to disrupt hierarchic structure, we may conclude that the clustering tendency must have been more conspicuous in the past than it is now and that the clustering tendency is a central feature of the process(es) by which self-gravitating systems were formed. (See GALAXIES AND COSMOLOGY.)

Stable astronomical systems are conventionally assigned to a number of broad categories: planets and their satellites, planetary systems, stars, small multiple stellar systems, star clusters (subdivided into open clusters and globular clusters), galaxies, groups and clusters of galaxies, and galaxy superclusters.

The extent to which the kind of structure exhibited by our own planetary system is reproduced around other stars is not yet known; and theories for the origin of stars and planetary systems are not yet secure enough to fill this gap in our knowledge. Many astronomers believe, however, that planetary systems are a common occurrence. There are continuing efforts to find evidence of planets around nearby stars. A massive planet with a tight orbit would perturb the orbited star's motion to an extent that is probably detectable with current techniques.

Most stars belong to double or triple systems. Simulations based on Newton's theory predict and observation confirms that triple systems tend to evolve into a close binary whose center of mass forms a binary system with the more distant third star.

Star clusters occupy the next hierarchical level. The largest and most compact clusters are nearly spherical systems with 100 000 to 10 million members. As mentioned above, the globular clusters in our own galaxy form a centrally concentrated spherical system. Open or galactic clusters are confined to our galaxy's central plane. They are much smaller, with at most a few hundred members.

Galaxies define a major level, in the sense that a large fraction of the mass in the universe is bound in galaxies. They range in mass from less than 10^{10} solar masses to more than 10^{12} solar masses. There also exist dwarf galaxies with masses of only 10^6 to 10^7 solar masses.

Galaxies, like stars, exhibit a strong clustering tendency. They are found in small groups, clusters, and superclusters.

2.5 Mass, Radius, and Cohesive Energy

Although a star and a stellar system, such as a globular star cluster, are both held together by gravity, the conditions that determine their respective sizes or mass densities are profoundly different. Most globular star clusters have masses in the range 10^5 to 10^7 solar masses and radii from 10 to 100 light years. But there is no known physical (as opposed to historical) reason why the range of cluster radii should not be 1000 or more times greater than it actually is. The relatively narrow range of cluster radii must be a consequence of initial conditions and evolutionary history.

By contrast, the radius of a star is largely independent of its initial conditions and evolutionary history. A star is in a condition of equilibrium in which its central temperature and density are just high enough for nuclear reactions in the deep interior to release energy at a rate that balances the rate at which energy is lost by radiation from the surface layers. When its supply of nuclear fuel is exhausted, a star (or what is left of it after some fraction of its mass has been more or less violently expelled) becomes a white dwarf, a neutron star, or a freely collapsing black hole. Knowing the initial mass, chemical composition, and age of a star, we can calculate its radius and predict its internal structure. Initial conditions are largely irrelevant, except insofar as they specify the mass and chemical composition.

From a theoretical standpoint, *cohesive energy* is a more significant characteristic than radius, because energy, like mass, is conserved in physical interactions. Cohesive energy is the energy per unit mass needed to disperse a system. For a self-gravitating system, it is proportional to the mass of the system divided by its radius. Mass and cohesive energy are the two most basic characteristics of a self-gravitating system. The present masses and cohesive energies of relatively tightly bound star clusters, galaxies, and galaxy clusters are probably close to their original values. It is reasonable to suppose that the diffuse clouds from which stars formed were comparable in size to the solar system. Under this assumption, the initial binding energies and masses of self-gravitating systems, from stars to galaxy clusters, obey a simple relation: the cohesive energy is proportional to the one-third power of the mass. Thus stars, globular clusters, galaxies, and rich galaxy clusters, with masses in the ratios $1:10^6:10^{12}:10^{15}$, have cohesive energies in the ratios $1:10^2:10^4:10^5$.

3. ASTRONOMICAL SYSTEMS

3.1 The Solar System

Since the early 1960s, observations with instruments mounted on spacecraft have greatly enriched our store of factual knowledge about the solar system. Thanks to these observations, we now have a wealth of information about geometric, physical, and chemical properties of planets and planetary atmospheres, satellites, asteroids, comets, and other small bodies. During the same period, the development of fast and powerful computers with large memories made it possible for theorists to study fundamental but previously unanswerable questions concerning the origin and evolution of the solar system. In particular, it became possible to investigate the long-term stability of orbits with a variety of initial conditions and to model the evolution of systems composed of large numbers of mutually gravitating components. Although these experimental and theoretical advances have not yet given us a secure theory for the origin of the solar system, they have yielded a greatly improved understanding of the conditions that such a theory must satisfy and of the difficulties it must overcome.

The objects that make up the solar system (apart from the Sun) may be classified according to the character of their orbits, according to their sizes, and according to their physical and chemical characteristics. That these three methods of classification do not yield the same groupings was known before the 1960s. For example, early telescopic observations showed that some satellites are bigger than some planets; and the fact that at least one satellite, Titan, a satellite of Saturn, has an atmosphere was discovered in 1944, by Gerard Kuiper. But information collected by instruments mounted on spacecraft has clarified the relations among the three sets of properties.

Orbits can be conveniently classified as *stable* or *unstable*. A stable orbit keeps its qualitative character for a period comparable to the age of the solar system, about 4.6 billion (=thousand million) years. Unstable orbits change significantly during periods shorter than 4.6 billion years. The point of this distinction is that unstable orbits do not reflect conditions in the early solar system, while stable orbits do. Stable orbits are dominated by either the Sun or one of the planets. As discussed below, instability arises from gravitational disturbances by a third body (or several "third bodies"). For example, gravitational disturbances by Jupiter create zones of unstable orbits in the asteroid belt.

All the planets except the tiny double planet (or planet-satellite system), Pluto-Charon, have stable orbits, as do most of the minor planets or asteroids whose orbits lie between Mars and Jupiter. These stable orbits are nearly circular, only slightly inclined to the central plane of the solar system, and prograde (counterclockwise as viewed from "above"). Pluto's orbital eccentricity of 0.25 and orbital inclination of 17° are considerably larger than those of the other planets. Its orbit may well have been very different in the remote past from what it is now.

Among satellite orbits, those that are circular, slightly inclined, and prograde (relative to the planet's spin axis and direction of spin) predominate. Of Jupiter's 16 known satellites, the eight nearest the planet move in prograde, essentially circular orbits in Jupiter's equatorial plane; the next four have prograde, nearly circular, orbits with moderate inclinations (27°–29°), while the outer four have retrograde orbits. The outermost of Saturn's 17 known satellites, Phoebe, has a retrograde orbit, as does Triton, by far the most massive of Neptune's 8 known satellites. By contrast, the orbits of all of Uranus's 15 known satellites (10 of which were discovered by Voyager 2 in 1985–1986) are prograde and circular, and lie in the planet's equatorial plane. The satellites with retrograde orbits are widely thought to have been captured relatively late in the solar system's evolution.

Although the great majority of asteroids have nearly circular, slightly inclined, prograde orbits whose radii lie between 2.2 and 3.3 astronomical units, some asteroids have eccentric, highly inclined orbits. (The astronomical unit is the radius of Earth's orbit.) Some asteroid orbits cross the Earth's orbit.

Meteoroids are small asteroids that pass close to Earth. Those that enter the Earth's atmosphere and become incandescent through friction with the atmosphere are called meteors; surviving fragments that reach the surface of the Earth are called meteorites.

The orbits of *comets* present a striking contrast to the orbits of the planets and satellites (apart from the exceptions noted above). These sometimes spectacular visitors to the night sky were first identified as solar orbiters by Tycho Brahe in 1577. Newton's theory of gravitation allowed his friend Edmund Halley to calculate the orbits of several comets and to predict the reappearance, on Christmas night of 1758, of a bright comet whose previous appearances had been recorded at 76-year intervals since 1531. Cometary orbits have large eccentricities (the orbits are nearly parabolic) and are randomly inclined to the central plane of the solar system. (Prograde and retrograde orbits are therefore equally numerous.)

Oort (1950) noted that the aphelion distances of cometary orbits tend to be close to 50 000 astronomical units. (An object's aphelion distance is its greatest distance from the Sun.) This is about one-quarter the average distance between stars in the Sun's neighborhood. It is also the distance at which an object's orbit is most sensitive to disturbance by a passing star. Comets with smaller aphelion distances are so tightly bound that they are not greatly disturbed by the tidal field of the Galaxy or by passing stars; comets with greater aphelion distances are disturbed so much that they are likely to be torn loose from the solar system. Oort surmised that comets with aphelion distances near 50 000 AU are most easily perturbed by passing stars into orbits that bring them close enough to the Sun to make them visible.

A comet becomes visible when it grows a tail or *coma*. This is produced by gases that boil off under heating by solar radiation. Spectroscopic analyses of these gases have shown that the volatile constituent of comets is largely (about 79%) water ice, with smaller quantities of many other ices, including ammonia, methane, carbon monoxide, and carbon dioxide. The nonvolatile constituents include hydrocarbons and silicates.

Where do comets come from? Their chemical composition suggests that they were formed in the outer solar system, beyond Jupiter's orbit. (The inner planets have a preponderance of nonvolatile elements, in the form of metal and rock; in the outer planets ices predominate.) Recent theoretical studies and numerical simulations strongly suggest that they originated as planetesimals between the orbits of Uranus and Neptune, and were then perturbed into their present highly elongated and highly inclined orbits by interactions with the outer planets (Duncan *et al.*, 1987, 1988). Numerical simulations have shown that once Jupiter and Saturn had formed, planetesimals on intervening orbits would have been quickly ejected from the solar system (Franklin *et al.*, 1989).

Some of the most interesting orbits in the solar system are those of the particles that make up *planetary rings*. Observations from spacecraft have shown that not only Saturn but also Jupiter, Uranus, and Neptune have ring systems. Saturn's ring system (Fig. 5) is by far the widest (20 000 km) and the most massive (10^{17}–10^{18} kg). Saturn's rings are made up of icy particles whose diameters range from a centimeter or so to a few meters. Uranus's rings are made of similar-sized but much darker particles. Uranus's ring system (Fig. 6) is only 100 km wide, and its mass is 1% the mass of Saturn's ring system. Jupiter's ring system is faint, transparent, and diffuse. It consists of micron-sized dust particles. Neptune has partial rings or arcs whose properties are still largely unknown.

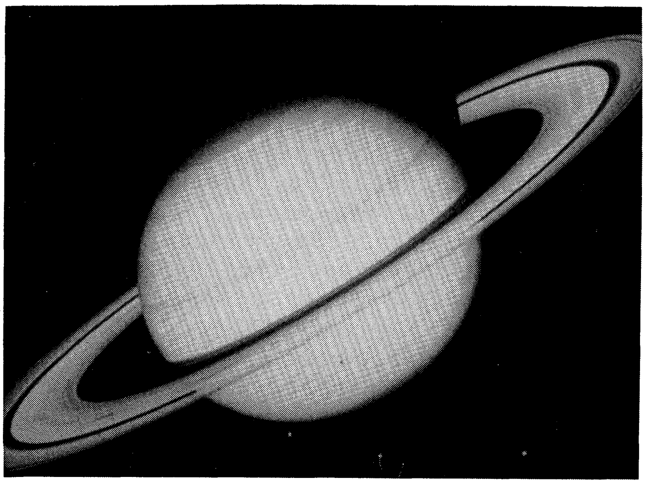

FIG. 5. Saturn and its rings as photographed by Voyager. (NASA/JPL photo.)

All or nearly all the material in each ring system lies within the planet's Roche limit. The rings may be composed wholly or in part of material that entered the zone of tidal disruption relatively recently or of primordial material that was prevented by the tidal field from coagulating into larger bodies.

The rings of Saturn and Uranus have an extremely intricate (and beautiful) fine structure (Fig. 7). Bright rings of varying widths alternate with narrow dark lanes. The dark lanes are caused in part by resonant interactions with the planet's satellites. A resonant interaction occurs between objects whose orbital periods are in the ratio of (usually small) whole numbers, such as 1:2 or 2:3. A ring particle whose orbital period is commensurable in this sense with that of a nearby satellite experiences a periodic disturbing force that causes its orbit to depart progressively more from its initially circular form. For example, there is a gap in Saturn's ring system where an orbiting particle would have exactly half the orbital period of the nearby moon Mimas.

Resonant interactions with Jupiter give rise to the so-called Kirkwood gaps in the asteroid belt. The gaps occur at distances from the Sun at which the ratio between an asteroid's period and Jupiter's period are small whole numbers.

Size and mass. Classification by these criteria cuts across classification by orbit. The planet Pluto is smaller than six satellites: Jupiter's four Galilean satellites, Titan (Saturn's giant satellite), and Triton (Neptune's giant satellite). Mercury is about the same size as, though denser and hence more massive than, the three largest satellites. Mars's two satellites and the innermost satellites of the outer planets, with diameters ranging from ten to a few tens of kilometers, are comparable in size with medium-sized asteroids. Chiron, an ob-

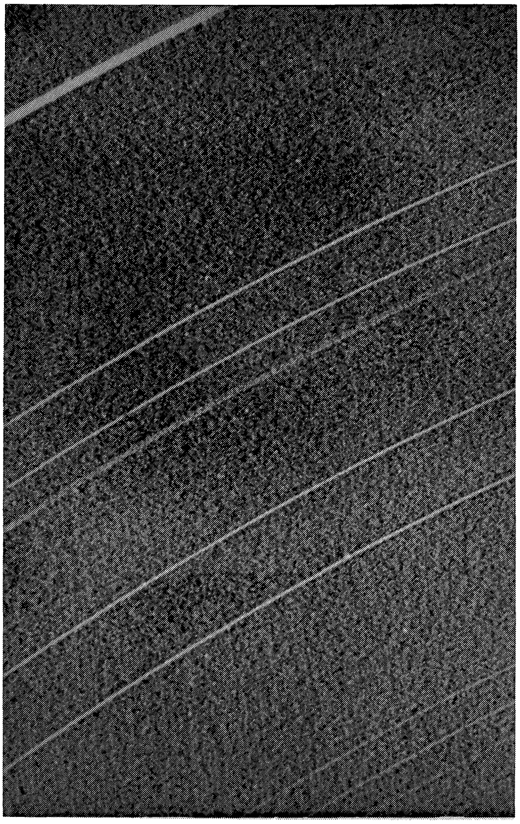

FIG. 6. Voyager image of the narrow, dark rings of Uranus. (NASA/JPL photo.)

ject with a diameter of 150 km (the size of a large asteroid) moves in an elliptic orbit between Saturn and Uranus, in one of the chaotic zones mentioned above. In 1988 it exhibited a faint but unmistakable coma, thereby qualifying for cometary status and the title of the largest known comet.

The number of small bodies in the solar system increases steeply with decreasing mass. Quantitative studies indicate that the number is proportional to the $-\frac{2}{3}$ power of the mass. Such a "spectrum" is consistent with the hypothesis that the small bodies formed through collisional fragmentation.

The ubiquity of cratering indirectly supports this hypothesis. The Moon, Mercury, Venus, Mars and its two satellites, and the large satellites of Jupiter, Saturn, and Uranus have all been found to have heavily cratered surfaces, produced by impacts with comets and asteroids. The data suggest that throughout the solar system the number density of small solid bodies was much higher in the past than it is now. An initial period of intense cratering activity lasted only 500 million years. The present distribution of small bodies subsequently evolved through accretion and collisional fragmentation.

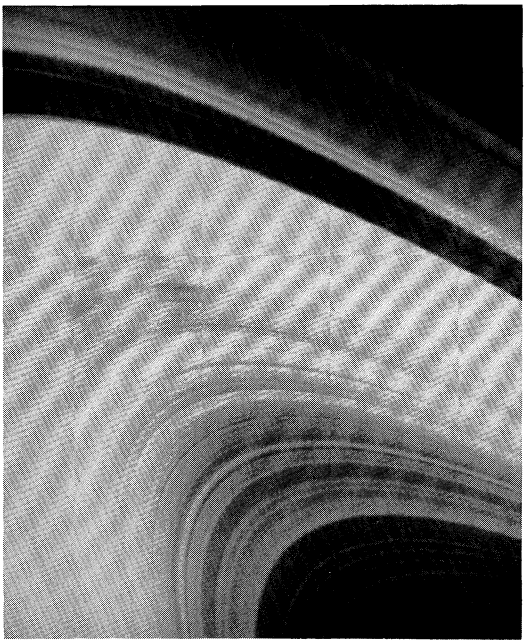

FIG. 7. Saturn's B ring in detail. The structure seen here has scales of tens to hundreds of km. Most of this structure has not been explained. (NASA/JPL photo.)

Meteorites. Most meteorites, unlike rocks on Earth, are chemically undifferentiated; that is, the various elements have not separated out according to their chemical properties, such as melting temperature. Moreover, these meteorites have the same chemical composition as the solar atmosphere, apart from a few volatile elements like the noble gases. Radiometric determinations of the ages of undifferentiated meteoritic material shows that it is about 4.5 thousand million years old. This is taken to be the age of the solar system. From studies of the structure and chemical composition of meteorites and experimental and theoretical information about the effects of heating and cooling in objects of different sizes, scientists have inferred that meteorites are fragments of larger bodies ranging in diameter from about a kilometer to a few hundred kilometers. Analysis shows that there must have been at least twenty or so different parent bodies, all the size of large asteroids, rather than a single large parent body of planetary size.

Extrapolations of observed meteor orbits indicate that the great majority of meteorites originate in the asteroid belt. Recently, however, some meteorites have been shown to have been formed on the surface of the Moon by relatively recent cratering events that also gave these objects enough kinetic energy to overcome the Moon's gravitational pull and reach the Earth. There is even evidence that some meteorites were produced by cratering events on Mars!

Meteorites encode an enormous quantity of information about the history of the inner solar system. So far, only a small part of the information has been decoded, but already it has served to constrain the range of hypotheses about the origin and evolution of the solar system.

3.2 Origin of the Solar System

Since the early 1960s, powerful computational techniques, sophisticated physical and chemical considerations, and data supplied by spacecraft and ground-based astronomical observations have all been brought to bear on this ancient problem. The most common theoretical approach, which goes back to Kant and Laplace, posits that the Sun contracted from an extended cloud of dust and gas, leaving behind a thin disk. Supporters of this picture cite recent high-resolution observations of young stars in molecular clouds (see below); but the interpretation of these observations is still controversial. However, there is firm evidence that dust particles with diameters of less than a micron are formed in gases ejected by supernovae and other massive stars.

The first step in the genesis of a planet is the aggregation of submicron-sized dust particles into self-gravitating "planetesimals" a few kilometers in diameter. A sufficiently thin layer of dust would indeed break up into just such planetesimals. Unfortunately, it has recently been found that interaction between the dust and the ambient gas effectively inhibits this process (Weidenschilling, 1980). The alternative process for forming planetesimals—simple coagulation (chemical binding)—also encounters severe difficulties. At the moment (1991), no way around this impasse is in sight.

Assuming that planetesimals have somehow been formed, theorists have used computers to simulate their subsequent evolution. With appropriate initial conditions, such simulations can be made to yield a realistic inner solar system (Mercury, Venus, Earth, Mars). But the models encounter as yet unsolved difficulties in predicting the outer planets and the asteroid belt. There is also an important difficulty with the inner planets: their predicted spin axes are randomly oriented, instead of being accurately perpendicular to the central plane.

3.3 Stars and Star Clusters

Stars are self-gravitating gaseous bodies whose centers are hot and dense enough to ignite thermonuclear reactions. The second condition requires the minimum mass of a star to be approximately one-tenth the mass of the Sun. The first condition implies that the maximum mass of an isolated star is around 70 times the mass of the Sun: in a more massive object, radiation pressure exceeds the pull of gravity.

The brightness and effective temperature of a homogeneous, nonrotating, nonmagnetic star are determined by its mass and chemical composition. Hence homogeneous stars with the same chemical composition should form a one-dimensional sequence. Now, it is reasonable to suppose that stars in the same cluster were formed at the same time with the same initial chemical composition. They are also at nearly the same distance (if the cluster subtends a small angle in the sky). So if we plot their apparent brightnesses against their effective temperatures, the plotted points should fall along a curve (rather than scattering over an area). Experience confirms this prediction, showing not only that the assumptions of equal age and initial composition are valid but also that rotation and magnetic fields, both of which are normally present and which vary from star to star, have relatively little effect on brightness and surface temperature.

The shape of the temperature-brightness (or Hertzsprung-Russell) diagram for a star cluster depends on both its age and initial chemical composition. With the help of calculations of stellar evolution (see ASTROPHYSICS) one can infer the age and initial chemical composition of a cluster from the shape of its temperature-brightness diagram. The ages of clusters in our own and other galaxies span a wide range. Globular clusters (see Fig. 8), with estimated ages between 12 000 and 15 000 million years, are the oldest. They form a vast spherical or spheroidal system. The youngest clusters (see Fig. 9) are less than a million years old. They lie in the central plane of spiral galaxies.

The age of a cluster is correlated with the initial abundances of elements heavier than helium. The oldest clusters have very low heavy-element abundances—as low as 0.01% or less. The youngest clusters have heavy-element abundances of 3% or more. The initial or primordial helium abundance seems to be much the same in all stars. It is currently estimated at between 22% and 24% by mass. (The difference between the upper and lower bounds is of crucial cosmological significance; see GALAXIES AND COSMOLOGY.)

Helium and heavier elements are formed in the interiors of massive short-lived stars. These stars go through an explosive evolutionary stage, ejecting their "processed" gases into the interstellar medium. New stars form from gas that has been more or less "enriched" in this way. Because gas and dust settles quickly into the plane of a spiral galaxy, it is understandable that stars in young clusters, which are also strongly concentrated toward this plane, have relatively high abundances of heavy elements.

3.4 The Interstellar Medium

The region between the stars is populated by clouds of dust and gas, in varying proportions. As discussed above, dust manifests itself in the dimming and reddening of light from distant stars and galaxies. Gas clouds in the line of sight to a more distant star impose their own absorption lines on its spectrum.

Hot blue stars are often embedded in interstellar clouds. They emit ultraviolet light copiously enough to ionize a large surrounding volume of hydrogen. In this ionized region, recombining hydrogen atoms emit light not only at the original ionizing frequency but also at a variety of other, lower frequencies, in the visible and infrared parts of the spectrum. As a result, such regions of ionized hydrogen are bright in visible and infrared light.

Spiral galaxies contain large quantities of atomic hydrogen in clouds strongly concentrated to their central plane. These clouds emit radiation at a wavelength of 21 cm. (The atomic transition responsible for this radiation connects the two hyperfine sublevels of the lowest level in hydrogen's energy spectrum. The two sublevels correspond to different relative orientations of the electron's and proton's magnetic moments. See ATOMIC SPECTROSCOPY.) Clouds of neutral hydrogen in our own and other galaxies are concentrated in spiral arms. As discussed above, estimates of the masses of spiral galaxies are based on measurements of the Doppler shifts of the 21-cm line emitted by hydrogen in their central planes.

3.5 Giant Molecular Clouds

Spiral galaxies contain massive (up to 10^7 solar mass), dense clouds in which hydrogen is bound predominantly in molecules such as OH, CO, and H_2. (Larger molecules, notably formaldehyde, have also been detected.)

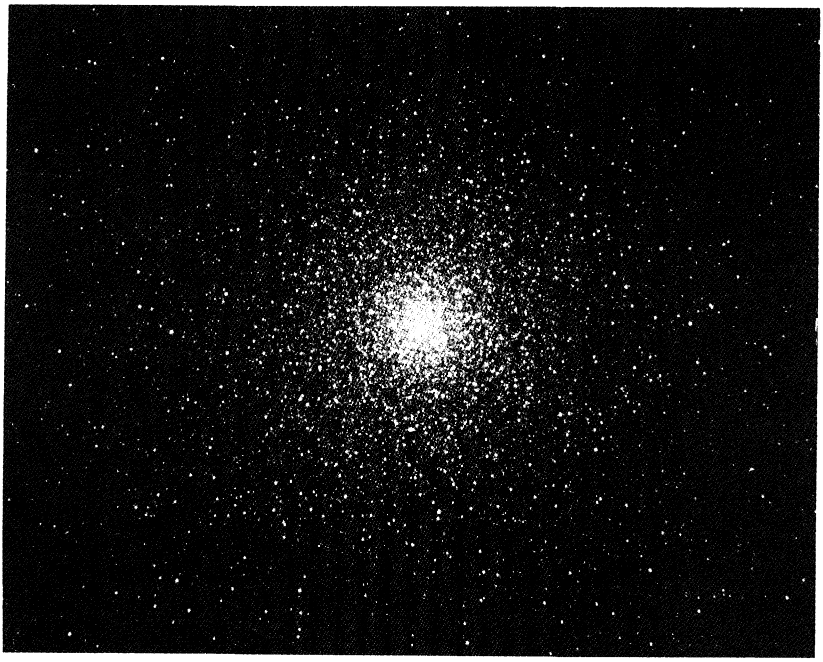

FIG. 8. The globular cluster M3 in the constellation Canes Venatici, the Hunting Dogs. [Pasachoff and Kutner (1978), Fig. 7-13.]

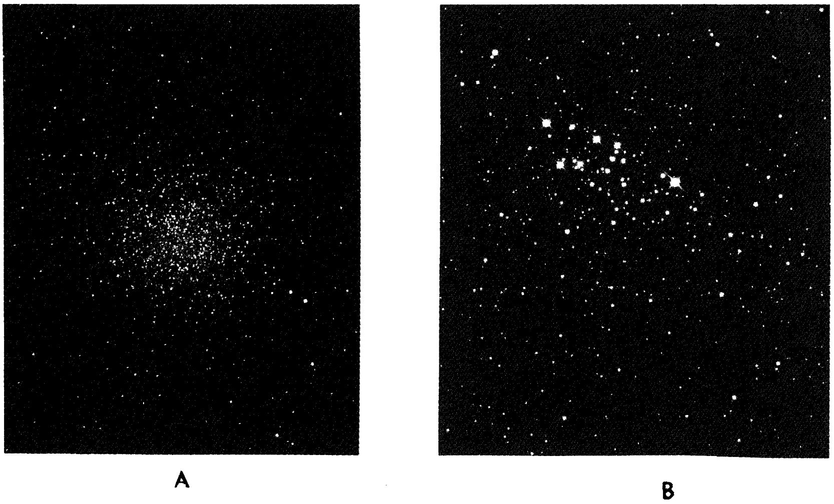

FIG. 9. (A) A rich galactic cluster, NGC 5897, in the constellation Libra. (B) A poor galactic cluster, NGC 7510. [Pasachoff and Kutner (1978).]

These molecules have emission lines in the radio part of the spectrum (see MOLECULAR SPECTROSCOPY). Molecular clouds or cloud complexes are particularly interesting because they contain newly formed stars and, presumably, stars in the process of formation. Among such stars are the so-called T Tauri stars, which have been intensively studied. They are always deeply embedded in dust and gas, emit strong winds, vary strongly and erratically in brightness, and give evidence of intense surface activity. The Sun is widely believe to have gone through a T Tauri stage in its evolution.

INTRODUCTION

Astrophysics is the branch of physics that attempts to understand the appearance and behavior of astronomical objects, especially those outside the solar system, including stars and galaxies, assemblages of these, and the material around them. Alternatively, one can describe astrophysics as the portions of astronomy that the physicists of any given generation regard as worthy of their attention.

The word first appears in the late nineteenth century to mean the application of principles of spectroscopy, atomic physics, and thermodynamics to measure the luminosities, temperatures, and chemical compositions of stars and nebulae, while astronomy meant positional measurements and their applications to the solar system, binary stars, and definitions of coordinate systems based on the earth's motions. All of these topics would today be regarded as parts of astronomy and rather old-fashioned ones at that.

Meanwhile, astrophysics has evolved to denote investigations of the internal structure, evolution, and formation of stars and galaxies. Nuclear astrophysics focuses on nuclear reactions as energy sources in stars and as synthesizers of the chemical elements. High energy astrophysics takes as its territory objects and processes where either the energy per particle or photon or the total energy is large (compared to thermal equilibrium or to average objects). Examples include supernovae, pulsars, and x-ray sources; cosmic rays; and quasars and radio galaxies.

Study of the structure and evolution of the universe as a whole is generally designated by the separate name cosmology, but is also addressed here. The properties of galaxies and these large-scale topics are covered in the article on GALAXIES AND COSMOLOGY.

1. STELLAR STRUCTURE AND EVOLUTION

The observed properties of stars include their masses, luminosities, radii, surface temperatures, surface chemical compositions, and (sometimes) an indication of age. A model star is a table giving values of mass, radius, luminosity, temperature, entropy, density, pressure, and composition from center to surface. It is arrived at by solving a set of four coupled nonlinear differential equations, constrained by three auxiliary tables or analytic relations for equation of state, opacity to radiation, and rate of generation of nuclear energy, and subject to suitable boundary conditions (mass=0 at the center; density=0 at the surface; etc.).

A sequence of model stars, reflecting changes with time in the fundamental quantities throughout the star, is an evolutionary track. The initial model is normally chemically homogeneous, in hydrostatic equilibrium (gravity balanced by pressure gradients), and representative of a star that has just begun fusion of hydrogen to helium at its core.

Clearly the primary goal of stellar structure and evolution studies is to obtain a one-to-one correspondence between real stars and model ones. This has, to a considerable extent, been achieved, though with many detailed effects due to rotation, magnetic fields, loss of material from the stellar surface, and presence of a close stellar companion still to be sorted out. Thus, we can be said to understand stars.

The most important determinant of a star's history is its initial mass, which largely sets its temperature, brightness, and lifetime, the sequence of nuclear reactions that will occur, and its end point as a white dwarf, neutron star, or black hole. Initial chemical composition, especially the percentage of helium and total heavier elements, has significant but rather subtle effects.

The classic treatments of stellar structure and evolution are the monographs by Chandrasekhar (1939) and Schwarzschild (1958). Recent texts include Collins (1989) and Rolfs and Rodney (1988). Late phases of evolution are addressed in Philip *et al.* (1987), Kwok and Pottasch (1987), Abbott and Conti (1987), and Torres-Peimbert (1989). Supernovae and their products have been reviewed by Woosley and Weaver (1986), Trimble (1988), Weiler and Sramek (1988), and Arnett *et al.* (1989). Special effects considered include pulsation and mass loss (Stalio and Willson, 1988), rotation and magnetic fields (Hartmann and Noyes, 1987), and binary companions (Pringle and Wade, 1985; Drechsel *et al.*, 1987; Sahade *et al.*, 1990).

1.1 Basic Equations and Their Solution

Let P, T, and ρ represent pressure, temperature, and density at a distance r from the center of a spherically symmetric star, and $M(r)$ and $L(r)$ represent the mass and luminosity interior to that point. Then the increase of mass with radius can be described as

$$\frac{dM(r)}{dr}=4\pi r^2\rho. \tag{1}$$

The condition that the star be neither expanding nor contracting rapidly (hydrostatic equilibrium) is that the inward force of gravity on a fluid element at r be balanced by the pressure gradient across it, that is,

$$\frac{dP}{dr}=-\rho\frac{GM(r)}{r^2}. \tag{2}$$

Nuclear energy generation is represented by the quantity ϵ in erg g^{-1} s^{-1} as a function of T, ρ, and chemical composition. Thus for a static star, the increase of luminosity outward is given by

$$\frac{dL(r)}{dr}=4\pi r^2\rho\epsilon. \tag{3a}$$

If some portion of the star is expanding or contracting rapidly compared to the time scale of the nuclear processes, then

$$\frac{dL(r)}{dr}=4\pi r^2\rho\left(\epsilon-\frac{dU}{dr}-\frac{P}{\rho^2}\frac{d\rho}{dt}\right), \tag{3b}$$

where the additional terms are the rate of change of internal energy per gram U, and the PdV work being done, where specific volume V has been replaced by its reciprocal ρ. At this point it becomes clear that integrating the equations together will require an equation of state, that is, analytic expressions or tables for $P(\rho,T)$ and $U(\rho,T)$ for each chemical composition of interest.

Finally, the gradient dT/dr follows for each possible mode of energy transport. Conduction is unimportant in stars (except for degenerate white dwarfs and neutron stars). Energy transport by radiation is opposed by the opacity of the gas, expressed by κ, defined so that $\kappa\rho dx$ is the fraction of the energy of a beam of light lost in traversing a distance dx. Then

$$\frac{dT}{dr}=\frac{3\kappa\rho L(r)}{16\pi r^2 acT^3}, \tag{4a}$$

where a is the radiation constant and c the speed of light.

If this temperature gradient is so steep that a test volume of fluid displaced from equilibrium position keeps going, then convection sets in and establishes a temperature gradient very close to the adiabatic one,

$$\frac{dT}{dr}=\left(1-\frac{1}{\gamma}\right)\left(\frac{T}{P}\right)\frac{dP}{dr}, \tag{4b}$$

where γ is the ratio of specific heats. This equation and the criterion for whether Eq. (4a) or Eq. (4b) applies become more complex in regions where there is a gradient of chemical composition.

A large fraction of the work in studies of stellar structure and evolution goes into getting the right numerical values for κ, ϵ, and the equation of state. Near the center of the sun, ϵ is 10–100 erg g^{-1} s^{-1}, κ is 0.01–0.1 cm^2/g, and T, ρ, and P are 1.5×10^7 K, 150 g/cm^3, and 6×10^{15} dyn cm^{-2}.

The main difficulties in solving these equations come from their nonlinearity, the large range of orders of magnitude involved, and the fact that not all the boundary conditions are known at either center or surface. In addition, there are numerical instabilities where M, L, and r go to zero together at the center. The usual strategies involve

1. a change of variables from physical ones to ratios like $q=M(r)/M$ and $p=P(GM^2/4\pi R^4)^{-1}$,
2. guessing the unknown boundary conditions, including P and T at the center and L and r at the surface,
3. standard approximations for getting started at the center and guessing suitable surface T and P, and
4. starting integrations from both directions and adjusting the guessed boundary conditions until the integrations meet up adequately at some intermediate point.

An initial stellar model must be obtained by this sort of (Schwarzschild) method. Numerically more satisfactory methods were developed about 1960 by Louis Henyey (see, e.g., Collins, 1989, for details). These methods require an initial approximate model (for instance, a chemically homogeneous Schwarzschild model or the one just obtained at the previous step in an evolutionary calculation). The independent variable is normally M rather than r, and the equations are expressed as finite difference equations across zones $i=1$–N, for instance

$$\frac{P_{i+1}-P_i}{M_{i+1}-M_i}=\frac{GM_{i+1/2}}{4\pi r^4_{i+1/2}}. \tag{2'}$$

The initial model is used to evaluate the quantities on the right-hand sides of all the equations, and the surface boundary conditions come from a separate model atmosphere calculation. There are then $4N-4$ equations in $4N$ unknowns, which can be solved by a Newton–Raphson iteration scheme.

To calculate an evolutionary track, the modeller takes a small forward time step, calculates the compositional changes resulting from nuclear reactions, and uses the previous model as the starting point for a Henyey calculation of the correct structure at the later time.

Most of the necessary cleverness goes into doing this in an acceptably short time. When Schwarzschild and others began calculating stellar evolution tracks in the late 1940s, they used desk calculators. A starting model took a day, and a track to the point where a star had exhausted its hydrogen fuel took a month. By the late 1960s, Henyey codes were running at many university and observatory computer centers, to which you carried your box of cards and returned later in the day for the printout resulting from about an hour of CPU time. Stellar evolution at this level of sophistication in the late 1980s fits on an office machine, and the answer comes out before you have had time to think what it is going to mean. Current research is thus focused on more complex cases, including nonspherical stars, ones that are rotating, pulsating, losing mass, or interacting with companions, and late evolutionary phases where many different nuclear reactions are simultaneously releasing and soaking up energy and changing the chemical composition (none of them having had time to come into equilibrium).

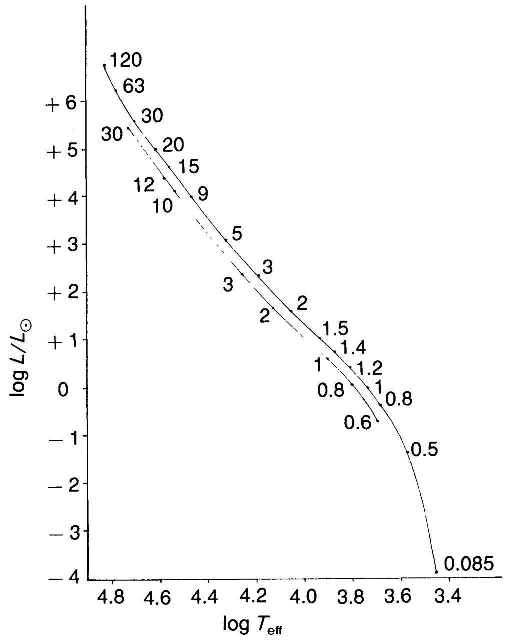

FIG. 1. Plot of log ($L/L_\odot$) ($L_\odot$=luminosity of the sun=3.86×10^{33} ergs/s) vs log T_{eff} (approximately surface temperature) of homogeneous, main sequence stars, so called because stars spend most of their lives in this core-hydrogen-burning phase, and thus most of the stars in a volume-limited sample will be in this phase. The parallel sequence to the left represents stars with 1%–10% of the metal abundance found in normal main sequence stars. Such subdwarfs dominate the old, halo population of our galaxy. Masses (in units of the mass of our sun) are indicated for representative stars along each sequence.

1.2 Main Sequence (Core Hydrogen-Burning) Stars

Models of chemically homogeneous stars of about 73% hydrogen, 25% helium, and 2% heavier elements (by mass and in standard proportions like those found in meteorites and spectroscopically at the solar surface) have the range of mass, luminosity, surface temperature, and radius and the correlations of those properties characteristic of real main sequence stars (Fig. 1, and see ASTRONOMY). The mass range is about $(0.08–100)M_\odot$ ($M_\odot$= the mass of the sun $=2\times10^{33}$ g). The lower limit is set by the need for the central temperature in hydrostatic equilibrium to be high enough for proton kinetic energies to get them over the Coulomb barrier so they can fuse, and the upper one by the stars becoming so luminous and unstable that material is blown off their surfaces by radiation pressure and pulsation.

Numerical models confirm analytic results (Schwarzschild, 1958) that, roughly, $L\propto M^3$ for bright stars and $M^{4.5}$ for fainter ones, $R\propto M^{1/2}$, and $T\propto M^{3/4}$. Since the fuel store is proportional to M, stellar lifetimes scale as M^{-2} or steeper (except close to $100M_\odot$, where $L\propto M$ and all stars have about the same 10^6-yr lifetime, compared to 10^{10} yr for $1M_\odot$).

A cloud of mostly hydrogen gas becomes a star when it has contracted and heated enough for hydrogen fusion to release as much energy as is being radiated from the surface, so that contraction stops. The nuclear reactions involved are those originally specified by Hans Bethe in 1939 (Rolfs and Rodney, 1988). Hydrogen atoms fuse either directly via the weak interaction ($H^1+H^1\rightarrow H^2+e^++\nu_e$, plus subsequent reactions) or via the strong interaction (but with intervening beta decays) with C, N, and O as catalysts (starting with $C^{12}+H^1\rightarrow N^{13}+\gamma\rightarrow C^{13}+e^++\nu_e$). These sets of reactions are known as the *proton-proton* (*pp*) and the *CNO chain cycle*, respectively. Some of the subsidiary reactions produce neutrinos of MeV energy, and the detection of them coming from the sun (albeit at only about 1/3 the expected level) constitutes direct confirmation that stars run on nuclear energy.

In either case, $4H\rightarrow He+30$ MeV (several percent of which is lost in neutrinos). Since a star can exhaust the hydrogen in about the inner 10% of its mass before drastic structure changes occur, the main sequence lifetime of a $1M_\odot$ star is about 10 Gyr. Diffusion and convective processes can lengthen stellar lifetimes by somewhat uncertain amounts (perhaps 10%) by bringing in fresh fuel.

Main sequence stars of less than about 1.5 $M_\odot$ run primarily on direct *pp* fusion. They have radiative cores, but convective envelopes, because hydrogen goes from neutral to ionized just below the surface, producing a zone of high opacity and steep temperature gradient [Eq. (4a)]. Stars above $1.5M_\odot$ have hydrogen ionized throughout, and thus radiative envelopes, but convective cores because CNO-catalyzed fusion produces most of the energy, and its reaction rate is a steep function of temperature, resulting in a steep central dT/dr. There are associated differences between low- and high-mass stars in how they generate magnetic fields, hot layers (chromospheres and coronae) above their surfaces, surface activity (like sunspots and flares), and winds (see SOLAR RADIATION). No star has convection in both envelope and core, and so the surface composition remains unaffected by interior nuclear reactions and reflects what the star was born with.

An initial composition less rich in heavy elements than the solar 2% produces stars that are somewhat bluer for a given luminosity (because you see deeper into them) and differ in the sizes of their convective envelopes and cores. They are called subdwarfs, make up the stellar population of the halo of our galaxy, and are left from early galactic evolutionary phases when very few heavy elements had yet been made in stars. The lifetime of a subdwarf that is just now leaving the main sequence sets the best lower limit we now have to the age of the universe. Unfortunately, uncertainties in the distances (hence luminosities) of these stars, in their abundances of helium and certain heavy elements, and in the effects of diffusion and convection still leave those lifetimes uncertain over a range of at least 11–15 Gyr.

1.3 Evolution Off the Main Sequence

Exhaustion of the central hydrogen fuel supply causes the core of a star to contract, since energy is still flowing out of it. The outer layers of the star expand, giving rise to red giants and supergiants, in which the main energy source is hydrogen fusion (always via CNO catalysis) in a thin layer around the helium core. Subsequent events and their time scales depend largely on the initial mass of the star and produce types of stars called horizontal branch, clump, and asymptotic giant branch stars, from their positions on plots of luminosity versus surface temperature (see Fig. 2, Renzini and Fusi Pecci, 1988, and ASTRONOMY).

Initial masses less than about $0.4M_\odot$ burn only hydrogen and leave behind degenerate cores (white dwarfs, see below) of nearly pure helium. The universe is not yet old enough for this to have happened to single stars, but such helium remnants are known in binary systems, where transfer of material from one star to the other has interrupted the evolution of an initially more massive star.

In stars above $0.4M_\odot$, the temperature of the contracting core, fed by hydrogen shell burning, rises to 10^8 K and helium fusion sets in (as a somewhat explosive helium flash in stars below $1.5M_\odot$ whose cores are already partially degenerate, peacefully in larger masses). The reactions $3\text{He}^4 \rightarrow \text{C}^{12} + \gamma$ and

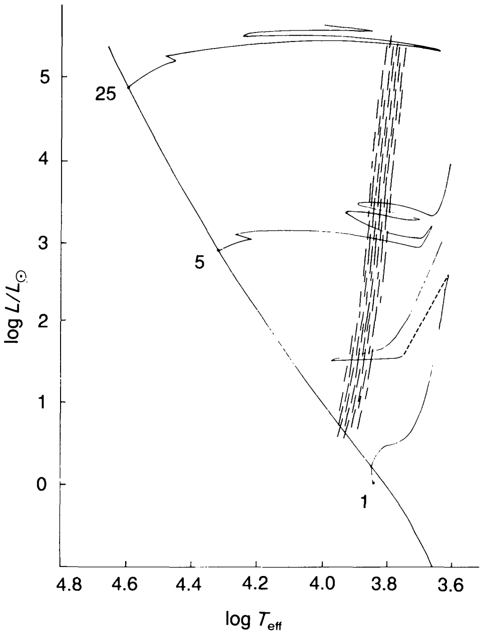

FIG. 2. Post-main-sequence evolution of stars of $25M_\odot$ (from Chiosi and Maeder, 1986), $5M_\odot$ (from Collins, 1989), and $1M_\odot$ (from Bowers and Deeming, 1984; posthorizontal branch from Chiosi *et al.* in Kwok and Pottasch, 1987). Hatched zone is the pulsational instability strip, with Cepheid variables at log $L = 3$–5, RR Lyrae variables near log $L = 1.5$, and δ Scuti stars on the main sequence. Solar composition (2% heavy elements) except for the $1M_\odot$ and its horizontal branch descendent of $0.62M_\odot$ which have 0.1% heavy elements. Evolution from red giant to horizontal branch phase (helium flash) is rapid and has not been modeled in full detail; thus it is shown as a dotted line.

$C^{12}+He^4 \rightarrow O^{16}+\gamma$ occur with comparable probabilities, so that helium burning produces roughly equal amounts of carbon and oxygen (as we observe). Interactions of zones burning hydrogen and helium can release free neutrons which are captured by iron already present in second-generation stars to produce about half of the still heavier elements (called *s*-process nuclides because the neutrons are captured slowly compared to beta-decay time scales).

Following helium core exhaustion, the star is fueled by both hydrogen and helium burning in thin shells, and becomes bright, distended, and unstable to convection in several layers. As a result, first, products of interior nuclear reactions, for the first time, reach the surface of the star, and, second, a large fraction of the initial mass is blown off in a wind. The ejecta are visible as a circumstellar shell, called a planetary nebula if the residual core is hot enough to ionize the material. Nuclear reactions stop at this point, leaving a carbon–oxygen core (CO white dwarf) if the star is stripped down to less than the mass needed to get hot enough to burn carbon (about $1.3M_\odot$ and 2×10^8 K). This happens for all or most stars initially less than at least $(5–6)M_\odot$ and possibly up to $(7–8)M_\odot$.

More massive stars fuse carbon. The dominant reactions are $C^{12}+C^{12} \rightarrow Ne^{20}+He^4$, $Na^{23}+p$, or $Mg^{23}+n$. At slightly higher temperatures, neon burns, then oxygen (with Mg, Si, and S among their products). Mass loss from the stellar surface continues, and a few stars are quenched during these reactions to leave degenerate cores of O, Ne, and Mg. More often, temperatures continue to rise toward 10^9 K, where silicon (made in Ne and O burning) in turn burns via $Si^{28}+\gamma \rightarrow 7He^4$, $Si^{28}+7He^4 \rightarrow Ni^{56}$. The Ni^{56} undergoes beta decay to Fe^{56}, producing a gradually growing iron core at 10^9 K and 10^9 g/cm^3. The core has no further nuclear energy sources available, and, when its mass has grown to the maximum value supportable by degenerate electron pressure, it will collapse suddenly and catastrophically (see Supernovae, below).

In addition to the nuclear reactions already mentioned, rapid capture of neutrons (*r*-process) produces additional elements heavier than iron, probably during supernova explosions. Cosmic rays hitting interstellar atoms contribute lithium, beryllium, and boron, and other rare processes make nuclides with relatively high p/n ratios. The sum of known processes, mostly in stars, accounts for the full range of stable nuclides, in roughly the proportions we see them. Some fine tuning occurs as supernova shock waves pass out through the layers of overlying heavy elements (see Rolfs and Rodney, 1988, for further details).

The last few burning stages in stars above $10M_\odot$ occupy less than 10^3 yr; thus core instability can overtake a star either when it is a red supergiant or on one of its swings back to higher surface temperature and blue color (as was the case for the progenitor of supernova 1987A).

Post-main-sequence evolution takes many stars through a range of L and T where the hydrogen and helium ionization zones just below the surface act like taps or faucets, releasing energy at high temperature and bottling it up at low. The resulting instability causes stars, including the Cepheid and RR Lyrae variables, to pulsate in radius, temperature, and luminosity on a time scale close to the free-fall time, $t=(G\rho)^{-1/2}$, and so to display relationships among their pulsation periods (hours to weeks), colors, and luminosities. Thus we can measure their distances and use them to trace out the structure of our galaxy and the distances to other galaxies. Detailed modeling of pulsation properties also provides an independent check of the correctness of interior models.

1.4 The End Points of Stellar Evolution

1.4.1 Planetary Nebulae and White Dwarfs. The existence of stars fainter than the main sequence was recognized early in the century. Their colors and small sizes (about the same as the earth, from measured temperatures and luminosities) prompted the name white dwarfs, though blue, yellow, and red ones are known. Well-observed white dwarfs trace out almost as tight a temperature-luminosity relation as the main sequence (it is a cooling curve), but about a factor of 10^4 fainter. Some of the hottest, brightest ones are still encircled by remnants of the envelopes of their parent stars. These are called planetary nebulae only because of their vague resemblance to Uranus and Neptune when seen through small telescopes.

They are enriched in He, N, C, and O, products of nuclear reactions in their parent stars.

A few white dwarfs in binary systems have measured masses of $(0.4\text{–}1.2)M_\odot$. Spectroscopic analysis of many more indicates an average near $0.6M_\odot$ (Philip *et al.*, 1987). Most rotate more slowly than conservation of angular momentum from the main sequence would suggest; braking by magnetic winds must continue throughout stellar life. A few percent have present magnetic fields of 1–200 MG (enough to remove the degeneracy of even hydrogen atomic states and produce remarkably complex Balmer line spectra); most of the rest are less than 1 MG.

Measured masses and radii yield average densities near 10^6 g/cm^3. At this density and the interior temperature of 10^7 K, electrons are degenerate. That is, there are more of them than there are available quantum states in phase space (two electrons per box of size $\Delta x \Delta p = \hbar$). The electrons thus necessarily occupy states of higher than thermal momentum (the energy having come from nuclear reactions and gravitational potential energy as the stellar core contracted during post-main-sequence evolution). Such electrons cannot readily change their momenta and have long mean free paths, leading to energy transport by conduction and isothermal interiors.

Degenerate electrons have a unique $P(\rho)$ and $U(\rho)$ equation of state, giving rise to a unique mass-radius relation for white dwarfs (Fig. 3; Chandrasekhar, 1939). In the absence of general relativistic effects, the radius would shrink to zero at a mass of about $1.44M_\odot$ (for He, CO, or ONeMg composition), called the Chandrasekhar limiting mass. In fact, relativistic and particle physics effects lead to rapid gravitational collapse for a white dwarf with mass just below that limit. And indeed we observe no larger ones.

Among the outstanding problems in white dwarf research (Philips, 1987) are the rate of cooling of the reddest (which should lead to an independent estimate of the age of the galaxy), the origin and thickness of the very thin layers of H and He found on most white dwarfs, and the existence of at least three categories of pulsating white dwarfs, each with its own instability strip in the temperature-luminosity plane.

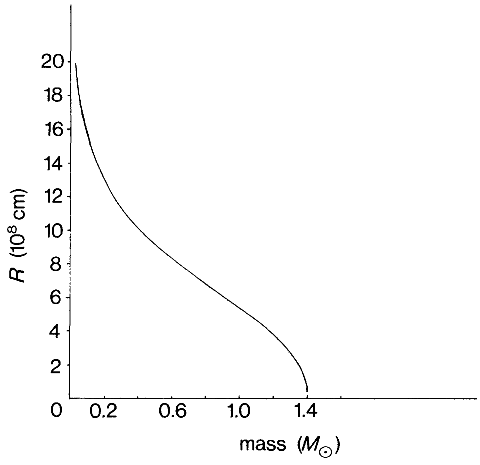

FIG. 3. Radius vs mass (Chandrasekhar, 1939) for zero-temperature degenerate dwarf with mean molecular weight per electron $\mu_e=2$ (e.g., pure He^4, C^{12}, O^{16}, Ne^{20}, etc.). In real stars, radii are increased 10% or so by finite temperatures, nondegenerate atmospheres, rotation, and magnetic fields. Effects of general relativity and particle interactions cause core collapse at about 90% of the mass at which radius vanishes in the idealized calculation. For other compositions, radius coordinates scale as μ_e^{-1} and mass as μ_e^{-2}.

1.4.2 Supernovae, Neutron Stars, and Pulsars. That neutrons as well as electrons could be degenerate was recognized very shortly after the discovery of the neutron in 1932; and the collapse of a normal star to a star made largely of neutrons was suggested as the energy source for stellar explosions by Baade and Zwicky in 1934. The 1968 discovery of a rapidly rotating magnetic neutron star (pulsar) in the center of the remnant of an explosion seen by the Chinese in 1054 (the Crab Nebula) triumphantly confirmed their main ideas (see Israel in Hawking and Israel, 1987, for more history).

About 500 pulsars are now known, including a handful in binary systems from which masses near $(1.4\text{–}1.5)M_\odot$ can be measured. The pulsed radio emission represents a searchlight effect when radiation beamed along the direction of powerful magnetic field lines sweeps across us. Most fields are $10^{12\pm1}$ G, and rotation periods range from 1.55 ms to 4 s. Fields apparently decay in $10^{6\text{–}7}$ yr, so that our galaxy must have 1000 or more times as many dead pulsars as live ones. A somewhat smaller number of neutron stars are found in binary systems (Sec. 1.5.2). The total number of known pulsars and binaries and their lifetimes are consistent with the measured supernova rate of a few per century in a largish, bright galaxy like ours.

In fact, there are at least two types of the powerful stellar explosions called supernovae. Those seen among young, massive stars result from iron core collapse (Sec. 1.3), liberate $(1–3)\times 10^{53}$ ergs (mostly in neutrinos), and leave both neutron stars and expanding gas clouds behind, the energy being the binding energy of the $1.5M_\odot$, 10 km neutron star. Those seen among older, less massive stars draw their energy from the nuclear deflagration of about $1M_\odot$ of C and O to Fe, and liberate only about 10^{51} ergs, mostly in kinetic energy of the disrupted stars, thus leaving only an expanding gaseous remnant. The progenitors seem to be white dwarfs in close binaries. Core collapse events are called Type II, nuclear events Type I or Ia.

In February 1987, a supernova in the nearby Large Magellanic Cloud galaxy rose to naked-eye visibility. Called 1987A (only because it happened to be the first supernova seen that year), it has confirmed our basic understanding of core collapse events (Trimble, 1988; Arnett *et al.*, 1990). The detected neutrino flux implied a total energy of $(2–3)\times 10^{53}$ ergs, and optical observations of both the progenitor star and the postexplosion object indicate that the collapse occurred inside a star of initial mass near $20M_\odot$ that had lost about half its envelope in winds.

Supernova explosions distribute through interstellar space the heavy elements synthesized by their progenitor stars and contribute much of the heating and turbulence that keeps interstellar gas in a state where star formation proceeds on a time scale of 10^{10} rather than 10^6 yr. Perhaps the thorniest problems connected with supernovae are

1. the precise progenitors of nuclear-deflagration events (white dwarf accreting from a companion? merging pair of white dwarfs?) and
2. the physical process that transfers 1% of the energy from core collapse to the envelope of a massive star to blow it off.

1.4.3 Black Holes. The maximum mass that can be supported by degenerate neutron pressure is much less certain than the Chandrasekhar limit to white dwarf masses. It depends on the poorly known, repulsive, short-range part of the nuclear potential and could be as small as measured neutron star masses [$(1.4–1.5)M_\odot$] or as large as $(2.5–3.0)M_\odot$. It must be near the low end of this range if any neutron star is to be compact enough to spin 2000 times a second. Notice that the masses measured by an observer at infinity are about 10% smaller than the baryonic masses that collapsed to form them, because of binding energy of the neutron star.

In any case, we expect at least some massive stars to be left with cores above that limit, and/or for later accretion to drive the remnant mass above it. Such cores, as was shown by Oppenheimer and Snyder (1939), will experience continued gravitational collapse until they reach radii less than $R=2GM/c^2$ and their escape velocities exceed the speed of light. The impossibility of receiving electromagnetic or other signals from within this radius, called the Schwarzschild horizon, is responsible for the name black hole.

The detailed properties of space-time in and around these collapsed objects present intriguing problems in general relativity (Thorne *et al.*, 1986) and are by no means uncontroversial. Quantum mechanical properties of black holes, including their potential for boiling away via Hawking radiation (Israel in Hawking and Israel, 1987), are not definitely connected with any observable phenomena.

From an astrophysical point of view (Blandford in Hawking and Israel, 1987) the important (and not controversial) properties are the existence of objects with sizes close to their Schwarzschild radii, so that accretion onto them must liberate an appreciable fraction of the rest mass of the accreted material, which will inevitably be heated thereby and radiate copiously. Isolated, nonaccreting black holes would seem to be detectable only as gravitational lenses, bending the light of background objects. No promising candidates are known.

The first, and still most persuasive, candidate for a stellar-mass black hole is the x-ray binary Cygnus X-1. The main points are that

1. it is an x-ray source with luminosity of about the maximum permitted before radiation pressure begins to blow a $(1–10)M_\odot$ object apart [Eddington luminosity $=(4\pi c m_p G/\sigma_t)\times M=6\times 10^{24}$ ergs/g,

where σ_t is the Thomson cross section], and so must contain a compact star,

2. the minimum mass of the compact component consistent with the binary orbit, light curves, and so forth is about $6M_\odot$, too large for a neutron star, and
3. the system is too compact for the x-ray component to consist, for instance, of a neutron star (providing the x rays) and a $5M_\odot$ main sequence star.

A handful of less well established cases include other systems in the Milky Way (SS 433 and A0620-00) and two (LMC X-3, LMC X-1) in the Large Magellanic Cloud.

The other context in which the existence of astrophysical black holes is generally regarded as established is as the central powerhouse in active galactic nuclei (see GALAXIES AND COSMOLOGY).

1.5 Binary Stars

Between 50% and 90% of stars are part of binary or multiple systems (distant faint companions being difficult to detect, their statistics are uncertain). In about half of these, in turn, the stars are close enough together to transfer material back and forth or otherwise influence each others' evolution (= close binaries). The result is a variety of phenomena not elsewhere possible.

Binaries are detected as such and studied by several methods, including

1. measuring positions of the images of the two stars over most of an orbit period (visual binaries, possible only for wide systems quite close to us),
2. following the changing position of an image centroid (astrometric binaries),
3. following the wavelength changes (Doppler shifts) of the absorption or emission lines of one or both stars (spectroscopic binaries), and
4. measuring the changing brightness through the orbit period as one star passes in front of the other (eclipsing binaries).

To the rest of astronomy, the chief importance of binary stars lies in the possibility of measuring stellar masses from the orbital periods P and semimajor axes a_1 and a_2 of the stars about their common center of mass using Kepler's third law,

$$G(M_1+M_2)P^2=4\pi^2(a_1+a_2)^3, \tag{5}$$

and the definition of center of mass,

$$M_1a_1=M_2a_2. \tag{6}$$

In general, this is possible only for visual binaries of known distance and for eclipsing spectroscopic binaries where two sets of lines are seen. The number of accurately known stellar masses is less than 200, and more are badly needed, especially for very bright, very faint, and highly evolved stars.

The evolutionary course of a binary system depends primarily upon the masses of the two stars and their separation, all of which can and do change from their initial values by large factors. The resulting richness of observational phenomena (variability, nonthermal emission, emission lines,...) has given rise to something like 50 different recognized types of binaries (often named for a prototype star like Algol, RS Canum Venaticorum, or SS Cygni) and some risk of botanization of the subject. Modeling of binary evolution consists of trying to keep track of the changes in mass and separation while the components attempt to pursue normal single-star evolutionary tracks and are frustrated in this by their partners. Nevertheless, it seems possible to fit most observed types into physically plausible scenarios and to find observed systems corresponding to most predicted evolutionary stages (Pringle and Wade, 1985; Sahade *et al.*, 1990).

About one binary in five or six actually consists of three or more stars, the highest known multiplicity being eight. Systems are hierarchical, with the ratio of one separation to the next being at least a factor of seven. The main effect seems sometimes to be to complicate orbit analysis beyond deconvolution.

1.5.1 Main-Sequence and Post-Main-Sequence Binaries. The classical problem in binary-star astronomy was the existence of large numbers of Algol variables, eclipsing spectroscopic pairs in which the more evolved (red giant) component was invariably less massive than the less evolved (main sequence) component, violating the well-established and -understood correlation of stellar lifetimes being proportional to about M^{-2}. The solution lies in the possibility of efficient transfer of material from one star to the other, which, in turn, arises from the geometry of the gravitational equipotential surfaces in a coordinate system that rotates with the system (Fig. 4, which is a two-dimensional cut along the axis through the centers of the two stars and should be visualized as rotated around an axis through the points L_1 and L_2—horizontal in the figure).

The closest-in equipotential enveloping both stars is called the Roche lobe (or inner Lagrangian surface); the point on it between the stars, L_1; and the point where an equipotential first connects with the outside world, L_2. Two time scales are important for the evolution of stars within this geometry—the thermal (or Kelvin–Helmholtz) time on which a star would radiate away its internal energy and on which it can readjust its structure when mass or energy is added or subtracted (10^7 yr for the sun), and the nuclear time scale, over which a significant fraction of the hydrogen or other fuel is used up (10^{10} yr for the sun on the main sequence).

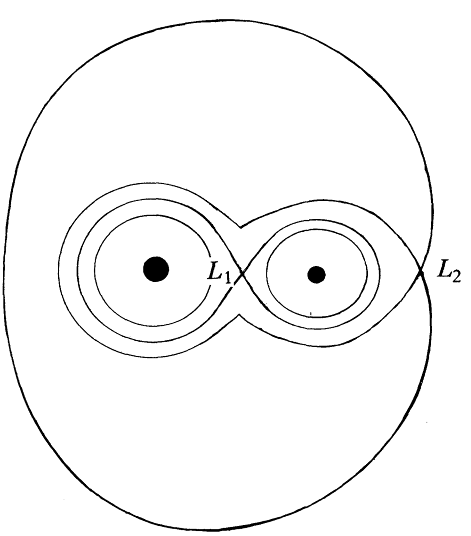

FIG. 4. Equipotential surfaces in the rotating coordinate system of a binary with initial masses in the ratio 2:3. The larger Roche lobe surrounds the more massive (and larger) star, the two lobes meeting at point L_1. A star which expands to fill its lobe can drizzle material onto its companion with high efficiency. There also exist contact systems in which both stars fill their lobes (orbit periods generally less than one day) and common envelope systems in which (usually as a result of rapid mass transfer) material extends out as far as L_2 and can be lost from the system, carrying energy and angular momentum with it. If the stars are assumed to be main sequence stars of (3 and 2)$M_\odot$ with the radii to scale as shown, then the orbit period would be about six days.

Consider two main-sequence stars separated by less than 100 or so stellar radii. The more massive, M_1, will use up its H first and begin to expand as it tries to become a red giant. Eventually it will fill its Roche lobe (subsequent details depending a good deal on whether it does this during core H burning, shell H burning, or shell He burning), and material is then free to stream exoergically down from L_1 onto M_2. The Roche lobe around M_1 shrinks, and so mass transfer occurs rapidly, on the thermal time scale, until the initial mass ratio is reversed and $M_2' > M_1'$. The Roche lobe then expands with further transfer, which therefore continues over the much longer nuclear time scale. Hence we see most systems with the mass ratio already reversed, resolving the traditional Algol paradox. Mass and angular momentum can also be lost completely from the system when, as often happens, transferred material forms a common envelope around both stars and reaches L_2.

In subsequent evolutionary phases, M_1' becomes a white dwarf, neutron star, or black hole (depending upon its mass); and M_2' completes its main sequence life, begins to expand, transferring material back onto the now-compact M_1'. M_2' eventually evolves also to a white dwarf, neutron star, or black hole, the system sometimes being disrupted in the process, but not always. Notice that at the time M_1' sheds a planetary nebula or becomes a core-collapse supernova, it contains less than half the total system mass; thus symmetric ejection from it cannot unbind the system. M_2', on the other hand, contains more than half the total mass at its demise.

1.5.2 Cataclysmic Variables, X-Ray Binaries, and Binary Pulsars. Transfer from the main-sequence or red-giant secondary back onto a white dwarf, neutron star, or black hole primary occurs for orbit periods of minutes to months, and the gas stream from L_1 always has far too much angular momentum to settle directly onto the compact recipient. Thus the gas is spun into an accretion disk (Fig. 5), and detectable light is possible from the disk, the gas stream, and a hot spot where they meet, as well as from the two stars. All these components are seen in some systems. Variability in luminosity and spectrum can be expected on time scales associated with the system orbit period, rotation of each of the

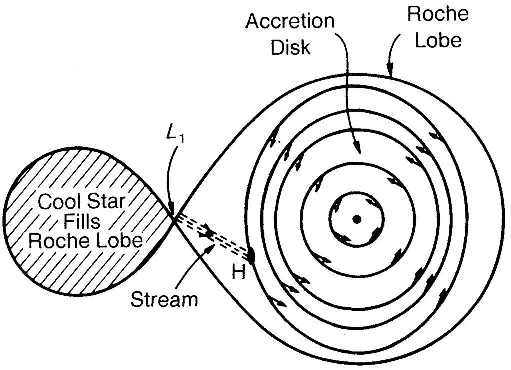

FIG. 5. Idealization of a highly evolved binary, in which an extended secondary is transferring material through L_1 back onto a compact (white dwarf, neutron star, black hole) primary. Diagram is drawn for a mass ratio compact:normal of about 1.5. Transferred gas has too much angular momentum to settle directly onto the compact object and so forms an accretion disk, with a hot spot where the gas stream hits the disk. Gradual outward transport of angular momentum in the disk (presumably by magnetic fields and turbulence) allows accretion onto the star, liberation of gravitational potential energy, and radiation of that energy.

stars, orbit periods in the disk, and assorted instabilities in both stars and disk. Again all of these are seen somewhere. The depth of the gravitational potential well determines that accreting white dwarfs will be sources of visible, UV, and soft x-ray radiation, while neutron stars and black holes will produce largely x rays and sometimes γ rays.

Systems with white dwarf recipients are the cataclysmic variables, including novae, dwarf novae, polars (where the white dwarf has a 10–40 MG magnetic field), and many others. Most of the light variations come from instabilities in the stars and disk, but the largest, nova, outbursts, in which 10^{44-45} ergs are emitted over a few weeks, represent explosive burning of a layer of degenerate hydrogen that has accumulated on a white dwarf surface over the past 10^{2-5} yr.

Most or all of the accumulated material is blown off in most cases. If the white dwarf can burn and keep the transferred material, this would provide a mechanism to drive an old white dwarf above the Chandrasekhar limit, producing a Type Ia supernova. Merger of two white dwarfs after the second star has completed its evolution is another possibility. At the moment, many binary white dwarfs are known, but none has sufficiently large total mass and short enough orbit period that an explosive merger could occur over the next 10^{10} yr.

Systems with neutron-star and black- hole recipients are the x-ray binaries. The black hole candidates are distinguished by

1. masses too large for stable neutron stars and
2. absence of periodic variations on the 1–1000-s time scale of neutron star rotation.

Again there are many subtypes, including young ones with companions more massive than the neutron star and old ones with less massive (down to $0.05M_\odot$) companions. Accreted hydrogen normally burns steadily, but the product helium can accumulate and explode in some systems, producing x-ray bursts lasting a few tens of seconds. Finally we have detected (initially with the Vela satellites, meant for monitoring nuclear explosions) several hundred short bursts of keV to MeV gamma rays. None of the sources has an unambiguous optical, x ray, or radio identification, and the population is remarkably isotropic around the sky (while pulsars and x-ray binaries are concentrated in the plane and toward the center of our galaxy). These gamma ray burst sources are successfully modeled as nuclear explosions on magnetic accreting neutron stars, but they could be something entirely different and perhaps extragalactic.

Neutron stars in close binaries are never seen as pulsars as long as the companion is a main-sequence or red giant star because stray gas from it keeps the local plasma frequency above the range of pulsar radiation. Once the second star becomes a white dwarf or neutron star, pulsar radiation can emerge. The number of known binary pulsars (12 at epoch 1989.7) is increasing rapidly. There are a few each with established white dwarf and neutron star companions, and orbit periods range from hours to months. In most cases, the pulsar displays a weak magnetic field near 10^9 G (as a result of more than 10^7 yr of decay) but a short rotation period of 1–100 ms (as a result of spin-up by gas transferred from the companion before it became compact). The handful of known weak-field, short-period single pulsars are thought to be former members of similar systems, liberated by the explosion of the companion or its gradual erosion. In principle, systems with two pulsars, one old and one young, should be possible, but none is currently known.

2. INTERSTELLAR MATTER AND THE FORMATION OF STARS

2.1 Structure and Kinematics of the Interstellar Medium (ISM)

Diffuse interstellar gas and dust make up roughly 10% of the (luminous, baryonic) mass of our galaxy. Of this $\sim 10^{10} M_\odot$, about 99% is gas (molecular, atomic, and ionized) and 1% is micron and submicron sized dust particles. The chemical composition is that of young stars, 73% hydrogen, 25% helium, and 2% heavier elements (in the same proportions as in the sun and meteorites), half of which is locked up in the grains of dust. The ISM shares the rotation of the galactic star disk and is the best tracer of it, since gas, being dissipative, cannot long sustain large chaotic noncircular motions.

Other spiral galaxies also have 5%–15% of their luminous material in gas and dust with properties much like that in the Milky Way. Irregular galaxies can be up to 50% ISM by mass, and the heavy-element abundance is normally lower. Elliptical galaxies are often free of neutral interstellar gas down to limits much less than 1% of their total masses, but many show emission lines from ionized gas (typically near the center), dust lanes (implying dense molecular gas), or x-ray emission implying up to 10% of their masses in ionized gas above 10^6 K.

Scheffer and Elsaesser (1987) provide a general introduction to the ISM; many of the detailed observations and processes are discussed in Hollenbach and Thronson (1987) and in Tenorio-Tagle *et al.* (1990).

2.1.1 Phases of the Interstellar Medium. Table 1 summarizes the components presently believed to coexist in the ISM. All, except probably the coronal, are very clumpy in both physical and velocity space. The components are many, partly because sources and sinks of both gas and energy are patchily distributed and partly because gas cooling rates (Fig. 6) are a complex function of temperature. With a cooling rate like that shown and constant heat input, pressure versus density takes the form shown in Fig. 7, so that there are two stable (and two unstable) phases in pressure equilibrium for the conditions that obtain in the ISM (for which the heating rate is very roughly $10^{-25} n_H$ erg/s, and the pressure in the equilibrium phases $nT = 3000$ K cm^{-3}).

In addition to the pressure equilibrium (cool neutral, warm neutral, warm ionized) phases, there are dense clouds of molecular gas, at higher pressure, but self-gravitating, so that, in the absence of additional turbulent and magnetic pressure support, they would collapse in their free-fall times, $t \approx (G\rho)^{-1/2} \approx 10^6$ yr. If this happened, the gas would all long since have been converted to stars (as in elliptical galaxies). These clouds are disrupted by the first generation of stars they produce and reform where less dense gas is swept together by magnetic pressure and expanding supernova remnants and stellar wind shells. A typical cloud has a mass of $10^5 M_\odot$ but is disrupted after forming a cluster of only 10^{3-4} stars, the process thus being not very efficient.

The chemistry of molecular clouds is exceedingly complex (Dalgarno in Tenorio-Tagle *et al.*, 1990) involving a combination of gas-phase reactions (usually with one of the reactants ionized) and molecule formation on dust grain surfaces followed by sputtering off. Some 50 distinct molecular and radical species have been found, primarily from emission lines in the microwave and infrared spectral regions. The largest numbers of distinct species occur in the densest clouds, at the galactic center and in the Orion Nebula. Many isomers (e.g., HCN and HNC) and isotopic variants ($C^{13}O$, CO^{18}, etc.) also exist.

H_2 is obviously the commonest molecule and observable only with difficulty (since it has no dipole moment). CO is the most abundant tracer, and the uncertainty in converting from number of CO molecules seen to number of H_2 molecules present is responsible for most of the disagreement about whether the molecular gas is at least half the total or only about one-quarter. Detected molecules include familiar substances like water, ammonia, methyl and ethyl alcohol, formaldehyde, and formic acid, and a number of the obvious radicals (OH, CH, CN), but also some combinations unknown in the laboratory like HC_9N.

Table 1. Phases of the interstellar medium.

Phase	Temp. (K)	Particle density (cm^{-3})	Scale height (pc)	Fraction of mass	Gas bulk speeds (km/s)	Fraction of volume	Observed phenomena	Heating processes	Cooling processes
Dust	5–40	10^{-12}	40	1%	2–4	Small	Reflection, extinction, polarization, reddening of starlight	Collisions, cosmic rays, photoabsorption	Thermal IR emission
Molecular clouds	10–30	10^{2-5}	60	1/3–1/2	2–4	Small	Molecular emission lines	Stellar radiation; collisions	Molecular lines, esp. CO
Neutral gas				1/2–2/3		35%			
Cool clouds[a]	80	30	100	1/4–1/3	7	5%	21 cm absorption & emission	Photoelectric heating by dust	Fine-structure lines of C, C^+, O, etc.
Warm intercloud[a]	8000	0.1–0.3	200	1/4–1/3	9	30%	H II emission lines	Photoelectric heating by dust	Atomic emission lines, esp. H
Ionized gas				10%		65%			
Warm ionized[a]	8000	0.1–0.3	⩾1000	10%	10–20	15%	Diffuse Hα emission	Stellar photoionization	Line emission of C, N, O, Ne
Coronal[a]	10^{5-6}	$10^{-3\pm1}$	⩾2000	Small	Up to 1000	50%	Soft x rays, coronal lines	Supernovae	Line emission and continua of H, C, O, He
H II regions	8000	⩾1–100	60	Small	10–30	Small	H recombination & ion emission lines	Individual stars	Emission lines

---

[a] Phases in approximate pressure equilibrium.

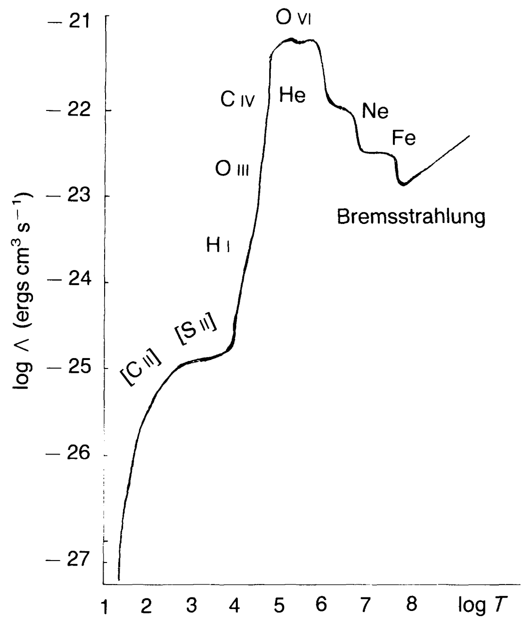

FIG. 6. Equilibrium cooling rate of interstellar gas in ergs cm^{+3} s^{-1} (The rate in ergs cm^{-3} s^{-1} is the plotted value times the square of the particle density) vs log T for average composition and ionization conditions. Ions shown are those that dominate the cooling at each temperature. [C II], etc., indicate forbidden transitions like the 158-μm line from a low-lying state of ionized C. Data from J. M. Shull in Hollenbach and Thronson (1987) and from B. Lazareff in Audouze *et al.* (1983).

The dust needed for H_2 formation consists (judging from its emission and absorption properties) of cores of silicates and carbon in several forms (graphitic, amorphous, and organic, perhaps polycyclic aromatic hydrocarbons) which form in the cool winds from evolved stars and in the ejecta from novae and supernovae. These are coated by mantles of ice (H_2O, CH_3OH, NH_3, CO, etc.) which they acquire in the dense molecular clouds.

Coronal gas, at the other end of the temperature range, emits the same sorts of lines of highly ionized species as does the solar corona (hence the name). It arises from interconnection of expanding supernova remnants. A topic of hot dispute is whether it occupies rather less than half, more than half, or essentially all of interstellar space. That is, do expanding supernova remnants sweep up all the diffuse gas they encounter into dense clouds, or do they manage to coexist with a comparable warm neutral and ionized phase? A good case can be made for the latter situation (Cox in Tenorio-Tagle *et al.*, 1990; Kulkarni and Heiles in Hollenbach and Thronson, 1987), which has been assumed in Table 1.

H II regions are residual molecular gas, left from star formation, ionized by the new, hot stars. Their sizes are set by the number of Lyman continuum photons emitted by the stars. Their pressures exceed that of the surrounding medium, so that they expand, opening up holes in the cool gas around them, as do winds from new stars. Where dust is copious, essentially all the radiation from these regions may emerge in the infrared.

The warm ionized gas contains most of the free electrons in the galactic disk. These account for the temporal dispersion of pulses received from pulsars and for the smearing of images of extragalactic radio sources. With n_e=0.3 cm^{-3} in that phase and $\langle n_e \rangle$=0.03 along the average pulsar line of sight, the filling factor must be about 10%. Given this distribution, the problems of heating and ionizing the interstellar medium largely decouple. The interstellar matter immediately surrounding the solar system belongs to this warm ionized phase (Cox and Reynolds, 1987).

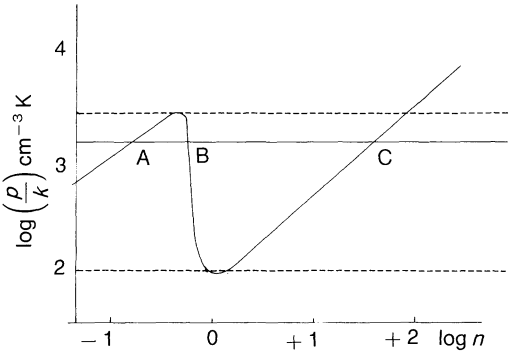

FIG. 7. Pressure (nT in cm^{-3} K) vs density (in cm^{-3}) for interstellar gas with constant heating rate and cooling vs temperature as shown in Fig. 6. For pressures between the dashed lines, several states have the same pressure. At any one P, like that indicated by the solid line, the phase B is unstable (because compression leads to lower P, not higher), while C represents the diffuse clouds and A the intercloud medium of neutral gas. There is a fourth, unstable, state at still lower density and T near 10^5 K, but gas at this temperature is in any case ionized, and the coronal component is not in equilibrium. Data from Scheffer and Elsaesser (1987) and from Shull in Hollenbach and Thronson (1987).

Pressure (or energy density) equilibrium of another sort exists among

1. motions of neutral gas clouds,
2. galactic cosmic rays, and
3. the galactic magnetic field.

All values are of order 1 eV/cm^3, the equipartition presumably resulting from physical interactions. The disk density of starlight energy is also about 1 eV/cm^3, which may be a coincidence. Cosmic rays are addressed in the article ASTRONOMY.

The magnetic field of the Milky Way (and of many other spiral galaxies) has a strength of a few μG in the galactic plane, with comparable energy densities in an ordered azimuthal pattern (aligned either with the spiral arms or with the circular gas motion) and in a chaotic component of scale length 10–100 pc (1 pc$=3\times10^{18}$ cm). The azimuthal component reverses direction at least several times across the galactic disk. Origin of the field has been attributed both to rotationally amplified primordial field and to a self-excited dynamo, with the dynamo models currently favored by most theorists (Zweibel in Hollenbach and Thronson, 1987). In addition to the azimuthal disk field, at least some spirals (including ours) have also field lines extending more or less vertically out of their planes to 1–2 kpc or more. This is thought not to be a separate component but to be a disk field dragged out by expanding supernova remnants and other gas flow structures. The field in the inner 50 pc is a dipole of mG strength (Morris, 1989, which addresses also many other important aspects of the galactic center).

2.1.2 Large-Scale Distribution and Motions of the ISM. The cooler gas phases, as indicated in Table 1, are largely confined to the galactic disk. That is, the distances over which their densities drop to 1/*e* of the in-plane values (scale heights) are 200 pc or less. In addition, the molecular clouds, especially the large ones, are concentrated

1. toward the galactic center,
2. in a ring at 4–6 kpc from the galactic center (on a scale where the sun is at 8.5 kpc), and
3. in the spiral arms of the galaxy (Scoville and Sanders in Hollenbach and Thronson, 1987).

Neutral hydrogen, on the other hand, is relatively sparse inward of 3 kpc but has roughly constant density from there out to 12 kpc and is measurable still further out. Both the molecular and the H I disks flare in their outer reaches. The outer part of the H I disk in addition is warped and rippled. These deviations from uniform flatness reflect the spherical shape of the outer galactic gravitational potential and interactions with the companion Large and Small Magellanic Cloud galaxies.

The extent of the galactic gaseous halo is an ancient topic of debate. The current consensus is (Tenorio-Tagle *et al.*, 1990) that coronal gas and the electrons persist out to at least several kpc. In addition, 15% or so of the H I clouds are outside 300 pc, some of them having large (often negative) velocities that are not obviously part of the general galactic rotation.

Gas is our best tracer of the galactic disk rotation because it does not readily sustain noncircular motions in the face of cloud collisions and dissipation. Out to the position of the sun, the most useful velocities come from Doppler shifts of the 21 cm line (hyperfine structure transition) of neutral hydrogen (H I), because there is no ambiguity about the position of the gas with the largest velocity along any given line of sight (see Mihalas and Binney, 1981, or Binney and Tremaine, 1987, for how the analysis is done). Outside the solar circle, this convenient property is lost. The best velocities are probably those from CO millimeter lines, because the distance to each CO complex can be found from young stars recently formed in it (Blitz in Athanassoula, 1983). The resulting plot of circular velocity versus radius (Fig. 8) is still flat or rising outside the solar position. This is one of the important pieces of evidence for dark matter in our galaxy, since the mass interior to point R with circular velocity V_c is roughly $M=V_c^2R/G$.

Gas flows both in and out of the galactic disk. Outflow is in the form of expanding bubbles (driven by supernova remnants and stellar winds) that pierce the disk layer and penetrate the halo. Most or all of that gas eventually returns in a sort of galactic fountain or champagne (Tenorio-Tagle *et al.*, 1990). In addition, some high velocity clouds of H I appear to be coming in on parabolic or hyperbolic orbits, and could be adding (1–2)$M_\odot$ of

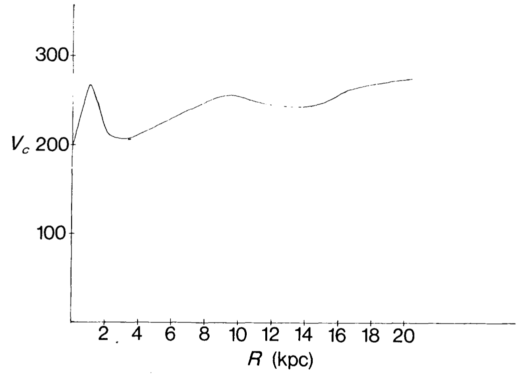

FIG. 8. Rotation curve of the Milky Way, showing circular velocity in the disk vs radius in kiloparsecs (1 kpc= 3×10^{21} cm), on the old scale where the sun is taken to be 10 kpc from the center and the circular velocity there 250 km/s. Ripples are expected from noncircular motions in spiral arms. Velocities are those of the 21 cm H I line out to 10 kpc (from Scheffer and Elsaesser, 1987, and Binney and Tremaine, 1981) and those of CO emission further out (from Blitz in Athanassoula, 1983). Still closer to the center, velocities have been measured for Ne II infrared emission lines (Morris, 1989). They imply a very compact (star cluster and/or black hole) central mass of about $10^6 M_\odot$.

unprocessed ($\frac{3}{4}$ H, $\frac{1}{4}$ He) material to the galaxy each year from the extreme halo or intergalactic space. Models of galactic chemical evolution (Sec. 3.1.4) indicate the need for such input.

2.1.3 Energetics and Stability. Supernovae contribute a few times 10^{49} ergs/yr of high-grade kinetic energy and heat to the ISM and maintain the coronal gas phase largely by boiling material away from cooler clouds. Winds from massive stars contribute comparable amounts of kinetic energy but at lower velocities (Lamers in Audouze *et al.*, 1983). Because stars form in clusters that often hold together for the lifetimes of the most massive stars in them, this energy input is very patchy and tends to blow large holes in the cooler gas phases (Tenorio-Tagle *et al.*, 1990).

Gas outflow speeds are in the range 10–100 km/s for stellar winds and 100–1000 km/s for aging supernova remnants. But sound speeds in the interstellar medium, $c_s = \gamma kt/\mu m_H$, are 1–10 km/s in the cool components (up to 100 km/s in the coronal gas). Thus interactions of outflow with surroundings take the form of shocks, whose structure and visible manifestations have received a great deal of attention (McKee and McCray in Dalgarno and Layzer, 1987; Shull and Draine in Hollenbach and Thronson, 1987).

Ionization in the diffuse gas is produced largely by ultraviolet photons from stars. Cosmic rays also contribute and are the main ionization source in molecular clouds, where they can penetrate but UV photons cannot. The several ISM components attempt to cool themselves, largely by line radiation, at the same rate they are heated. This line radiation is conspicuous in the spectra of other spiral galaxies, though the luminosity available from reprocessed supernova and stellar wind energy is only a few percent of the stellar continuum luminosity. Where there is vigorous star formation in dusty regions, up to half the luminosity of a galaxy may emerge as thermal infrared; it is probably about 10% for the Milky Way.

The multiphase interstellar medium is surprisingly stable (Cowie in Hollenbach and Thronson, 1987). Runaway heating would occur only for a star formation rate nearly 1000 times the present one. A smaller increase automatically damps itself down by stirring gas up too much to condense. Decreases in star formation rate seem to be similarly self-regulating (Dopita in Faber, 1986), though there exists one galactic-mass concentration of H I, in the galaxy group around M96 in Leo, where apparently no star formation has ever occurred.

2.2 Star Formation

About $10 M_\odot$/yr must have condensed from gas into stars on average over the age of our galaxy. The present rate is probably somewhat lower, (3–5)$M_\odot$/yr. If the interstellar gas were not replenished, the galaxy would be within the last 10%–20% of its life as a star-forming entity. About $1 M_\odot$/yr is returned by evolving stars and (1–2)$M_\odot$ of chemically pristine gas may be falling in from the outer halo or intergalactic space, but the Milky Way is clearly past its prime as a star maker.

Modern studies of star formation are largely the domain of infrared and radio astronomers, because the processes occur in dense, dusty clouds of molecular gas (opaque at optical wavelengths) and at low temperature. Evidence for recent or ongoing star formation in a given region includes

1. massive, short-lived stars,
2. less massive stars with colors and luminosities away from the main sequence relation and with surface activity and vigorous winds (T Tauri variables),
3. compact infrared sources with color appropriate to contracting clouds or reradiation of starlight by dust, and
4. molecular clouds that are unusually warm or that contain compact cores of stellar mass and density $\gtrsim 10^4$ cm^{-3} detectable in the lines of NH_3, H_2CO, CS, HC_3N, etc.

A peculiarity of star formation is its low efficiency. Large molecular clouds have masses in excess of $10^5 M_\odot$. Young star clusters in the Milky Way rarely reach $10^4 M_\odot$, and many clouds where we see young stars are already in the process of dissipating, with most of the gas uncondensed. This is clearly the norm, or all spirals would have exhausted their gas long ago. But a few "star burst" galaxies display current (and obviously temporary) star formation rates of $(100\text{–}1000) M_\odot/\text{yr}$ without having enormously larger quantities of gas than does the Milky Way. They are, therefore, converting gas to stars with very high efficiency, that is, on the gas free-fall time scale. Bound clusters of stars result only from relatively efficient ($\gtrsim 10\%\text{–}50\%$) star formation. Less than 10% of all stars seem to have formed in such bound clusters, and most of them have been torn apart since.

The ultimate goal of star formation studies is to be able to predict from the properties of a given gas cloud or assemblage of clouds in a galaxy the rate at which it will convert gas into stars and the spectrum of stellar masses, $N(M)$, it will produce (including the numbers, mass ratios, and separations of binary pairs). We cannot currently do any of these. Thus star formation rate and mass spectrum are treated as adjustable parameters in studies of galactic evolution, though each must really be determined by the gas properties.

The observed spectrum of stellar masses (Scalo, 1986) varies from one cluster to another, though the average over a whole galaxy may be fairly constant. Broadly, $N(M) \propto M^{-2}\text{–}M^{-2.5}$ over the range $(1\text{–}100) M_\odot$. The power law becomes less steep (Gaussian fits are at least as good) below $1 M_\odot$, with a broad maximum from $(0.6\text{–}0.15) M_\odot$. Very few stars below $0.1 M_\odot$ are known. Whether the deficiency is real or the result of observational selection acting on a population that really continues to increase toward smaller masses is a topic of as hot debate as can be expected for such cool stars (Liebert and Probst, 1987).

Star formation is probably not a single process. In particular, high- and low-mass stars form in different kinds of clouds and perhaps with different dominant physics. In addition, we see present star formation only in disk (spiral and irregular) galaxies. Very different conditions may have been obtained during the formation of spheroidal populations (elliptical galaxies, halos of spirals, globular clusters, gas flows in x-ray emitting galaxies). Next to nothing is known observationally about star formation in these contexts. The argument has, in fact, been made (Larson in Faber, 1987) that essentially all star formation really occurred in disk systems, the spheroids resulting from later mergers of them.

Shu *et al.* (1987) have reviewed the general subject of star formation with an emphasis on the importance of magnetic fields. Overviews of specific processes can be found in Faber (1987), Hollenbach and Thronson (1987), Lonsdale-Persson (1987), Gilmore and Carswell (1987), Peimbert and Jugaku (1987), Boss (1988), Tenorio-Tagle *et al.* (1990), and Capuzzo-Docetta *et al.* (1990).

2.2.1 Contraction and Condensation of and in Molecular Clouds. Molecular clouds are self-gravitating and gravitationally bound, with respect to both the tidal field of the galaxy and their own internal energies. Another way to say this is that, in average neutral diffuse clouds, the Jeans mass (the smallest perturbation that will grow),

$$M = \left(\frac{5kT}{Gm_H}\right)^{3/2} \left(\frac{3}{4\pi\rho}\right)^{1/2} = 1.82 \times 10^{23} T^{3/2} \rho^{-1/2}\ \text{g}, \tag{7}$$

is equal to a typical molecular cloud mass, and within the clouds it ranges from $100 M_\odot$ on down. Admittedly gravitation alone cannot create density perturbations, but in the present interstellar medium, there are plenty of cloud–cloud collisions, expanding wind shells, and so forth to do this. Yet star formation is inefficient, and clouds do not fragment into stars on either their dynamical or their thermal time scales.

Additional pressure support comes from three sources (Audouze *et al.* 1983; Scalo in Hollenbach and Thronson, 1987)—turbulence within the clouds, rotation, and magnetic fields. It has been widely believed that most clouds were in equilibrium between gravitation and these pressures, and so the onset of star formation had to be triggered by a collision. Collisions with shock waves at the leading edges of spiral arms would then give rise to star formation concentrated in well-defined arms (as seen in some spirals), while collisions with other clouds, expanding H II regions, and supernova remnants would give rise to star formation propagating away from a starting point. Differential rotation then twirls the zones of star formation into the semblance of arms (as seen in some other spirals). Such triggered star formation should start on the impacted side of the cloud and work its way inward. Such patterns are seen, but are by no means universal (Lonsdale-Persson, 1987; Peimbert and Jugaku, 1987). In particular, the molecular cores that precede low-mass stars seem to be studded at random through their parent clouds (Emerson in Peimbert and Jugaku, 1987).

The alternative is that star formation is an intrinsic (but slow!) property of molecular clouds, and that the real effect of density waves and collisions is to collect the gas into spiral arm structures, so that star formation is indeed seen there (Elmegreen in Peimbert and Jugaku, 1987). One implication is that large clouds are not necessarily long-lived. They may assemble out of smaller clumps within spiral arms and get torn apart again within a few crossing times ($\approx 10^7$ yr). Since the binding energy of a typical cloud is only 10^{50-51} ergs, one strategically placed supernova or the winds of a few massive stars can accomplish the dissection.

Star formation will be intrinsic if magnetic pressure dominates (Shu *et al.*, 1987; Mouschovias in Tenorio-Tagle *et al.*, 1990), that is, if

$$M/R^2 \leqslant CB/G^{1/2}, \tag{8}$$

where C is a combination of small numbers $= 0.13$. Notice that this is a condition on surface or column density through the cloud. For typical cloud fields of 10–100 μG, the limit is 0.005–0.05 g/cm^2 or a column density of 10^{21-22} atoms/cm^2. Clouds more compact than this will be able to take the field with them, and may yield efficient triggered or propagating star formation via hierarchical fragmentation (since the Jeans mass drops as density rises). Fragmentation stops when its products are optically thick and cannot radiate efficiently, at about $0.01M_{\odot}$.

Less compact clouds might seem able to collapse at least along the field lines. In practice, the presence of a field means that any form of turbulence generates magnetohydrodynamic waves and so pressure along, as well as perpendicular to, the field. Most of the gas is neutral and, in order to contract, must diffuse relative to the field-carrying ionized component (maintained by cosmic ray ionization even when no UV photons are present) in the face of very short time scales for ion-neutral collisions. The process is called ambipolar diffusion, and, for ionization fractions, densities, and thermal velocities characteristic of molecular clouds, has a time scale 5–10 times the dynamical one, that is, $\sim 10^7$ yr. Density fluctuations then grow quasistatically until they exceed the criterion of Eq. (8) and can collapse more rapidly. Thus fragmentation and star formation still occur, but more slowly.

Support for this two-mode picture of star formation comes from several directions. First, surveys of other galaxies indicate that the rate of formation of massive stars is proportional to gas density squared, as you would expect for a process involving collisions and such, while that of low-mass stars is linear in the gas density, as expected for an intrinsic process (Scoville and Sanders in Hollenbach and Thronson, 1987). Second, newborn, low-mass (T Tauri) stars and the cores that precede them are found both in relatively low-mass cloud complexes (like that in Taurus) and in giant ones (like the Orion Nebula region), while only a fraction of the largest clouds contain new massive stars and protostars. Since small, cold clouds that can form low-mass stars are found throughout the galactic disk, only massive star formation should be heavily concentrated in spiral arms, as indeed seems to be the case.

Two points may be noted. First, in neither form of star formation is the physics closely related to what the product star is going to do. Thus there is no reason to expect the mass spectrum to terminate at the $0.085M_{\odot}$ and $100M_{\odot}$ limits for stable, nuclear-burning stars. Larger entities blow themselves apart, but smaller ones should persist. In some sense, we expect substellar objects. Second, angular momentum must be disposed of at all stages of contraction and collapse. Observed rotation speeds of the clumps in molecular clouds are small (1–2 km/s) but imply far more angular momentum than could be accommodated by the product stars. Braking is universally assumed to be magnetic, but details (including the density at which ambipolar diffusion allows most of the flux to escape) remain obscure.

2.2.2 Protostellar Cores. Molecular maps of nearby cloud complexes have revealed hundreds of stellar-mass cores with densities $\gtrsim 10^4$ cm^{-3}. About half of these contain infrared sources detected by the IRAS satellite (Myers in Peimbert and Jugaku, 1987) and so already have luminous objects inside. Statistical arguments indicate that, for an eventual $1M_\odot$ star, the times to form a core, produce a protostar at the center, and clear away enough residual material for the star to be seen are each of order 2×10^5 yr.

A core produced by gravitational collapse (after ambipolar diffusion has removed the magnetic field) has approximately the structure of an isothermal sphere, $\rho \propto 1/r^2$; thus all time scales are shortest at the center, and evolution proceeds from the inside out. Accretion of surrounding material onto the core occurs at a rate that is crudely independent of time and core mass, though not of gas density, temperature, etc., and is about 2×10^{-6} $M_\odot$/yr for conditions inside the Taurus molecular cloud. Detailed models of emergent infrared flux imply a core-halo structure, where interpreting the halo as an accretion disk yields at least as good a fit as other symmetries (Myers in Peimbert and Jugaku, 1987; Shu *et al.*, 1987; Tenorio-Tagle *et al.*, 1990).

Apparently the mass of a star is set by whatever process terminates the accretion (Larson in Tenorio-Tagle *et al.*, 1990), since the molecular cloud provides an effectively infinite reservoir of accretable material. It is not clear how the termination of accretion is related to other differences, previously noted, between the sites of high- and low-mass star formation.

The transition phases in which accretion terminates and gravitational energy production gives way to nuclear energy production are not well observed. For massive objects, the accretion time scale is longer than the Kelvin–Helmholtz time, and we do not expect to observe any true protostars. Even among low-mass objects, there are no unambiguous cases of contraction- or accretion-dominated luminosity. The problem may be largely observational, arising from poor angular resolution at long wavelengths and obscuration at shorter ones.

2.2.3 Pre-Main-Sequence Stars and Planetary Formation. All or most stars retain traces of their protostellar disks when deuterium burning begins (Rodriguez, Kaifu, Nakano in Peimbert and Jugaku, 1987). While the deuterium-to-hydrogen ratio is only $(1\text{–}2)\times10^{-5}$, deuterium fusion releases enough energy to stop or slow down contraction and to drive convection, which enables dynamo-generated magnetic fields to turn rotational energy into surface activity and winds (Shu *et al.*, 1987). The wind emerges first at the poles and gradually fans outward until most of the residual circumstellar material has been cleared away. The intervening phase of bipolar outflow gives rise to a variety of mappable and modelable emission and reflection features, which are the subject of vigorous investigation, partly (but only partly) because the collimation of the flows by the residual disks seems to have some relevance to the collimation of jets from quasars and active galaxies (Koenigl in Belvedere, 1989; Pudritz and Fich, 1989).

From an anthropocentric point of view, the most important aspect of these disks is that many of them appear to have the masses, Keplerian structure, and sizes attributed to the protoplanetary disk from which our own solar system formed. Something like half of $1M_\odot$ pre-main-sequence stars have disks of this kind in one survey (Sargent in Tenorio-Tagle *et al.*, 1990).

2.3 Star Clusters and Stellar Populations

These subjects fit naturally together because the two classes of star cluster, globular and open (or galactic), represent the extremes of galactic stellar populations, consisting respectively of the oldest and the youngest stars. Figure 9 is a schematic representation of an edge-on view of our Milky Way galaxy.

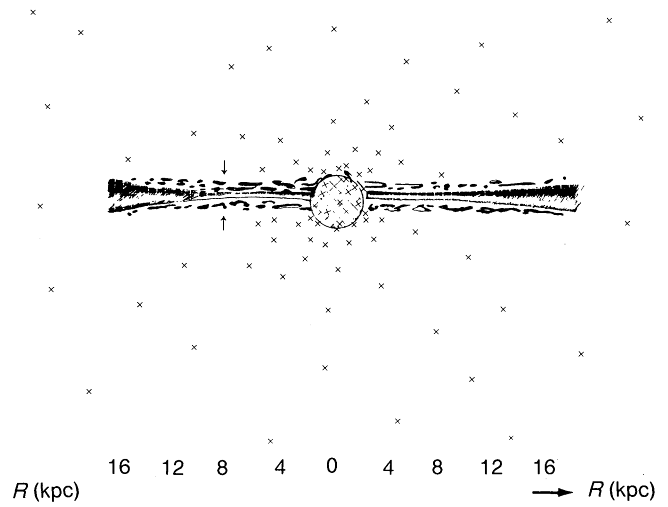

FIG. 9. Schematic representation of our galaxy seen edge-on. Central nuclear bulge contains old, metal-rich stars. The thin disk (flaring outside the position of the sun, shown by arrows at 8.5 kpc radius) includes the interstellar medium and young stars (formed in clusters, studded through the spiral arms in the disk). Globular clusters, shown as X's, trace the halo population (though making up only 1% of its stars) and extend out much further than shown, to at least 50 kpc, though the majority are closer to the center than is the sun. There is probably also a transitional thick disk population with a scale height of about 1 kpc as shown.

The youngest stars, along with the interstellar gas and dust, are confined to a thin disk. These are called Population I objects, are relatively rich in heavy elements ($\gtrsim$ 2 %), and will look blue from a distance because the brightest stars are hot main sequence ones. In a face-on view of the galaxy, star formation regions and the youngest open clusters would be dotted like beads along the spiral arms.

Globular clusters of $\approx 10^5$ stars each are the most conspicuous members of the spheroidally distributed Population II, though 99 % of the halo stars are not cluster members. The stars are all $\gtrsim 10^{10}$ yr old and have heavy element contents $\lesssim 0.5$ % (down to 10^{-6} or less but never zero). The brightest Pop II stars are red giants, so that from a distance, the halo would look redder than the disk. The extreme halo population is essentially nonrotating, and as many stars and clusters have retrograde as prograde orbits, many of them quite eccentric.

Older, but still metal-rich, Population I objects inhabit a somewhat thicker disk than the youngest ones, and there may be a transition population, between disk and halo, averaging about 0.3% heavy elements and having a scale height near 1 kpc. This thick disk includes some of the more metal-rich globular clusters and rotates more slowly than the thin disk whose circular velocity versus radius is shown in Fig. 8. Notice that astronomers use "metals" to mean all elements apart from hydrogen and helium (even though C, O, and Ne make up about half the total), because the heavy elements with strong lines at stellar temperatures really are mostly metals—Na, Ca, Fe, Ti, etc.

The two cluster types have in common that each represents a sample of stars of a single age and chemical composition. As a result

1. plots of surface temperature versus brightness can be used to measure their ages (by comparison with models for the time taken to exhaust hydrogen fuel, Sec. 1.3) and to test our understanding of stellar evolution, and
2. counts of stars versus brightness in them tell us that the mass spectrum of stars $N(M)$ is not a unique function.

In addition, a few clusters of each type contain 2–20 stars brighter and bluer than should still be there for their ages measured from the majority of stars. These so-called blue stragglers could be the products of merged binary pairs, stars that have somehow managed to mix large amounts of fresh fuel down into their cores, or straying non-cluster-members of lesser age.

Properties of star clusters and their use for age determinations and tests of stellar evolution are discussed in Hesser (1980) and Renzini and Fusi Pecci (1988). The globular clusters in our own and other galaxies are covered by Grindlay and Philip (1988) and the dynamical evolution of globular clusters by Saslaw (1985), Spitzer (1987), and Elson *et al.* (1987). A wealth of information on stellar populations is to be found in Norman *et al.* (1986), Faber (1987), Freeman (1987), and Frogel (1988).

2.3.1 Open Clusters. More than 1000 clusters in the galactic plane have been catalogued, though only about 100 have detailed data on stellar motions, brightnesses, colors, and so forth. Closely related are a couple of hundred known stellar associations, consisting of newly formed stars and probably not gravitationally bound. The inventory of these clusters is nowhere near complete. Star counts range from 100 to 10^4 per cluster and ages from $\lesssim 10^6$ yr (for associations like that in Orion) to (5–7)$\times 10^9$ yr (for NGC 188 and Mel 66). The scarcity of these oldest open clusters and the absence of older ones may mean either that the galactic disk is much younger than the halo or that the older clusters have all been torn apart by tidal encounters with molecular clouds or other massive objects.

Figure 10 is a plot of luminosity versus temperature for the stars of a nearby open cluster (the Pleiades at about 130 pc; notice that the Seven Sisters—or Six from most urban sites—are merely the brightest few of many stars). The cluster contains one white dwarf; stars of $6M_\odot$ have exhausted their hydrogen fuel and are in the process of becoming red giants (telling us that the cluster is about 6×10^7 yr old) and stars of less than about $0.5M_\odot$ have not yet had time to complete their pre-main-sequence contraction and start hydrogen burning. In fact, we can never see the complete main sequence of any one cluster. Stars that differ by more than 10^3 in luminosity have such different time scales that the bright ones are gone before the faint ones begin nuclear fusion.

At least some young clusters and associations appear to be deficient in low-mass stars even when this effect is allowed for. The deficiency is presumably another aspect of the two-mode star formation addressed in Sec. 2.2. In some cases, however (including the nearby 10^9-yr-old Hyades cluster), the low-mass stars have simply drifted further from the center than the bright ones and tend to get missed in counting. The phenomenon is called mass segregation and is established for a handful of clusters.

Low-mass stars will inhabit the cluster outskirts if kinetic energy is shared equally among all stars (smaller masses implying then larger velocities around the average of 1–2 km/s for most clusters). An occasional star will, on the other hand, acquire far more than its fair share of energy through close encounters, and leave the cluster at high speed. This process accounts for some or most of the high-velocity young stars seen in our galaxy. Such runaway stars have also been attributed to the disruption of binary systems by supernova explosions of the primary star. But the runaway population includes some binaries, and, in addition, the exploding star will be the

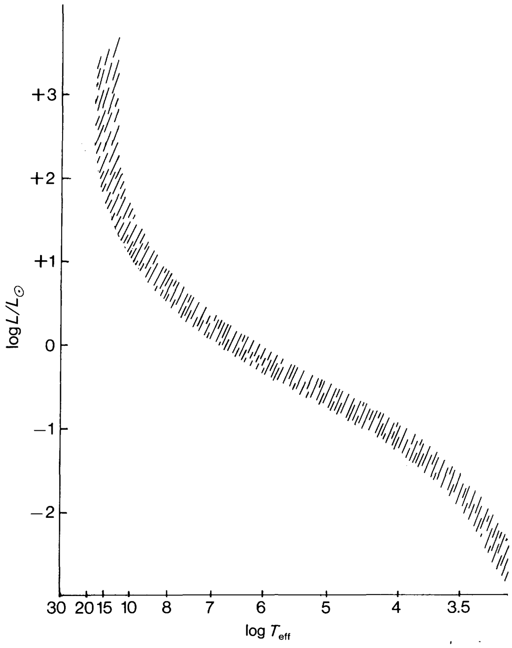

FIG. 10. Plot of brightness [log $(L/L_\odot)$] vs surface temperature (nonlinear scale) for stars in the Pleiades, the brightest 6 or 7 of which are naked-eye stars. Data have been published in a number of different places for about 100 stars, including one white dwarf, whose presence in the cluster indicates that stars of at least $6M_\odot$ (the mass that is just now leaving the main sequence) can shed their outer envelopes down to below the Chandrasekhar mass (Sec. 1.4) rather than becoming supernovae and neutron stars. Observations of stars are reported as brightness within a finite waveband (rather than as bolometric luminosity) and as a logarithmic measure of color temperature (rather than in K). Comparison of theory with data should properly be done in the observed coordinates (converting modeled quantities to observed ones rather than the other way around). This diagram is, therefore, somewhat schematic. Because of the coordinates properly used, such plots are called color–magnitude diagrams, or, in honor of the first people to attempt them, Hertzsprung–Russell or HR diagrams.

less massive member (Sec. 1.5.2) and so unlikely to disrupt the system.

2.3.2 Globular Clusters. Historically globular clusters were important because the distances to them measured by Harlow Shapley in the 1930s demonstrated that the sun is nowhere near the center of the galaxy (Fig. 9). The clusters are strongly concentrated around a point about 8.5 kpc away from us which later work at radio wavelengths established conclusively as the dynamical center of the galaxy.

About 150 globular clusters are known, and another 50 or so may lurk in obscured regions near the galactic center. Other galaxies have similar populations with anywhere from a handful of members (around a dwarf galaxy that in turn orbits the Milky Way) to 10^3 or more (around a large elliptical galaxy, M87, in the Virgo cluster). Some galaxies with very large gas contents may still be forming globular clusters at the present.

Recent studies of globular clusters have focused heavily on

1. determining their ages, as the best lower limit we have to the age of the universe, and
2. following their dynamical evolution.

Everyone would agree that the ages are in the range $(7\text{–}17)\times 10^9$ yr. Unfortunately, this is just the same range of uncertainty as is presented by other approaches, including backward extrapolation of the expansion of the universe (see GALAXIES AND COSMOLOGY). The difficulties in narrowing the range arise from imperfect knowledge of distances, chemical compositions, and physics of gas convection and diffusion inside stars (Renzini and Fusi Pecci, 1988). A related interesting question is the origin of the heavy elements in the globular clusters. For those with the smallest abundances, the entire cluster metal content could have come from only a couple of supernovae, which might well have occurred in the cluster itself and polluted its gas before the stars we now see had condensed. If this had happened, we would expect to see wider variation in heavy element content from one star to another in a single cluster. On the other hand, it is hard to see how to avoid such self-enrichment or to understand precisely where else the heavy elements might have come from.

The dynamical importance of globular clusters arises from their having evolutionary time scales comparable with the age of the universe. The observed distribution of stellar density on the sky through a cluster can be fitted heuristically as

$$\sigma(r)=c\{[1+(r/r_c)^2]^{-1/2} - [1+(r_t/r_c)^2]^{-1/2}\}^2, \qquad (9)$$

where σ is surface density versus radius, r_c is a core radius, c a scaling parameter, and r_t the limiting tidal radius set by the gravitational field of the rest of the galaxy. Typical values of r_c are 1–10 pc and $r_t/r_c \sim 10$. A cluster whose orbit carries it through the galactic plane or close to the galactic center may find r_t approaching r_c, so that it is disrupted. The present cluster population represents the survivors (anything from 90% down to 10% or less in various investigations) and so may not be typical of the entire original population.

No true equilibrium configuration is possible for a star cluster, since a star that acquires the escape velocity leaves, taking its kinetic energy with it, so that the remaining stars become monotonically more tightly bound. Effects of this sort from two-body encounters will become noticeable in a relaxation time given by

$$t_R=\frac{v^3R^3}{24\, G^2m^2N\ln(N/2)}, \qquad (10)$$

where v is the central velocity dispersion (10–30 km/s), R is a characteristic radius (2–10 pc), m is the mass of an average star ($0.8M_\odot$), and N the number of stars in the cluster ($10^{5\pm1}$). For the actual range of cluster parameters, t_R straddles the age of the universe.

On the time scale t_R, one expects the center of the cluster to collapse. Dynamical evolution of a stellar population can be followed using Eq. (11), variously called the Liouville, Vlasov, collisionless Boltzmann, or Fokker–Planck equation, depending on one's background:

$$0=\frac{\partial f}{\partial t}+u\frac{\partial f}{\partial x}+v\frac{\partial f}{\partial y}+w\frac{\partial f}{\partial z}-\frac{\partial v}{\partial x}\frac{\partial f}{\partial u}-\frac{\partial v}{\partial y}\frac{\partial f}{\partial v}-\frac{\partial v}{\partial z}\frac{\partial f}{\partial w}, \qquad (11)$$

where $f(x,y,z,u,v,w,t)$ is the time-dependent density of points in a phase space with three spatial dimensions, x,y,z, and three velocity dimensions, u,v,w. Many assumptions of symmetry and other simplifications are normally made before tackling solutions of the equation. The problem has, in recent years, also become approachable numerically through computer simulations that treat the motions of test particles in a predetermined potential—or, better, the simultaneous interaction of N point masses.

Both analytic and numerical studies confirm the onset of a "gravithermal catastrophe" in which the core collapses, bounces, and then oscillates. Surprisingly, the cluster survives, and [apart from a steeper central density gradient than implied by Eq. (9)] may not even look greatly different from a precollapse cluster.

The details are heavily dependent upon the exchange of energy between the cluster core as a whole and close binary systems that form and get torn apart during the approach to collapse. This interrelation between dynamical evolution and binaries couples to observations in two ways. First, globular clusters (and perhaps other halo populations) are notoriously lacking in confirmed close binaries on or near the main sequence. On the other hand, they are richly endowed with the highly evolved kinds discussed in Sec. 1.5.2 (Trimble in Hesser, 1980). Formation by late capture is an obvious interpretation. Recently, it has transpired that the clusters are rich not only in cataclysmic variables and x-ray binaries with low-mass companions, but also in binary pulsars and in the single (short period, low magnetic field) kind that are probably binary relics. These systems require either that the clusters keep for 10^{10} yr the neutron stars left by their massive stars until they can capture normal companions as the core evolves, or that white dwarfs do the capturing and get driven to collapse by accretion of material from their acquired companions. Each scenario presents difficulties.

2.3.3 Stellar Populations. The traditional dichotomy, laid down by Walter Baade more than 40 years ago, is Population I = young, thin disk, metal rich, associated with gas and dust, brightest stars blue, rotates with the disk (so the stars seem to have low velocities as seen from the solar system), and Population II = old, halo, metal poor, no gas or dust, brightest stars red, little rotation (so the stars seem to have high velocities as seen from the solar system). The observed increase in stellar velocity dispersions with age has also a "real" component, caused by the stars' encountering molecular clouds, star clusters, each other, etc., and so getting scattered into noncircular orbits.

In addition to extreme Pop I and II, the Milky Way clearly contains an old disk population (to which the sun belongs) consisting of stars with ~2% heavy elements, ages of [1–6 (or more)] × 10^9 yr, and velocities that can carry them a couple of hundred parsecs out of the galactic plane. The existence of a thick (1–2 kpc) disk, transitional between the old disk and the halo, and separable in age, kinematics, and metallicity, is hotly debated (Gilmore and Carswell, 1987).

The dichotomy really applies only to stars that come close to the sun, and breaks down in other contexts. Massive elliptical galaxies and the center of our own contain old, metal-rich stars. Irregular galaxies and the extreme outer disk of our own include very young, metal-poor stars. And, if we could look at sufficiently distant galaxies to catch the first generations of star formation, we would expect them all to be dominated by young, massive, metal-poor objects.

The average properties of stars thus vary

1. with time,
2. from one galaxy to another, and
3. from place to place in a single galaxy.

The dominant trends are that metallicity and degree of population evolution increase with time, with total mass of a galaxy, toward the centers of spheroidal populations, and toward the planes of disk ones. The central tasks of stellar population studies are to make these relationships quantitative, to identify and understand deviations from them, and to model the properties (as the sum of successive contributions of stellar generations) in a way that is consistent with what we know about behavior of individual stars (e.g., Mathews, 1988).

GLOSSARY

Algol Variables: Pairs of closely orbiting stars in which one star has become a red giant and transferred enough material to its companion that, although it started out as the more massive, it is now the less massive. Most known systems eclipse. Named for the prototype in Perseus.

Black Hole: The most extreme possible result of gravitational contraction or collapse. The escape velocity is at least the speed of light and gravitational redshift for light attempting to escape is infinite, so that no signals can be propagated to infinity.

Cataclysmic Variable: Close pair of orbiting stars in which one is a white dwarf. Material is accreted erratically from the more normal star and burns explosively from time to time, giving rise to a variety of kinds of rapid brightness changes, including novae and dwarf novae.

Cepheid Variable: A massive star which has completed core hydrogen burning and so evolved to a zone in the temperature–luminosity plane where its outer layers act like a periodic tap, holding and releasing luminous flux, so that the star pulsates in and out, changing its brightness by a factor of four or more over a period of 1–100 days.

Chandrasekhar Limit: The largest mass of cold, dense material in which degenerate electron pressure can balance gravity; about 1.4 times the mass of the sun for most chemical compositions.

Chromosphere: The thin layer at about 10^4 K just above the visible surface (photosphere) of the sun or other stars, named because of its red glow visible during solar eclipses.

CNO Cycle: A set of three coupled, catalyzed cycles of nuclear reactions, in which four hydrogen atoms fuse to form one helium atom with C, N, and O as catalysts. A typical C or N atom may catalyze formation of 100 or more helium atoms in the life of a star. Also referred to as CN cycle and CNO tricycle.

Corona: The thick layer at about 10^6 K above the chromosphere of the sun or other stars. The gas is too thin to be visible except during solar eclipses, but significant x rays are radiated.

Coulomb Barrier: The height, in energy units, of the electromagnetic repulsion between two nuclei when they are separated by the smallest distance allowed by classical mechanics. Quantum mechanical penetration through this barrier is required for nuclear reactions to occur in stars.

Dark Matter: Any gravitating mass which does not radiate roughly its fair share of one solar luminosity per solar mass.

Galactic Halo: The spheroidal component of the galaxy, consisting primarily of old stars. The phrase is occasionally also used to mean a spheroidal distribution of dark matter, probably somewhat more extended in radius than the stars.

Hawking Radiation: A somewhat hypothetical quantum mechanical phenomenon that enables very small black holes to boil away over the age of the universe, though having thermodynamic temperatures related to the sizes of the Schwarzschild horizons.

Hertzsprung–Russell Diagram: Plot of luminosity versus surface temperature for stars. Since these are the two most readily observed stellar properties, such diagrams are useful for comparing observations and theoretical models of stellar structure and evolution. Temperature increases to the left in such diagrams, just to show that astronomers do not think quite the way other people do.

H I Disk: The flat portion of the Milky Way or other spiral galaxies when viewed in the 21-cm radio emission line of neutral hydrogen.

H II Regions: Clouds of ionized gas. Since astronomical gas is everywhere mostly hydrogen, it is the ionization potential of H which dominates the conditions in such clouds.

Jeans Mass: The smallest mass that can contract under its own self-gravitation in a medium of uniform density and temperature.

Kelvin–Helmholtz Time: The thermal time scale on which a star would radiate away its gravitational potential energy or thermal energy content if no nuclear reactions released additional energy.

Magnetic Wind: Gas flowing off the surface of a star with appreciable surface magnetic field, so that the gas is constrained to corotate with the star out to some distance from its surface and so transports angular momentum outward.

Main Sequence: The phase in a star's life when its energy is derived from hydrogen fusion in its core. This phase occupies about 90% of a star's life, about 10^{10} yr for the sun.

Nebula: Any diffuse-appearing astronomical object, including star clusters, galaxies, and ionized gas clouds. Though modern practice tends somewhat to restrict the term to the last category, historical usages, like Andromeda Nebula for a nearby large galaxy, persist.

Neutron Star: A degenerate configuration in which pressure of neutrons balances the force of gravitation. Typical remnant of core collapse in massive stars.

Planetary Nebula: The outer layers of an intermediate-mass star, expelled at the end of the helium-burning phase, leaving the inert core as a white dwarf. The name derives from the appearance in a small telescope, which resembles that of Uranus or Neptune, and has no further significance.

Population I: The stars in the solar neighborhood that are relatively young, rotate with the galactic disk, and contain about 2% of elements heavier than hydrogen and helium.

Population II: The stars in the solar neighborhood that are about 10^{10} yr old, have orbits within the galactic spheroid, and contain less than about 0.2% of elements heavier than hydrogen and helium.

Proton-Proton Chain: The series of nuclear reactions converting four atoms of H to one atom of He, in which the first step is the weak interaction $p+p \rightarrow \mathrm{H}^2+e^+ + \nu_e$.

Pulsar: Neutron star that reveals itself through coherent radio emission beamed into a narrow cone. The pulses appear as the beam sweeps across us with the rotation period of the neutron star.

Quasar: The radio-emitting subset of quasistellar objects (QSOs). The QSOs in general are characterized by broad emission lines at high redshift, compact optical appearance, and total luminosities 100 or more times that of typical galaxies.

***r*-Process:** The rapid addition of neutrons to iron (usually) to produce the neutron-rich isotopes of elements with Z greater than 26. Captures alternate with beta decays; the most likely site is highly processed layers of stars undergoing core-collapse supernovae.

Radio Galaxy: A galaxy (typically, though not always, a giant elliptical) whose luminosity in radio waves exceeds about 10^{43} ergs/s.

Red Giant: A star whose primary source of energy is hydrogen fusion in a thin layer around an inert helium core. This structure results in a distended cool envelope (hence the name), and the phase lasts about 10% of the life of a typical star.

Roche Lobe: The innermost equipotential surface in a binary system that (in the rotating coordinate system) envelops both stars.

RR Lyrae Variable: A low-mass star which has completed core hydrogen burning and evolved to a zone in the temperature-luminosity plane where its outer layers act like a periodic tap, holding and releasing luminous flux, so that the star pulsates in and out, changing its brightness by a factor of two or more over a period of 0.3–1.5 days.

Runaway Stars: Stars whose velocities are sufficiently large to require some explanation other than motion in the general galactic potential. Some are thought to result from disrupted binary systems, others from close encounters with other stars in clusters.

***s*-Process:** The slow addition of neutrons to iron or other elements to produce the most tightly bound isotopes of elements with Z greater than 26. Captures alternate with beta decays; the most likely site is the nuclear-burning zones of highly evolved, intermediate-mass stars.

Schwarzschild Horizon: The spherical (imaginary) surface around a black hole from which the escape velocity $=c$ and gravitational redshift is infinite. Named for Karl Schwarzschild.

Schwarzschild Model: Solution of the coupled equations of stellar structure achieved by mathematical methods codified by Martin Schwarzschild (son of Karl).

Stellar Flares: Sudden releases of energy on the surfaces of stars leading to brightening at optical, radio, and x-ray wavelengths. The basic energy source is thought to be magnetic.

Supernova: The sudden brightening of a star by a factor of more than 10^4 to a peak luminosity of order 10^{44} ergs/s. Total energy release is 10^{51-53} ergs, and the primary energy source is collapse of a dense core of a massive star (Type II supernova) or the explosive burning of about $1M_\odot$ of carbon and oxygen to iron (Type I supernova).

T Tauri Variable: Late phase of the star formation process, in which nuclear reactions have already begun in the core, but the surface appearance of the star is still dominated by winds and other phenomena involving the gas from which it formed.

White Dwarf: A degenerate core of carbon and oxygen (usually; occasionally helium or heavier elements) left when an intermediate-mass star expels its outer layers at the end of nuclear fusion. Gravitation is balanced by the pressure of degenerate electrons.

X-Ray Binary: A pair of closely orbiting stars, one of which is a neutron star or a black hole and which accretes material from its more normal companion. The gravitational well of the compact star is deep enough that the accreted gas inevitably heats to x-ray emitting temperatures.

INTRODUCTION

The science of acoustics encompasses the production, transmission, and reception of sound. When applied to the atmosphere each of these fundamental aspects of acoustics is affected to some extent by the properties of the atmosphere itself. Atmospheric properties vary in both space and time giving rise to a close interaction between atmospheric acoustics and the broader field of atmospheric physics. The interaction of sound with this complex atmosphere as well as the surface of the earth requires that a wide spectrum of physical phenomena be understood to describe completely a sound field in the atmosphere.

The need to communicate audibly in the atmosphere has traditionally motivated studies of atmospheric acoustics. The physical phenomena which affect atmospheric acoustics were generally identified in the 1800s although many of the details and mathematical techniques for dealing with these phenomena have evolved more recently. An excellent example of early experimental work in atmospheric acoustics was that of Tyndall using the large horn shown in Fig. 1.

The large size of the horn results from the relatively low density [1.29 kg/m^3 at standard temperature and pressure (STP): 273 K, pressure of 1 atm with 0% relative humidity] and speed of sound in air (331.6 m/sec at STP with 0% relative humidity). More recently, studies of atmospheric acoustics have been motivated by concerns for environmental noise. Most activities associated with modern society result in some noise but perhaps none is more pervasive than that associated with transportation. Noise in and around airports and along highways has led to attempts to increase transmission loss as well as reduce source generation. A detailed treatment of many of the topics addressed in this article can be found in Pierce (1981).

A variety of natural processes give rise to atmospheric sound. Some of the more common sources are thunder associated with lightning, noise generated by wind, and sounds produced by animals of all types.

Sound is often classified in terms of amplitude and frequency. Amplitudes of acoustic waves are generally given in dB ref 20 micropascal (μPa). A very quiet anechoic chamber might have a sound level of 0 dB. Outdoors on a quiet day, the sound level is typically 40 dB. Above 90 dB, audible sound begins to result

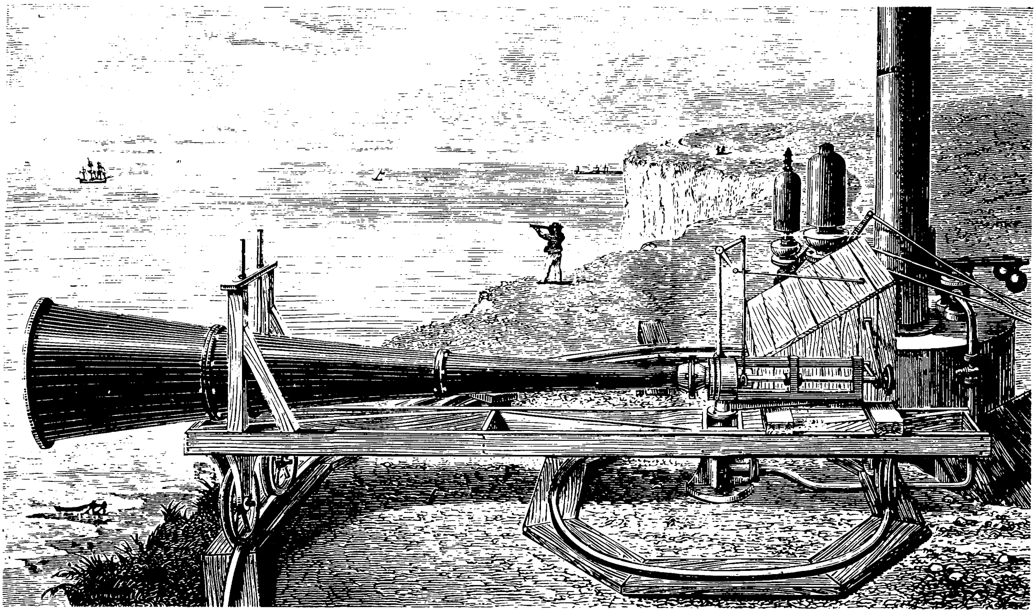

FIG. 1. Tyndall's apparatus for studying sound propagation in the atmosphere (from Tyndall, 1874).

in hearing loss in the case of very long exposures. A jet aircraft taking off might produce 120 dB. Above 130 dB, acoustic waves begin to exhibit nonlinear behavior. Above 140 dB, immediate and permanent hearing loss occurs.

Another way to categorize sound is according to frequency. Acoustic waves with a frequency above 20 Hz (units of $\sec^{-1}$) but below 20 kHz are referred to as audible sound. Lower frequencies are classified as infrasound; higher frequencies as ultrasound. At low frequencies acoustic waves couple into the buoyant restoring force of gravity in the atmosphere and two modes result (Brown, 1987). At very low frequencies ($\sim 10^{-2}$ Hz) the propagation is dominated by the buoyant force (internal gravity waves). At the opposite end of the frequency spectrum, ultrasonic waves are rapidly attenuated in the atmosphere with an attenuation coefficient approximately proportional to frequency squared. As a result, ultrasound does not travel over great distances although over short distances it can be important (echolocation used by bats and echoranging by cameras, for example).

Once sound is generated, there are a variety of physical processes which affect transmission. The most obvious of these is spreading of the wave. The amplitude of a spherically spreading wave decreases as $1/r$ (6 dB per doubling of distance). Even highly directional sources (such as a bat) begin to show this type of spreading some distance from the source. For this reason, 6 dB/doubling of distance is generally taken as a standard loss and all other factors which affect the received amplitude are referred to in terms of excess attenuation (attenuation in addition to 6 dB/doubling of distance).

Physical processes which contribute to excess attenuation are molecular absorption, interaction with the ground, refraction due to temperature and wind gradients, diffraction due to those gradients or topography, and scattering. In all cases, except for the ground interaction (and even there to some degree), the effects depend strongly on specific local atmospheric conditions. This strong dependence of propagation on meteorological condition can be used as a basis to sense the atmosphere remotely using echo sounders or radio sounders.

Application of atmospheric acoustics usually defines the receiver. The detection and location of aircraft might involve an array of microphones sensitive to phase changes between individual elements. Noise control applications typically consider a human ear as the receiver. These applications plus the atmospheric sounders already mentioned continue to provide motivation for studies of atmospheric acoustics.

1. SOUND SOURCES

A number of sources of atmospheric sound were mentioned in the Introduction. In this section, specific sources will be considered in more detail to illustrate the different phenomena which give rise to sound and the atmospheric properties which affect the sound generated. First, man-made sources will be considered, then natural sources.

1.1 Aircraft Noise

Jet aircraft represent a pervasive noise source. Aircraft noise is generated by both propulsive and nonpropulsive sources (Smith and Schien, 1989). Propulsion sources normally result in the dominant noise. Propulsion sources include turbomachinery noise generated internal to the engine and jet exhaust mixing and shock noise attributed to processes external to the engine. Nonpropulsive noise is generated in flight by the air flowing past the vehicle structure and is called airframe noise.

Turbomachinery noise sources include fan noise, compressor noise, combustion noise, and turbine noise.

Fan noise is caused by the unsteady component of the flow which interacts with rotor or stator blade rows. When a perturbation in flow pressure or velocity encounters a blade or strut surface, an acoustic pressure pulse is generated. Primary fan noise generation mechanisms are

1. inlet flow inhomogeneities interacting with the rotor blades, and
2. rotor wakes and pressure fields interacting with the stator blades.

Sound is generated primarily at the blade passing frequency and its harmonics, although there is a broadband component as well.

Key parameters affecting fan noise generation are the number of rotor and stator blades, rotor-stator axial spacing, blade loading, fan rpm, stage pressure ratio, and rotor tip speeds. Upstream stators (inlet guide vanes) increase acoustic levels. At high engine power settings, supersonic tip speeds give rise to tones at harmonics of the shaft rotation speed, which are known as multiple pure tones.

Compressor noise is similar in nature to fan noise, and has the same key parameters as the fan, applied to the compressor stages. Compressor noise is usually of higher frequency than fan noise and is attenuated as it passes through adjacent blade rows. Similar in nature to fan and compressor noise, turbine noise is generated downstream of the combustor and radiates from the core exhaust duct.

Instabilities in combustors give rise to sound waves. These instabilities are usually a result of flow turbulence, so that combustion noise is broadband in nature, normally peaking at 400–500 Hz. Key engine operating parameters affecting combustion noise generation are engine mass flow rate, compressor pressure and temperature ratio, and combustor temperature rise.

Jet exhaust noise is generated by two mechanisms in the jet plumes aft of the exhaust nozzles: turbulent mixing and shock cell perturbations.

Jet mixing noise is generated by the turbulent mixing process between the exhaust flow and the atmosphere. Noise generation is strongest in the turbulent shear layer between the laminar core and the ambient air. This source correlates most strongly with the velocity of the jet at the plane of the exhaust nozzle, varying as approximately the eighth power of the velocity. Secondary parameters are the jet flow density and exhaust nozzle area. Forward motion of the aircraft has a strong attenuation effect on jet mixing noise, because it reduces the magnitude of the shear layer velocity gradient.

Jet mixing noise is spectrally broadband in nature, usually peaking at frequencies below 1000 Hz, depending on the nozzle diameter and jet velocity. It is most intense in the downstream direction and peaks at a radiation angle of approximately $\theta = 140°$, measured from the aircraft nose (i.e., tail-to-nose vector is $\theta = 0°$).

The jet mixing noise generated by air vehicles and high-performance military aircraft is a significant source of noise. This source is difficult to suppress, since it is generated entirely outside the aircraft. Most successful reductions in jet noise have been due to reductions in jet velocity, which generally requires an increase in fan bypass ratio to maintain thrust. Modern commercial aircraft (referred to as Stage 3 aircraft) have large bypass ratio engines. Such engines are visually greater in diameter.

When an air vehicle's convergent exhaust nozzles are operated supersonically, a quasi-periodic shock cell structure will form in the jet. Shock cell noise is produced by the unsteady interaction between the flow turbulence and this structure. The intensity of shock noise is a function of the Mach number (ratio of speed to total speed of sound) of the fully expanded exhaust flow.

Shock-associated noise possesses characteristics distinct from those of turbulent mixing noise. In contrast to the mixing noise radiation pattern, broadband shock cell noise will be most prominent in the forward arc ($\theta < 90°$) directions for a static engine, due to the high jet mixing noise levels. However, for high flight speed, shock noise may dominate the signal in the forward arc and at all radiation angles.

Airframe or nonpropulsive noise is generated by the airflow over the wings, fuselage, vertical and horizontal stabilizers, slats, gears, or any element of an aircraft. The interaction of aircraft elements with large scale turbulence in the atmosphere results in large fluctuations in lift and drag. These forces and the subsequent radiation occur with any lifting element of the aircraft. The sound power radiated from this source of noise increases with the size of the lifting surface, the turbulence intensity, and the fourth power of the aircraft speed. This source of noise has been considered as insignificant for low flight speeds but could be a significant contributor to the aircraft signature when the aircraft speed and the turbulence intensity are high. For this case the radiated power would be high and the frequencies would be low resulting in little excess attenuation due to propagation through the atmosphere.

There are four components of noise associated with radiation from the turbulent boundary layer. These include the following:

1. a surface distribution of dipoles associated with the fluctuating pressures within the flow causing fluctuating forces on a rigid surface;
2. a volume distribution of quadrupoles generated by the fluctuating forces in the boundary layer;
3. reflected quadrupole noise due to the presence of the surface;
4. noise radiation resulting from the motion of the surface beneath the turbulent layer.

Current thinking, based on commercial aircraft experience at low Mach number, considers only the surface distribution of dipoles. For such a distribution, the sound pressure is taken to vary as AU^6 (Reed, 1977) where U is the flow velocity and A is the radiating area. At low Mach numbers this source is less than that predicted for the trailing edge.

Although the surface distribution may be a valid model throughout the subsonic Mach number range there is no evidence to show that dipole-type radiation will be dominant at high subsonic Mach numbers. That is, quadrupole-type sources may become the dominant source at high subsonic Mach numbers. This has not been satisfactorily answered at this time.

The acoustic radiation from structures excited by turbulent boundary layers has been investigated primarily in terms of the noise levels in aircraft cabins and noise radiation underwater. There has been little emphasis on this source of sound with respect to airframe noise. There is something of a conflict as to its importance at low Mach numbers.

The noise radiated directly from wakes and vortices is quadrupole in nature and, as such, is not a significant source. However, when wakes or vortices impinge on a structure or rotating blade, significant levels of noise can be generated. These sources are similar to whole body noise, but at higher frequencies because of the smaller scales.

Trailing edge noise is generated by turbulence being swept over the trailing edge with the creation of half-baffled dipoles. The source of the turbulence is the turbulent boundary layer. There is a large data base at low Mach number ($M < 0.4$) which appears to confirm that trailing edge noise is proportional to the aircraft velocity to the fifth or sixth power.

Rotary wing and propeller-driven aircraft generate sound quite different from that of jet aircraft even though many of the noise generation mechanisms are the same. Machinery noise, for example, is common to both. The biggest difference is the role that the helicopter blade or aircraft propeller plays. In many cases, for these types of aircraft, this blade noise is dominant and characterizes the audible sound.

Four mechanisms are important for noise generation provided the blade tip speed does not exceed the speed of sound. One is the discrete loading noise which dominates the lower harmonics of the blade passage frequency. Next is the blade-vortex interaction which is a discrete source of impulsive character. At higher frequencies, broadband noise due to blade interactions with turbulence in and around the rotor wake begin to dominate. Broadband self-noise due to blade interaction with boundary-layer and near wake turbulence controls the high-frequency part of the spectrum.

The relative importance of each of the above mechanisms depends upon aircraft operating conditions. In most cases, however, the aircraft is characterized by sound associated with the blade passage frequency. This frequency is variable for a propeller-driven aircraft depending upon flight operations. Rotary wing aircraft tend to operate at a lower, fixed, blade passage frequency. A military UH-1D helicopter main rotor rotates at 324 rpm and has twin blades, which gives a fundamental frequency of 10.8 Hz. The tail rotor rotates more rapidly producing a fundamental of 60.5 Hz at a level much lower than for the main blade. Since the human ear is not sensitive to 10.8 Hz, audible sound is due to harmonics of the fundamental blade passage frequency.

1.2 Traffic Noise

Another pervasive source of man-made noise is that due to traffic (Dept. of the Army, 1978). Traffic noise results primarily from the engine and exhaust system and interaction of tires with the road surface. The maximum noise emitted by an automobile increases approximately with the third power of vehicle speed. This is due primarily to tire noise created by the tire-roadway interaction. (Figure 2 illustrates automobile noise spectra at different speeds.)

The noise output of trucks is a more complicated phenomenon. First, trucks should be considered in three distinct classes according to their noise emission characteristics: light, medium, and heavy. *Light trucks* are two-axle, four-wheel vehicles such as panel and pickup trucks; their noise characteristics are similar to those of automobiles. *Medium trucks* are typically gasoline-powered two-axle, six-wheel vehicles, such as city trucks without a vertical exhaust muffler. The noise generation characteristics of these vehicles are also similar to those of automobiles. However, medium trucks are usually 10 dB noisier than automobiles for the same flow and speed.

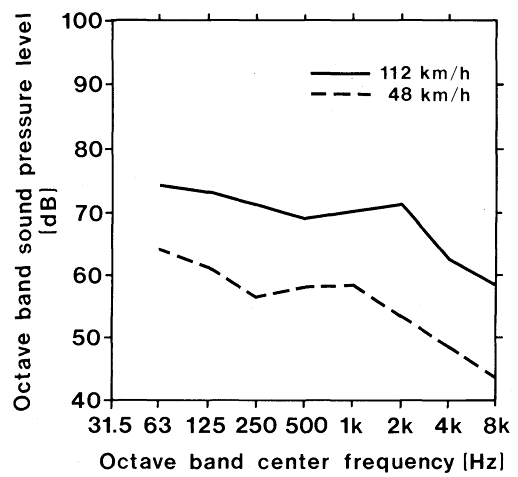

FIG. 2. Typical automobile spectra for two average speeds.

Heavy trucks are a more complex noise source. These diesel-powered, three- or more-axle vehicles have a multitude of noise mechanisms, i.e., tire noise, exhaust noise, intake noise, engine noise, and gear noise. Shown in Fig. 3 is a typical truck noise spectrum for the three major component sources: tires, engine, and exhaust. Tire-roadway interaction, the major noise source for automobiles and light and medium trucks, occurs at ground level. For heavy trucks an additional noise source, the exhaust stack opening, is nominally located eight feet above the ground. Heavy truck noise does not exhibit great variability. While tire noise varies with speed, the engine noise sources generally show little dependence upon road speed. Furthermore, drivers tend to maintain relatively constant engine speed for all road speeds.

As previously discussed, roadway noise exposure is a function of the traffic flow and pa-

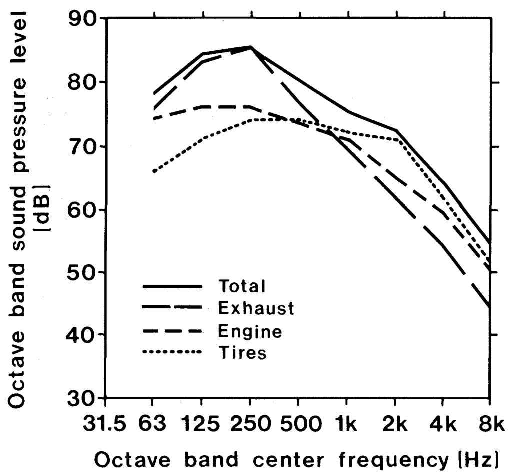

FIG. 3. Typical spectra for diesel truck and component sources.

rameters of the classes of vehicles using the roadway. Where vehicles are uniformly distributed along a single-lane roadway that is straight, infinitely long, flat, level terrain, the noise exposure is a function of the volume flow and average speed of each group of vehicles.

In practice, roadway factors will affect noise levels. Noise exposure is *increased* by uphill grades (for heavy trucks and transport vehicles). The noise exposure is decreased by buildings, land forms, or other barriers located between the roadway and the observer.

The drop-off of noise levels with distance from a roadway will typically range from 4 to 5 dB per doubling of distance. This drop-off rate is affected substantially by ground cover. Beyond two to three thousand feet, the drop-off can increase to about 6 dB per doubling of distance, due to the additional effect of atmospheric attenuation. However, the noise levels from roadway traffic will rarely be high enough to be of concern at these larger distances.

1.3 Explosions

Less common, though more dramatic, sources of sound are impulsive. Man-made explosions ranging in amplitude from nuclear blasts to the blast from a hunter's rifle can provide very large peak sound pressure levels. The variation of pressure with time from an explosive source can be approximated by the wave form shown in Fig. 4.

Near the explosion, the wave form is not so fully developed. In the far field, the most noticeable features of the impulse are the rise time, peak overpressure, and wave duration. The overpressure is given approximately as (Reed, 1977)

$$\Delta p = 0.0469 W^{b/3} R^{b}, \qquad (1)$$

where the value 0.0469 of the coefficient for yield W is given in kg of high explosives, the distance R in km, and Δp in kPa. Values for b are determined empirically to be 1.1–1.2. The wave duration determines the fundamental frequency $\nu_f = 1/\tau$ where τ is the duration in sec. The duration for a 0.57-kg charge of C-4 is typically 0.025 sec (at 100 m). Assuming spherical spreading, ν_f should be proportional to $W^{-1/3}$. Application of these scaling laws to atmospheric conditions other than

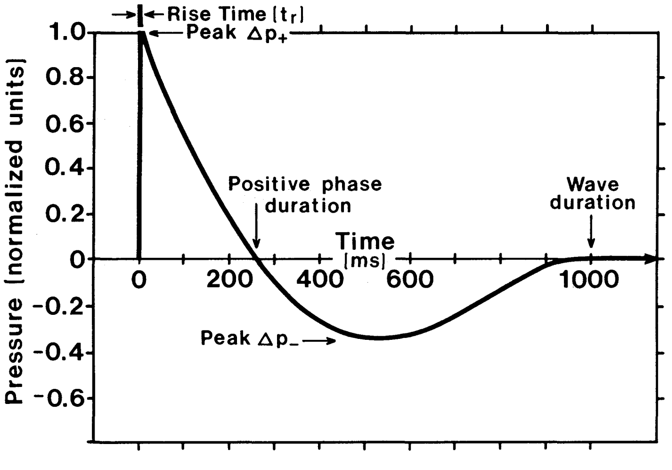

FIG. 4. Explosion-wave pressure/time signature [Reed (1977)].

STP can be accomplished, assuming the charge does *PdV* work against an ideal gas atmosphere.

1.4 Supersonic Projectiles

When an object is traveling at a speed v greater than the local speed of sound c, a wake forms behind the object. Since the object travels a distance vt while pressure waves travel a distance ct, a Mach cone develops ahead of which there is no sound and behind which the pressure rises very rapidly. The angle between the edge of the Mach cone and the projectile flight path is given as θ_M where $\cos\theta_M = c/v$. As the Mach cone passes over an observer on the ground, a sonic boom is heard.

The duration of the shock wave generated by supersonic projectiles depends upon the size of the projectile and the distance to the observation point. Near a projectile with simple geometry the duration $\tau \cong -l/v$ where l is the projectile length. As described later, propagation effects will cause the shock wave to increase in duration as it propagates.

1.5 Sounds in Nature

Natural processes provide a wide variety of atmospheric sounds (Brown, 1987). Referring to Fig. 5, we note that in the infrasound regime, earthquakes, large explosions (volcanoes, for example), and weather fronts give rise to very low-frequency atmospheric waves. Since these low-frequency waves are attenuated very little, they propagate great distances. It is not unusual to detect infrasound from these events after full circuits around the earth.

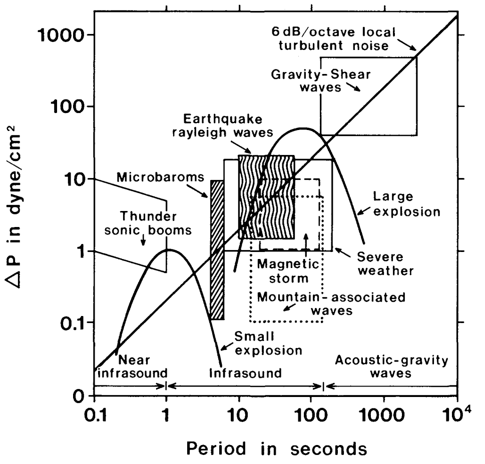

FIG. 5. Regions for infrasound sources. (Courtesy of A. J. Bedard.)

Earthquakes and other strong infrasound sources have the strange properties that the initial part of the received wave can arrive as much as a half hour before the main feature. The explanation for this effect is that high-speed Rayleigh waves traveling through the surface of the earth at a speed much greater than the speed of sound in air constantly leak energy into the atmosphere which can be detected long before the infrasound wave propagation through the atmosphere. It is frequently reported that birds and animals are startled by such arrivals, giving a warning of the upcoming infrasound.

Wind generates noise as it blows across leaves, wires, etc. The primary mechanism for the sound generation is turbulent vortex shedding. In addition to acoustic noise generated at one region and propagating to a receiver, a receiver such as a microphone or the ear responds to pressure fluctuations carried by wind. These fluctuations are not propagating but, since they result in variations in pressure as they flow past the receiver, the receiver cannot distinguish them from propagating waves. A receiver placed in the flow can also give rise to turbulent eddies providing additional noise.

Since wind noise results from the flow of turbulence, one would expect the amplitude to increase as U^2 where U is the mean flow velocity. In addition, wind noise decreases in amplitude as the frequency increases as $\nu^{-5/3}$ for moderate wind speeds. At very large wind speeds, the distribution of turbulence (discussed in more detail later) dictates fewer turbules available to flow by the wind screen resulting in a leveling off in amplitude with frequency. This effect is most pronounced at low frequencies.

An extreme case of wind noise is the sound of tornadoes (Arnold *et al.*, 1976). A model of a severe-traveling-storm cell chosen for discussion purposes is shown in Fig. 6.

Rotation of the air masses is chosen to be cyclonic in the model. The sources of sound S_i located at the coordinate (X_i, Y_i, Z_i) considered are presented in Fig. 6 and may be described as

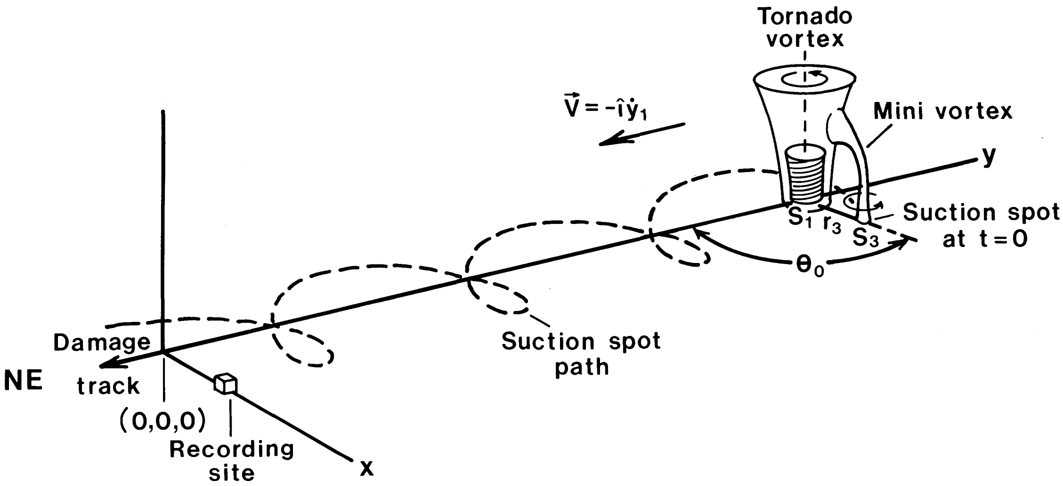

FIG. 6. Geometry assumed for the track of the Guin, Alabama, tornado and a possible minivortex. The terrain has been assumed flat although there were variations in elevation of approximately +15–20 m from the elevation at the recording site.

1. the wind-surface noise S_1 generated by interaction of the high-speed tornado winds with the ground,
2. atmospheric noise associated with the tornado vortex,
3. wind-surface noise S_3 generated by the suction spot of a minivortex,
4. atmospheric noise associated with a minivortex,
5. atmospheric noise associated with the parent storm, and
6. general nonlocalized atmospheric noises associated with the parent storm(s).

We define I_i as the acoustic power from the ith source and I_0 to be the total acoustic power (expressed in dB) when the noise (integrated over frequency) is a maximum. Maximum power probably occurs when the sound source S_1 (wind-surface noise generated by the tornado vortex) is located at or near the origin (0,0,0), and therefore the source S_1 is chosen to be located at the origin when the maximum (integrated over frequency) power is recorded at the recording site (located at position r_0,0,0).

For discussion purposes, only two principal sound sources S_1 and S_3 (which represent wind-surface interactions for the tornado vortex and suction spot, respectively) need to be considered. When the storm is most distant, the sources can be treated as spherical or point sources of sound.

One tornado studied in detail was the one which destroyed Guin, Alabama in 1974. There were no good photographic records for the Guin storm, so the distance of the suction spot from the center of the tornado vortex was assumed to be 0.6 km, and the small vortex was assumed to be moving in a circular path around the rotation axis of the tornado with a period of 60 sec. This means that the rotational (linear) speed of the suction spot was 240 km/h (150 miles/h). Combining this with the translational speed [assumed to be 96 km/h (60 miles/h)] indicates that the suction spot would have maximum wind speeds towards the recording site of 340 km/h and minimum speeds away from the receiver of 140 km/h. The high speeds involved here immediately suggest that Doppler effects should be included. For the present, however, assume that the tornado was a white-noise source. In this case, the distance from the suction spot to the receiver is given by

$$R_3=\{[6.4-26t-640\cos(\pi t/30)]^2 + [160-640\sin(\pi t/30)]^2\}^{1/2}. \qquad (2)$$

Now consider contributions at the receiver from both sources S_1 and S_3. It should be possible to combine noise from both sources and achieve a reasonable account for the qualitative and quantitative variations in the acoustic power level as the tornado approached and receded. For convenience we have chosen the level generated by each to be equal. Figure 7 presents a comparison of the relative acoustic power data and the relative power at the recording site if noise from the spherical (or point) sources S_1 and S_2 are combined. The agreement between the data and the calculated relative power is better than considering the sources separately.

Audibly, the tornado sounds like low-frequency noise (not unlike a freight train or jet aircraft landing) modulated by the rotation of the suction spot.

Thunder represents an excellent example of natural impulsive sound. As lightning discharges, the gas along the discharge channel rapidly heats and expands. This expansion propagates outward, away from the channel. To a good approximation, the frequency of maximum emission for a lightning discharge is given by (Bass, 1980)

$$\nu_n = c/[2.6(E_l/P_0\pi)^{1/2}], \tag{3}$$

where E_l is the energy per unit length dissipated in the discharge (typically 3 kJ/m) and P_0 is the ambient pressure.

Near the discharge channel, the pressure wave is a cylindrically spreading, highly nonlinear wave. For a truly cylindrical wave, all observers would hear a single clap associated with the point along the discharge path nearest to them. Real lightning, however, is very tortuous. This tortuosity gives rise to a "string of pearls" effect where thunder can be modeled as a long line of spherically spreading sources. As the thunder propagates, nonlinearity and absorption shift the spectrum to low frequencies. These combined effects give rise to the extended low-frequency rumbles associated with distant lightning and explain the sharp crack heard when lightning strikes nearby.

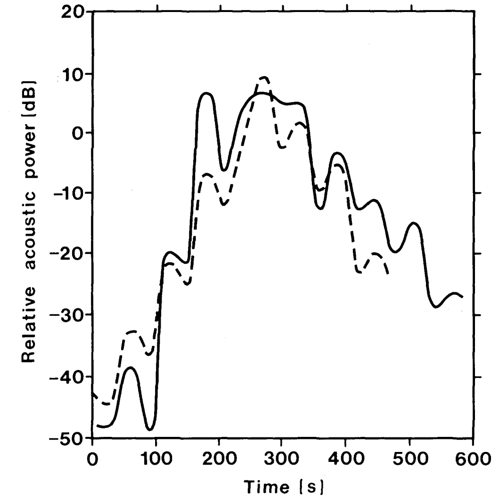

FIG. 7. Temporal variations in the relative acoustic power at 350 Hz for the Guin, Alabama, tornado compared to the variation expected from point sources S_1 and S_3. Solid line represents experimental data corrected for automatic volume control and the dashed line is predicted.

The animal world produces diverse sounds for communications (Busnel, 1977). Many animals use these sounds for warning and mating signals. The range of emission organs is quite varied and are found on all parts of the body. Invertebrates may use a toothed file to stimulate a vibrating element, vibration of nonspecialized wings (mosquitoes), semiresonant plates activated by muscle contractions, or reedlike organs activated by aspiration and respiration of air. In higher vertebrates specialized organs generate sound using forced or aspirated air. The frequency of the sound generated is controlled by varying the geometry or tension on the organs. At this point in time, sound generation mechanisms are well understood but there has been very little research which carefully characterizes total sound energy emitted. The recent discovery of communications between elephants via infrasound further emphasizes our general lack of knowledge.

Whether an animal equipped with sound emission organs will or will not activate them depends upon a number of factors such as temperature, humidity, light, and hormonal state. When sound is emitted, it follows a code involving rhythm, pulse, repetition rate, amplitude variation, and frequency. In lower animals, many of these quantities are controlled by the physical properties of the sound-producing mechanisms. In higher-order species, the code is more controlled by the central nervous system.

Messages broadcast by animals contain two specific elements of information. The first indicates presence and in a general sense, location. Hierarchical status is included for gregarious species. The second element of the message is motivation. It might also contain information giving location of an object, a territory, or a predator. Vocabularies in the animal kingdom vary widely in their complexity.

Perhaps the most interesting application of acoustics by animals is the sonar used by bats to capture flying prey. The sonar operates in two modes, search and home. In the search mode, the 35-kHz signal propagates reasonably well and has a beam width sufficiently wide to cover a large volume. Once an echo indicates a potential meal, the bat switches to a high frequency chirp (40–90 kHz). The higher frequencies provide better spatial resolution, and as the bat approaches the target, the added atmospheric absorption characteristic of high frequencies is less important. Spatial resolution automatically improves as the range to target decreases.

2. PROPAGATION

2.1 Absorption

Atmospheric absorption occurs by two basic mechanisms (Bass *et al.*, 1984):

1. classical losses associated with the transfer of acoustic energy (or the organized systematic motion associated with the kinetic energy of the molecules) into equivalent heat energy (uncoordinated random motion associated with thermal agitation) by a redistribution of translational energy among the molecules; and
2. relaxation losses associated with the redistribution (relaxation) of translational or internal energy of the molecules.

A complete calculation of sound absorption would necessarily include not only the contribution of each mechanism singly but also their interdependence; e.g., the effect of molecular relaxation processes on the classical loss mechanisms. Fortunately, it has been demonstrated by successive approximations to a solution to the Boltzmann equation and measurements at low pressures that, for frequencies below 10 MHz, absorption due to classical losses and molecular relaxation are additive. The effects of absorption will be represented by an absorption coefficient $\alpha(m^{-1})$ such that the acoustic pressure $P = P_0 e^{-ar}$. Often, the absorption coefficient is given with units of neper/m. The neper is not a unit in the normal sense but, rather, specifies that it is associated with the Naperian base *e*. The component of absorption due to viscous effects is

$$\alpha = (\omega^2/2\rho_0 c^3)(4\mu/3), \tag{4}$$

where ω is the angular frequency ($2\pi f$) in s^{-1}, c is the speed of sound in m/s, ρ_0 is the density in kg m^{-3}, and μ is the coefficient of viscosity in kg m^{-1} s^{-1}.

Energy loss from the sound wave can be separated into two distinct processes. First, since the sound wave causes a sinusoidal variation in temperature in space, heat will be conducted from the regions of high temperature to those of lower temperature. This heat conduction process converts the energy of the sound wave into random thermal motion of the gas molecules. Heat conduction increases the absorption to

$$\alpha = (\omega^2/2\rho_0 c^3)[4\mu/3 + (\gamma-1)\kappa/(\gamma c_v)], \tag{5}$$

in m^{-1}, where κ is the coefficient of thermal conductivity in J (kg mol)$^{-1}$ K^{-1} kg m^{-1} s^{-1}, and c_v is the specific heat at constant volume (J/K).

In addition to energy loss due to heat conduction, energy can also be lost due to relaxation of internal degrees of freedom. As the local temperature increases, the energy of internal modes also increases. If the temperature changes very slowly, the internal energy changes by an amount equal to $c_{\text{int}}\Delta T$, where c_{int} is the specific heat of the internal energy modes (e.g., due to rotational and vibrational processes), and ΔT is the local difference between the ambient temperature and the temperature in the presence of the sound wave. For low frequencies, any energy which goes into the internal modes while the local temperature is at a maximum will be diminished as soon as the local temperature begins to decrease. However, this transfer of energy from the translational energy of the gas to internal energy modes and back can only take place during collisions between the gas molecules. During any one collision, there is the probability of energy being transferred which depends on the particular internal mode of concern. So, as the frequency is increased, the process of transferring energy back and forth between internal energy modes and translation introduces a time lag between the time needed for the local temperature to decrease and the time needed for the internal energy modes to give energy back to the translational modes. This time delay results in a decrease in the energy of the sound—an attenuation. For a particular energy mode, at very low frequencies, no absorption will result. As the frequency is increased to a value referred to as the relaxation frequency f_r of the mode (or alternatively as the frequency of maximum absorption), the absorption increases. Then, as the variations in the local temperature become so rapid that the internal mode is always behind in transferring energy, the relaxation absorption becomes constant. For any particular relaxation process, the absorption can be expressed by a relation having the form

$$\alpha=\frac{\pi s_v}{c}\,\frac{f^2/f_r}{1+(f/f_r)^2} \tag{6}$$

in Np m^{-1}, where s_v is the relaxation strength in nepers, which depends on the specific heat of the relaxing mode.

For air, three relaxation processes are important; those associated with O_2 vibration, N_2 vibration, and rotation. Rotational relaxation occurs at very high frequencies so that f/f_r in the denominator of Eq. (11) can be ignored below 10 MHz at 1 atm of pressure (limit decreases in proportion to the local pressure). In this case, rotational relaxation has the same form as classical absorption and the two can be combined into a single term. Using atmospheric values for density, viscosity, and the speed of sound, the combined term is

$$\alpha_{\mathrm{cr}}=1.83\times 10^{-11}\,\frac{(T/T_0)^{1/2}f^2}{(P/P_0)}, \tag{7}$$

where $T_0=293.15$ K and $P_0=1$ atm.

Oxygen and nitrogen relaxation depend strongly on the mole fraction of water vapor. In terms of the relative humidity h_r, in percent, the mole fraction, h_f in percent, can be written as

$$h_f=h_r(P_{\mathrm{sat}}/P_0). \tag{8}$$

The ratio of saturated vapor pressure to atmospheric pressure (P_{sat}/P_0) adopted by the World Meterological Organization is

$$\begin{aligned}\log_{10}(P_{\mathrm{sat}}/P_0)=&10.795\,86[1-(T_{01}/T)]-5.028\,08\log_{10}(T/T_{01})\\&+1.504\,74\times 10^{-4}\{1-10^{-8.296\,92}[(T/T_{01})-1]\}\\&+0.428\,73\times 10^{-3}\{10^{4.769\,55}[1-(T_{01}/T)]-1\}-2.219\,598\,3,\end{aligned} \tag{9}$$

where T is the air temperature in kelvins, and T_{01} is the triple-point isotherm temperature with the exact, internationally agreed value of 273.16 K.

The values for the relaxation frequencies of oxygen $(f_{r,\mathrm{O}})$ and nitrogen $(f_{r,\mathrm{N}})$ can be extracted from the experimental data. The best available values for these quantities are

$$(f_{r,\mathrm{N}})=(P/P_0)(9+200h_f) \tag{10}$$

and

$$(f_{r,\mathrm{O}})=(P/P_0)\{24+4.41\times 10^4 h_f[(0.05+h_f)/(0.391+h_f)]\}. \tag{11}$$

With these relaxation frequencies and assuming that dry air is composed of 20.9% O_2 and 78.1% N_2, the total absorption becomes

$$\begin{aligned}\alpha=f^2\Bigg[&1.83\times 10^{-11}(P_0/P)(T/T_0)^{1/2}\\&+(T_0/T)^{5/2}\left(1.278\times 10^{-2}\,\frac{e^{-2239.1/T}}{f_{r,\mathrm{O}}+(f^2/f_{r,\mathrm{O}})}\right)\\&\times\left(1.069\times 10^{-1}\,\frac{e^{-3352/T}}{f_{r,\mathrm{N}}+(f^2/f_{r,\mathrm{N}})}\right)\Bigg]\end{aligned} \tag{12}$$

in Np m^{-1}, with $f_{r,\mathrm{O}}$ given by Eq. (11) and $f_{r,\mathrm{N}}$ by Eq. (10) and with the percent mole fraction h_f related to relative humidity h_r by Eqs. (8) and (9). In Eq. (12), air temperature T is in kelvins; $T_0=293.15$ K; atmospheric pressure P is in N m^{-2}; and $P_0=1.013\,250\times 10^5$ N m^{-2} (1 atm). The combined effects of these different loss terms are shown in Fig. 8.

Fogs and aerosols can introduce additional sound absorption mechanisms (Wei *et*

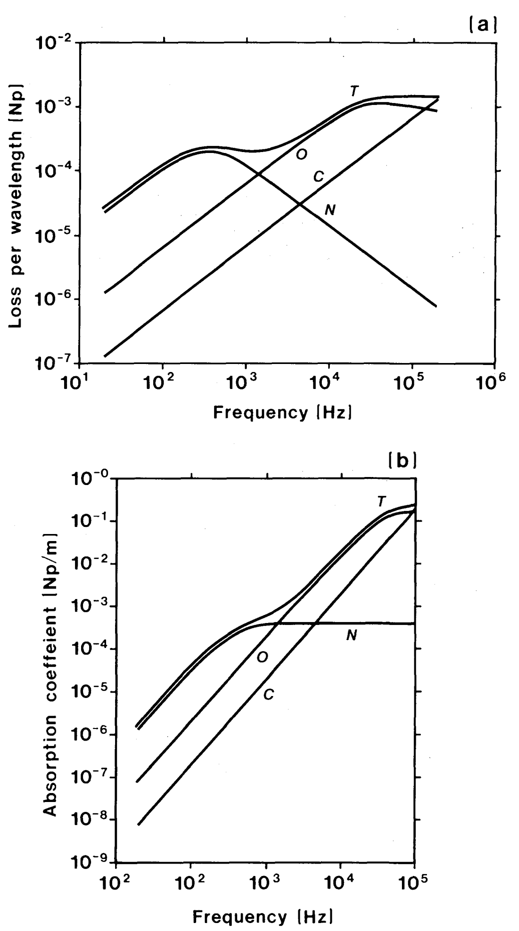

FIG. 8. Components and general behavior of total air absorption in air in terms of (a) loss per wavelength and (b) loss per unit distance. The contributions to the total absorption *T*, are *C*, classical and rotational relaxation; O, oxygen relaxation, and N, nitrogen relaxation.

al., 1987). These include evaporation and condensation around the droplets, partial entrainment of droplets by velocity fluctuation of the sound wave, heat transfer between droplets and surrounding air, the excitation of shape oscillations in the droplets, and gradients in the temperature and velocity along with heat fluxes and viscous effects. There have been little data taken in real fogs so our understanding of the mechanisms relies on theory and laboratory data.

Real fogs are composed of droplets with a wide range in size and number per unit volume. An average droplet radius is probably 8 μm and a typical ratio of liquid water content to air mass per unit volume might be 1.5×10^{-3}. A typical curve of fog absorption per unit length is given in Fig. 9 for different size droplets.

For comparison, molecular absorption at 100% relative humidity is also included. It can be seen, by comparison of these, that the two are comparable at low frequencies but that standard molecular absorption begins to dominate at high frequencies.

2.2 Effects of the Ground Surface

Research results of the past decade have greatly advanced understanding of sound propagation near the surface of the earth. Two major contributions have led to this rapid increase in understanding. The first was development of an accurate mathematical description of the sound field from a point source near a complex impedance boundary (Attenborough *et al.*, 1980). The second was the development of a microscopic description of the interaction of airborne sound with the earth (Sabatier *et al.*, 1986). Due to these advances, the physical understanding of sound propagation above plane homogeneous earth rivals that of atmospheric absorption. Referring to Fig. 10, the total acoustic field at the receiver can be written as

$$\phi_{\mathrm{TOT}}=\frac{e^{ik_1R_1}}{R_1}+\frac{e^{ik_1R_2}}{R_2}\{R(\theta_i)+B[1-R(\theta_i)]F(w)\}. \qquad (13)$$

In this expression for ϕ_{TOT}, k_1 is the propagation constant for air (m^{-1}), R_1 is the direct distance from the source to receiver, and R_2 is the path length from source to receiver that

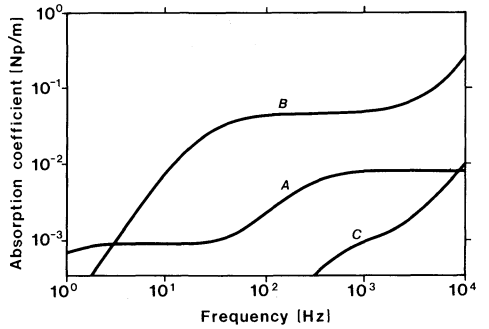

FIG. 9. Sound attenuation coefficient α_f, in units of Np/m, vs frequency. Curve A, $r=8$ μm, curve B, $r=1$ μm, curve C, molecular absorption [see Bass (1980)].

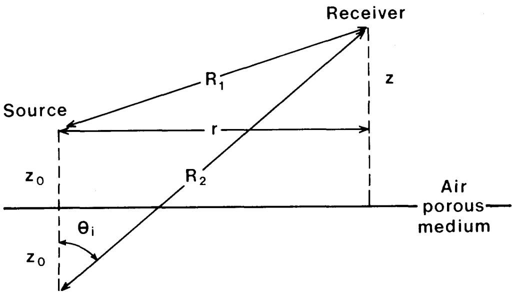

FIG. 10. Geometry of point-to-point propagation over a porous half-space.

includes one ground reflection. The quantity in curly braces is a reflection coefficient which has been modified for spherical waves reflecting from a complex-impedance flat boundary. Inside the curly braces is the usual plane-wave reflection coefficient $R(\theta_i)$, plus a term that depends on B and $F(w)$. The term B takes into account phase changes upon reflection from a complex impedance surface. For a locally reacting surface; (typical outdoors) $B\cong 1$. $F(w)$ arises from the need to match the curved wave front to a plane boundary. The quantity w is referred to as the numerical distance. It is useful to consider the numerical distance as representing the propagation distance scaled by the impedance. As w increases, wave fronts become more planar and $F(w)$ decreases.

The plane-wave reflection coefficient is given by

$$R(\theta_i)=\frac{\cos\theta_i-m(n^2-\sin^2\theta_i)^{1/2}}{\cos\theta_i+m(n^2-\sin^2\theta_i)^{1/2}}, \qquad (14)$$

where the angle θ_i is the angle of incidence of the incoming wave with the ground, measured from the vertical. The symbol n is the wave-number ratio

$$n=k_2/k_1, \qquad (15)$$

where k_2 is the propagation constant in the ground. The value for m may be deduced from the relation

$$\beta_c=mn=1/Z_c, \qquad (16)$$

where β_c and Z_c are known as the normalized characteristic admittance and the normalized characteristic impedance, respectively. The characteristic impedance can be written in terms of real and imaginary parts as $Z_c = R + iX$.

The equations for B and $F(w)$ are presented in their extended reaction form, both for added generality and a slight increase in accuracy. For the extended reaction case,

$$B=\left(\frac{[\cos\theta_i+\beta_c(1-\sin^2\theta_i/n^2)^{1/2}](1-n^{-2})^{1/2}}{[\cos\theta_i+\beta_c(1-n^{-2})^{1/2}/(1-m^2)^{1/2}](1-\sin^2\theta_i/n^2)^{1/2}}\right)\times\left(\frac{[(1-m^2)^{1/2}+\beta_c(1-n^{-2})^{1/2}\cos\theta_i+\sin\theta_i(1-\beta_c^2)^{1/2}]^{1/2}}{(1-m^2)^{3/2}(2\sin\theta_i)^{1/2}(1-\beta_c^2)^{1/4}}\right). \qquad (17)$$

For local reaction, which is often a good approximation, $B\cong 1$. The equation for the "sphericity" factor, $F(w)$, is

$$F(w)=1+i\pi^{1/2}we^{-w^2}\,\mathrm{erfc}(-iw), \qquad (18)$$

where erfc denotes the complementary error function, w is the so-called "numerical distance" defined by

$$w^2=ik_1R_2\{1+[\beta_c\cos\theta_i(1-n^{-2})^{1/2} -\sin\theta_i(1-\beta_c^2)^{1/2}]/(1-m^2)^{1/2}\}, \qquad (19)$$

and all square roots are taken so that their real parts are non-negative.

The first and second terms in Eq. (13) are readily identified as the direct and reflected waves. The last term ($[1 - R(\theta_i)]F(w)$ recalling that $B\cong 1$) arises mathematically from the need to match the boundary conditions, in particular the variation in wave-front curvature with distance (Piercy *et al.*, 1977). The function $F(w)$ in Eq. (18) is plotted for various values of the phase angle [$\phi=\tan^{-1}(X/R)$] in Fig. 11.

In order to understand the third term in Eq. (13) consider the case where the source and receiver are both on the ground ($\theta_i=90°$). For this case, $R(\theta_i)$ in Eq. (13) becomes -1 and, since $R_1 = R_2$, the first two

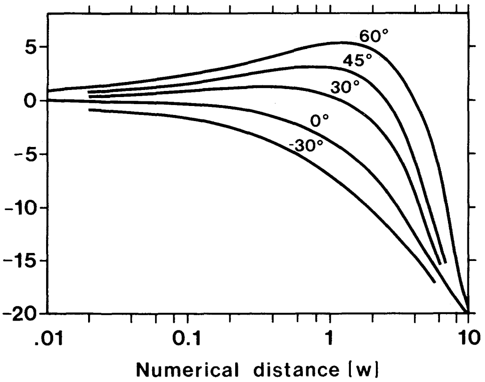

FIG. 11. Amplitude factor $F(w)$ of the ground and surface waves vs numerical distance w for various values of the phase angle ϕ of the surface impedance.

Table 1. The propagation distance d_w for numerical distance = 1, and height z_{sw} for the amplitude of the surface wave to decrease by $1/e$ from its value at the boundary, calculated from the impedance for mown grass.

f (Hz)	d_w (m)	z_{sw} (m)
50	4000	58
100	1500	23
200	270	7.3
500	24	0.9
1000	3.6	0.5
2000	1	0.15

terms in Eq. (13) completely cancel to form a shadow zone. This shadow zone is penetrated by the third term. For $\phi=0$ (purely resistive surface), the third term is referred to as a ground wave in analogy to electromagnetic propagation. The curve for $\phi=0$ in Fig. 11 indicates that for short distances, the ground wave suffers no attenuation in excess of spherical spreading but for longer distances falls off with an additional 6 dB per doubling of distance.

It will be shown later that for real ground surfaces, ϕ varies between 30° and 60° so F in Fig. 11 differs from that for $\phi=0$ by the pressure of a substantial increase for $w \geqslant 1$. This increase is due to the contribution of a surface wave in the air which propagates with an amplitude that decreases exponentially with height above the boundary. For $w<1$, the contribution of the surface wave is smaller than that of the ground wave because the surface-wave amplitude decreases at only 3 dB per doubling of distance. For $w>1$, the amplitude of the surface wave again becomes smaller because of attenuation by viscous losses in the pores of the boundary.

The scale of the distance and heights of the ground and surface waves is given in Table 1 for a grassy surface. Figure 12 gives relative contributions of the various waves.

Values of w, ϕ, and $R(\theta_i)$ all depend upon the complex normalized characteristic impedance of the sound. The four-parameter model of Attenborough (1985) can be used to calculate ground impedance. For ground surfaces commonly encountered, the complex normalized characteristic impedance of the ground can be approximated by

$$Z_c \cong \left(\frac{4q^2}{3\Omega} + \frac{iS_f^2\sigma}{\omega\rho_0}\right) \Big/ k_b, \tag{20}$$

where $q^2 = \Omega^{-n'}$ and n' is a constant which relates tortuosity (q) to porosity (Ω), S_f is the pore shape factor ratio, Ω is the porosity of the ground, σ is the flow resistivity of the ground (kg s^{-1} m^{-3} or g s^{-1} m^{-3}), ω is the angular frequency (s^{-1}), ρ_0 is the density of air (kg m^{-3}), and k_b is the normalized wave number (m^{-1}).

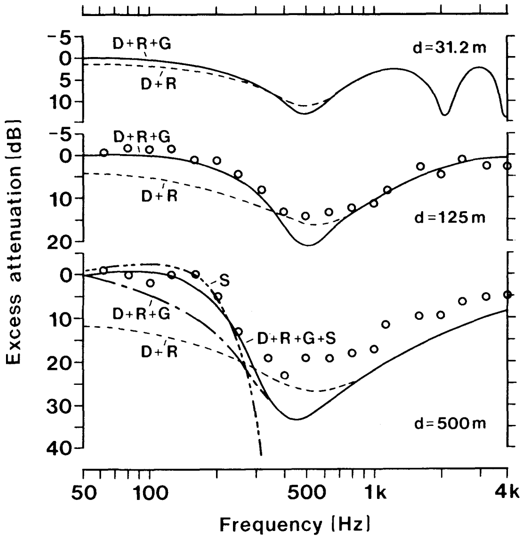

FIG. 12. Excess attenuation for propagation from a point source over mown grass, source height = 1.8 m, receiver height = 1.5 m. The calculated curves show the contributions from the various waves—direct D, reflected R, ground G, and surface S. The points are measurements of jet noise at comparable distances. The excess attenuation is relative to that for a point source placed on a perfectly hard surface.

The normalized wave number k_b is computed as

$$k_b \cong (\gamma\Omega)^{1/2}\left[\left(\frac{4}{3}-\frac{\gamma-1}{\gamma}N_{\text{pr}}\right)\frac{q^2}{\Omega}+\frac{iS_f^2\sigma}{\omega\rho_0}\right]^{1/2}, \tag{21}$$

where γ is the ratio of specific heats (1.4), and N_{Pr} is the Prandtl number (0.72).

The variables S_f, Ω, and n' have been varied individually until agreement between theoretical and measured values for impedance has been achieved for a variety of surfaces. As a result of such comparisons, n' is always set equal to 0.75 and S_f is always set equal to 0.875. Recommended values for porosity and flow resistivity are given in Table 2.

At intermediate to high frequencies, the semiempirical expression by Delany and Bazley (1977) and Chessel (1977),

$$Z_c=(R+iX)/[1-(k/k_\alpha)]^{1/2}, \tag{22}$$

where

$$\begin{aligned} R&=[1+9.08(f/\sigma_e)^{-0.75}],\\ x&=11.9(f/\sigma_e)-0.73,\\ k_\alpha&=(\omega/c_0)[1+10.8(f/\sigma_e)^{-0.70}\\ &\quad -i10.3(f/\sigma_e)^{-0.59}], \end{aligned} \tag{23}$$

has been found to give adequate agreement between predictions and experiment. In these equations, f is in Hz and σ_e is in cgs rayls. The effective flow resistance $\sigma_e \cong S_f^2\sigma/\Omega$. For large σ_e, Attenborough's four-parameter model reduces to

$$Z_c \cong 0.218(1+i)(\sigma_e/f)^{1/2}. \tag{24}$$

Some ground surfaces have a layered structure which results from the gradual deposition of material over a soil base. The effective impedance $Z(d)$ for a layer of depth d and impedance Z, above a semi-infinite layer of impedance Z_2 is given by

$$Z(d)=\left(\frac{Z_2-iZ_1\tan(k_bd)}{Z_1-iZ_2\tan(k_bd)}\right)Z_1, \tag{25}$$

where k_b is the bulk propagation constant in the upper layer. The quantities Z_1, Z_2, k_b are computed from Eqs. (21) and (22) or (23).

The effect of ground reflection can be seen in Fig. 13. The excess attenuation is given relative to what it would be in the free field (positive excess attenuation means lower level). The computed curve is for a source height of 15 m, receiver height of 0.55 m, range of 500 Hz, and specific impedance Z of $9.34-8.75i$.

The first dip is the so-called ground effect dip caused by interference between direct and reflected sound paths. At frequencies above the ground effect dip, constructive interference leads to an enhanced signal level followed by additional interference minima. At very large ranges, the direct and reflected paths will be nearly equal leading to a surface-induced shadow region.

Table 2. Parameters required for the four-parameter model; n' is always set equal to 0.750 and S_f (shape factor ratio) is always set equal to 0.875.

Description of surface	Ω	σ (cgs)
Dry snow, new fallen 0.1 m over about 0.40 m old snow	0.850	23
Sugar snow	0.825	48
In forest, pine or hemlock	0.825	60
Grass: rough pasture, airport, public buildings, etc.	0.675	330
Roadside dirt, ill-defined, small rocks up to 0.1 m mesh	0.575	960
Sandy silt, hard packed by vehicles	0.475	3 470
"Clean" limestone chips, thick layer (0.01–0.025 m mesh)	0.425	6 470
Old dirt roadway, fine stones (0.05 m mesh) interstices filled	0.400	7 500
Earth, exposed and rain-packed	0.350	17 100
Quarry dust, fine, very hard-packed	0.300	41 700
Asphalt, sealed by dust and light use	0.250	120 000

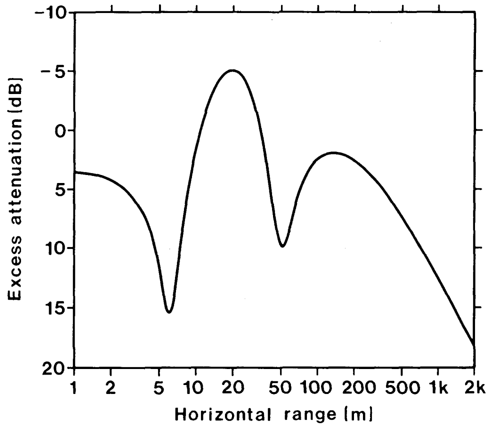

FIG. 13. Excess sound attenuation due to surface.

2.3 Refraction and Diffraction

The atmosphere is never quiet, but in some cases it is convenient to describe it in terms of temperature or, in the case of a steady wind, speed of sound as a function of altitude (Brown and Hall, 1978). Throughout the troposphere and stratosphere, the atmosphere has a relatively constant (with some variation with humidity) molecular weight of 28.97. Above infrasonic frequencies, the speed of sound c will be given by

$$c=343.3(T/293.15)^{1/2}\ \mathrm{m\,s^{-1}} \tag{26}$$

and the density will be given by the ideal gas law, $\rho = P_0/RT$ where P_0 is the static pressure and R is the universal gas constant. Figure 14, from Lindsey (1974), shows the speed of sound as a function of altitude for a model atmosphere. A model atmosphere, however, seldom if ever exists (Brown and Hall, 1978). The first few kilometers above the ground undergo significant diurnal variations. Inversions caused by radiative heating at night give rise to a sound speed which in creases with altitude near the surface. Following sunrise, rapid surface cooling causes surface air to rise pushing this inversion higher before destroying it. Wind causes the speed of sound to be dependent upon direction and can eliminate inversions by mixing air from different levels.

When the speed of sound as a function of altitude varies linearly, high-frequency sound follows a curved path represented by the arc of a circle shown in Fig. 15.

Wind causes the local speed of sound to become dependent upon direction. Sound propagating upwind will be refracted upward; downwind, waves are diffracted downward. When computing the local speed of sound, the important quantity for near horizontal propagation is

$$c=c+w\cos\theta, \tag{27}$$

where θ is the angle between the direction of propagation (propagation speed c) and the wind (wind speed w). Gradients in this quantity give rise to enhanced refraction and, at low frequencies, diffraction.

For horizontally stratified media, the ray paths are given by Snell's law,

$$\frac{\cos\theta(z)}{c_z}=s=\frac{\cos\theta_s}{c_s}, \tag{28}$$

where c_z is the sound speed at altitude z, c_s is the sound speed at the source, and s is a constant. The initial angle measured from horizontal is θ_s with upward-sloping rays having positive launch angles. When the sound speed gradient ($g_s = dc/dz$) is linear,

$$\cos\theta_f=s(c_s+g_sh), \tag{29}$$

where θ_f is the angle made with the adjoining interface and h is the separation between interfaces. Solving for h yields

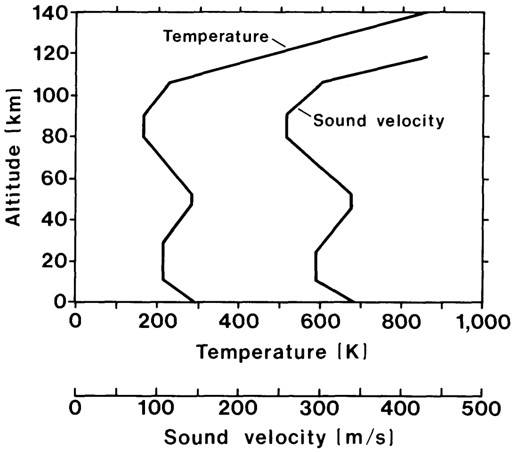

FIG. 14. Temperature and sound velocity in the model atmosphere as developed by the Air Research and Development Command in 1959. Details of the real atmosphere vary with location on the earth's surface and with the seasons. Wind speed also influences sound velocity (Lindsey, 1974).

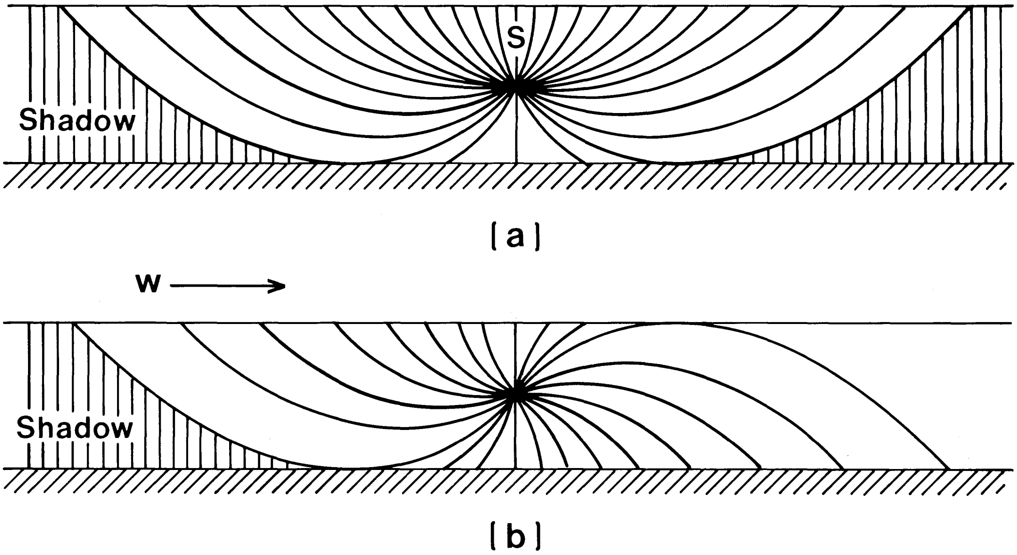

FIG. 15. Acoustic rays and shadow zones for (a) decreasing temperature and (b) increasing horizontal wind.

$$h=\frac{1}{sg_s}\cos\theta_f+\text{const.} \tag{30}$$

We note that the ray path is circular with radius $1/sg_s$. A single linear variation in c seldom applies in the first hundred meters or so. In addition, when significant (greater than 1%) variations in the speed of sound occur in a distance comparable to the acoustic wavelength, diffraction results. Ray tracing is not valid in this case and one must resort to numerical or approximate solutions to the wave equation.

The effects of diffraction are most pronounced near a shadow boundary. For an upward-refracting atmosphere, rays emanating from a source will bend upward creating an ever enlarging zone on the surface where rays cannot penetrate. In this shadow boundary, diffracted and scattered waves dominate.

A residue series has been obtained to treat the case of a stratified atmosphere where the sound speed varies linearly with height above a flat surface (Pierce, 1981; Berengier and Daigle, 1988). When $r > h_s + h$, where $z=h$ is the height of the receiver (see Fig. 16), the solution can be written

$$p(r,z)=\frac{\pi e^{i\pi/6}}{l}\sum_n H_0^{(1)}(k_nr)\,\frac{\text{Ai}[b_n-(h_s/l)e^{2i\pi/3}]\text{Ai}[b_n-(z/l)e^{2i\pi/3}]}{[\text{Ai}'(b_n)]^2-b_n[\text{Ai}(b_n)]^2}, \tag{31}$$

where

$$b_n=\tau\exp(2i\pi/3)=(k_n^2-k_0^2)l^2\exp(2i\pi/3) \tag{32}$$

are the zeros of the expression

$$\text{Ai}'(b_n)+q[\exp(i\pi/3)]\text{Ai}(b_n)=0. \tag{33}$$

The notation $H_0^{(1)}$ signifies the zeroth-order Hankel function of the first kind and Ai signifies an Airy function with primes denoting derivatives.

The abbreviations in Eqs. (31)–(33) are

$$q=ik_0\,\rho_0 lc/Z_c,$$
$$l=(R/2k_0^2)^{1/3},$$
$$\tau=(k^2-k_0^2)l^2,$$

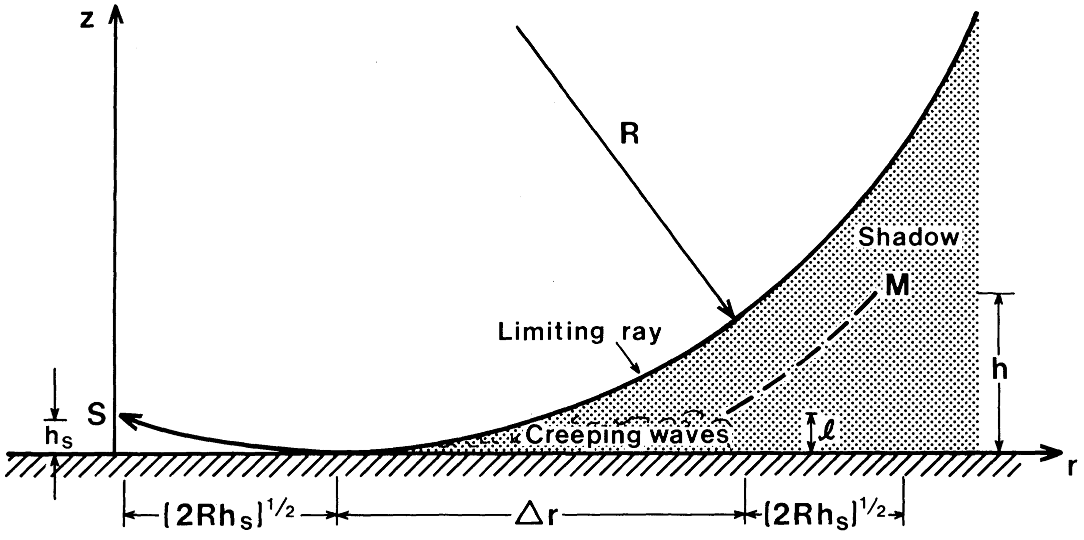

FIG. 16. Sketch showing the geometrical definitions for propagation in a stratified atmosphere above flat ground.

where $k_0 = \omega/c(0)$ and Z_c is the specific impedance of the surface.

The solutions of Eq. (33) for the b_n are simple only in the limiting cases of a rigid surface ($Z_c \approx \infty$) and that of a pressure release surface ($Z_c \approx 0$). In the intermediate cases of a surface of complex finite impedance Z_c, Eq. (33) must be solved numerically for its zeros for each value of n required in the series. The expression in Eq. (33) is a complex function of the complex variable b. Finding the zeros involves solving two nonlinear equations with two real unknowns for which a number of numerical methods exist.

The theory [Eq. (31)] is valid for propagation above a curved surface if z is interpreted as the height h transverse to the curved surface, r is interpreted as the arc length along the surface, and the radius of curvature R becomes, for the case studied here, the radius of the curved cylindrical surface.

When the receiver is deep within the shadow, but not close to the ground, the expression in Eq. (31) can be approximated by the first term in the series and, further, the Hankel and Airy functions can be approximated by their asymptotic behavior. For the purposes of this article it is sufficient to restrict the analysis to the magnitude of the pressure and these approximations yield the following expression:

$$|p(r,z)| = \left(\frac{1}{2k_0 r l^2}\right)^{1/2} \frac{1}{K(Z_c)} \left(\frac{1}{h_s}\right)^{1/4} \times \left(\frac{1}{z}\right)^{1/4} \exp[-\alpha(Z)\Delta r], \tag{34}$$

where k_0 and l are defined above. The function $K(Z)$ essentially describes the contribution of the denominator in Eq. (31) and has limiting values of $K(\infty) = 1.04$ in the case of a rigid surface and $K(0) = 1.74$ in the case of a pressure release surface. Similarly, the function $\alpha(Z)$ describes the attenuation of the creeping wave along the portion of the path Δr and takes on the following limiting values:

$$\alpha(\infty) = 0.7(k_0/R^2)^{1/3}, \tag{35}$$

in the case of a rigid surface, and

$$\alpha(0) = 1.61(k_0/R^2)^{1/3}, \tag{36}$$

in case of a pressure release surface.

As the frequency gets lower, the creeping wave approximation requires more and more terms in the expansion favoring a numerical solution to the wave equation.

2.4 Effects of Topography

Up to this point, the surface of the Earth has been assumed flat. The presence of hills, trees, buildings, and constructed sound barriers will modify, to some extent, the amplitude of the received sound field. The sound field behind a semi-infinite, thin, rigid plate with no ground surface can be predicted using the integral equations of Fresnel. In this simple treatment, the top edge of the barrier acts as a line source diffracting energy into the region behind the barrier. In practice, the problem is much more difficult.

If one considers a long barrier (Isei *et al.*, 1980), the sound paths shown in Fig. 17 will all contribute to some extent to the field at the receiver *R*. The total field Φ at receiver *R* depends on the fields from the real source *S* and the image source in the ground *T*, and the values of these fields at the image of the receiver position *X*, namely

$$\Phi=\Phi_{SR}+\Phi_{TR}+\Phi_{SX}+\Phi_{TX}, \qquad (37)$$

where Φ_{SR} is the direct diffracted field due to source *S* at receiver *R* (shortest path $SBR = d_{SB} + d_{BR}$), Φ_{TR} is the diffracted field due to image source *T* in the ground at receiver *R* (shortest path $TBR = d_{TB} + d_{BR}$), Φ_{SX} is the diffracted field due to image source *T* at image receiver *X*, both in the ground (shortest path $TBX = d_{TB} + d_{BX}$). More rigorously, the contribution from image source *U* in the barrier should not be overlooked. Then, instead of Eq. (37), we have

$$\Phi=\Phi_{SR}+\Phi_{TR}+\Phi_{SX}+\Phi_{TX}+\Phi_{UR}+\Phi_{UX}, \qquad (38)$$

where Φ_{UR} is the diffracted field due to image source *U* in the barrier at receiver *R* (shortest path $UBR=SBR$) and Φ_{UX} is the diffracted

FIG. 17. Ray path diagrams and equations used for calculating the six components (lines II–VII) of the diffracted sound field at *R*. Line I shows how to calculate, without the barrier, the reference sound field needed for describing barrier insertion loss. Column 1 shows the actual ray path, including reflections, that relates to the field component Φ. Column 2 shows the equivalent ray path used for calculations of the diffracted field corrected for reflection and possible presence of ground waves, using the equation of column 3, in order to obtain the desired field component Φ.

field due to image source *U* at the image receiver *X* (shortest path *UBX*=*SBX*). Furthermore, if the receiver *R* is directly illuminated by the source *S*, or its image *T*, then another two fields, due to geometrical spreading from each source, should be added to the field Φ.

The evaluation of each of these terms gives rise to predictions such as that shown in Fig. 18. As expected, at low frequencies, barriers provide little shielding.

Natural barriers such as hills can be represented by wedge shaped barriers or a wedge with a horizontal top (wide barrier). Again, the largest insertion loss is observed at high frequencies.

In practical applications, the insertion loss shown in Fig. 18 near 5 kHz is seldom achieved. Refracted and scattered sound often fill in interference dips providing less attenuation. Typical results are shown in Fig. 19 (from Daigle, 1982) with highway noise as a source and a receiver on the opposite side of a barrier 1 m above an asphalt surface. Note that at high frequencies where diffraction theory predicts the greatest insertion loss, the experimental measurements liewell above theoretical predictions. Scattering degrades the effect of the barrier.

For noise control, it is often desirable to make use of plants (trees, shrubs, etc.) (Price *et al.*, 1988). At low frequencies (below ~800 Hz), the primary effect of plant growth along the propagation path is a modified surface impedance due to deposited organic matter. The surface flow resistance is typically decreased in such regions to below 100 cgs rayls. Further, the organic layer requires the use of a two-layer model for the surface impedance. At higher frequencies, scattering by trees can become significant for dense growths.

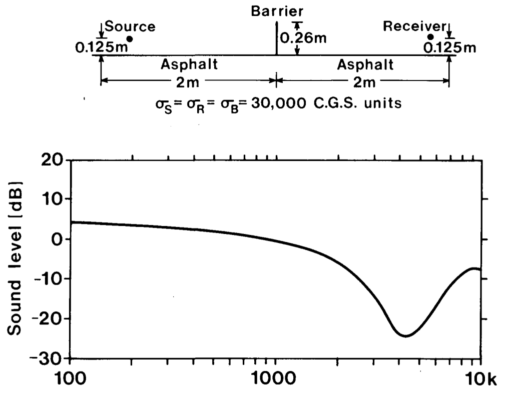

FIG. 18. Attenuation spectrum predicted by diffraction theory for the particular symmetrical configuration of source, receiver, barrier, and hard ground sketched at the top of the figure.

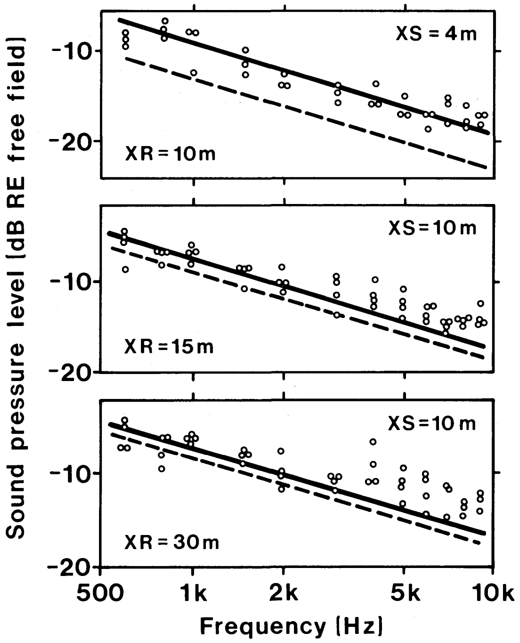

FIG. 19. The points are the measured sound pressure levels from a point source diffracted at the edge of a barrier 2.44 m high. XS and XR are, respectively, the horizontal distances from source to barrier and receiver to barrier (on hard ground—asphalt). The dashed curve is the prediction of diffraction theory.

Even at high frequencies, however, insertion loss due to trees is typically small. Figure 20 gives results for a very dense coniferous site where measurable sound attenuation is achieved. The trees can be modeled as scattering cylinders which are assumed to be identical, vertical, and infinitely long. Multiple scattering is allowed. The use of two arrays is intended to represent scattering both by tree trunks and by foliage.

2.5 Effects of Turbulence

The sound level at a receiver is seldom the value expected assuming the mechanisms discussed to this point. The real atmosphere is far from stationary with changes in acoustic index of refraction occurring on a time scale of milliseconds to seconds due to atmo-

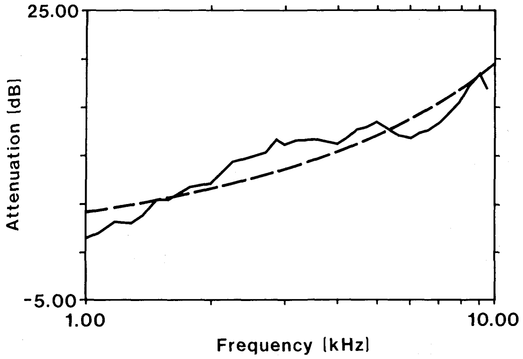

FIG. 20. Mean measured attenuation in dB per 24 m at site 3 (mixed coniferous) compared with a prediction (broken line) based upon the sum of two scattering arrays of cylinders: (a) rigid, radius 0.066 m, density 0.0724 m^{-2} and (b) nonrigid, radius 0.001 m, density 100 m^{-2}; σ_e (of surface) 860 $g^{-1}\,cm^{-3}$.

spheric turbulence. There are two sources for the turbulence. The first is that due to heating and cooling of the surface which gives rise to thermal plumes (thermally driven turbulence). The second is due to the presence of the ground surface which causes a gradient in wind leading to shear and turbulent eddy formation. In most cases, this wind-driven turbulence dominates. Acoustically, this turbulence serves to scatter sound into shadow zones and causes sound beams to spread.

First, consider a simple model of turbulence effects on the acoustic field. A simplified representation is shown in Fig. 21. As an acoustic ray travels toward the receiver, its direction and phase will be modified slightly when it encounters a turbule. The received signal will be some vector sum of these individual path segments plus any random noise at the same frequency. The next (either later or adjacent) acoustic ray will follow a slightly different path arriving with different amplitude and phase. The net result is that the received amplitude and phase will form a pattern in phase space rather than a point.

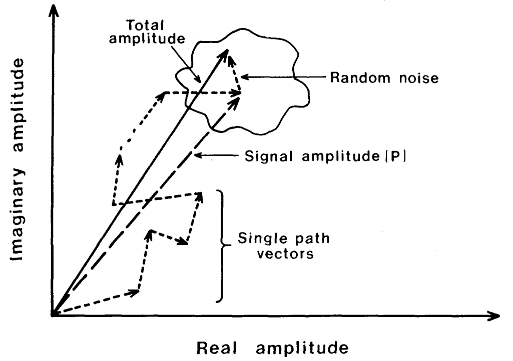

FIG. 21. Representation of acoustic ray scattered by turbulence.

If we now look along the amplitude vector, the probability (P) of observing the received sound with a given amplitude, p, can be represented by a Ricean distribution (Rayleigh at high frequencies, Gaussian at low frequencies) as shown in Fig. 22 and given by

$$P(p)=\frac{p}{\delta^2}\,(e^{-(p^2+p_0^2)/\delta^2})I_0(pp_0/\delta^2), \tag{39}$$

where p_0 is the average sound pressure, δ is a measure of the width of the distribution, and I_0 is the modified Bessel function.

It is sometimes convenient to represent phase and log-amplitude fluctuations in terms of structure functions D_s and D_x, respectively, in a plane perpendicular to the direction of propagation. For two microphones separated by distance ρ at a distance r from the source,

$$D_x(r,\rho)=\langle[x(\mathbf{r}+\rho)-x(\mathbf{r})]^2\rangle \tag{40}$$

and

$$D_s(r,\rho)=\langle[\phi(\mathbf{r}+\rho)-\phi(\mathbf{r})]^2\rangle, \tag{41}$$

where $x(\mathbf{r})$ is the log-amplitude measured at one microphone and $x(\mathbf{r}+\rho)$ is the log-amplitude measured at the second.

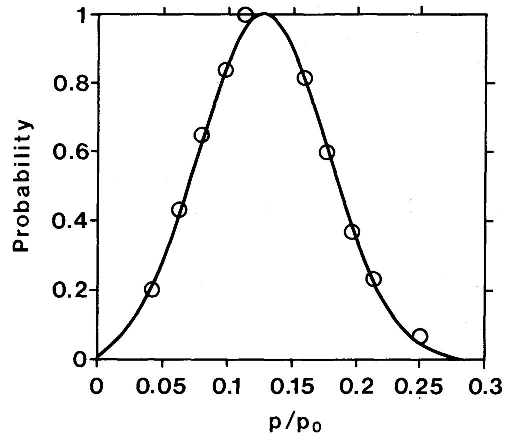

FIG. 22. Probability of observing an acoustic amplitude p, as a function of that amplitude divided by the free-field amplitude p_0. Open circles are experimental points. Solid line computed for Eq. (39) with $p_0=0.117$, $\delta=0.052$.

For $(\lambda r)^{1/2} \gg L$ where L is the scale of turbulence, simple single-scattering theory predicts that

$$D_x(r,\rho) = 2[\langle x^2\rangle - B_x(\rho)], \tag{42}$$

$$D_s(r,\rho) = 2[\langle s^2\rangle - B_s(\rho)], \tag{43}$$

where

$$\langle x^2\rangle = \langle s^2\rangle = \left(\frac{\sqrt{\pi}}{2}\right)\langle \mu^2\rangle k^2 rL, \tag{44}$$

μ is the rms fluctuation in the acoustic index of refraction, and k is the propagation constant. $B_x(\rho)$ and $B_s(\rho)$ are, respectively, the covariances of the log-amplitude and phase fluctuations,

$$\frac{B_x(\rho)}{\langle x^2\rangle} = \frac{B_s(\rho)}{\langle s^2\rangle} = \frac{\Phi(\rho/L)}{\rho/L}, \tag{45}$$

where

$$\Phi(\rho/L) = \int_0^{\rho/L} e^{-u^2} du. \tag{46}$$

In practice Eq. (44) agrees with experimental results for $\langle s^2\rangle$. However, measurements show that at large distances $\langle x^2\rangle \ll \langle s^2\rangle$ and, in addition, the log-amplitude fluctuations quickly saturate.

The two parameters that are used to characterize fluctuating wind speed and temperature are the strength and the scale (Johnson *et al.*, 1982). The strength of the turbulence is represented statistically by the standard deviation of the fluctuations (denoted by σ_T or σ_v for the temperature or wind speed, respectively). The scale of the fluctuations (denoted by L) is determined from the spectral density function or the correlation function.

To model the variation in scale and magnitude of convective and mechanical turbulence with altitude under unstable conditions, we must introduce two types of scaling: Monin–Obukhov scaling and mixed-layer scaling.

Monin–Obukhov's similarity theory allows the development of relationships between the turbulence variables and the surface roughness, wind speed, and convection to be expressed in terms of the single scale L_{MO} and the altitude z. The Monin–Obukhov length is a function of wind speed, heat flux, and surface roughness.

In practice, L_{MO} can be estimated from the Turner classes, which were developed for use in air pollution studies. The Turner class is determined from the wind velocity and an estimate of solar radiation (see Table 3). Since L_{MO} is also a function of surface roughness, this parameter must also be included in estimating L_{MO} from the Turner class. In Table 4 we present the range of Monin–Obukhov lengths for a given Turner class for a site which has a roughness length of about 0.05 m. For all conditions investigated, L_{MO} is negative.

The planetary boundary layer (PBL) represents the farthest extent of surface heating and cooling. This layer varies in thickness from a few hundred meters at night to a few kilometers on a sunny day. The region in the planetary boundary layer above $-L_{\mathrm{MO}}$ is known as the "mixed" layer. The scaling parameter in this layer is the mixing depth h, the vertical extent of the planetary boundary layer. This type of scaling is called mixed-layer scaling. In the mixed layer, certain turbulence statistics can be written as universal functions of z/h. Some statistics, in particular those associated with vertical velocity fluctuations, still obey Monin–Obukhov scaling in the mixed layer.

With these two scaling factors in mind, we can now examine the theoretical variation of

Table 3. Estimation of Turner classes (daytime only).

Surface wind speed (at 10 m) (m/s)	Incoming solar radiation		
	Strong	Moderate	Light
<2	1	1	2
2–3	1–2	2	3
3–5	2	2–3	3
5–6	3	3–4	4
>6	3	4	4

Class 4 should be assumed for overcast conditions.

Table 4. Turner class versus L_{MO} for a flat site in Illinois.

Turner class	$-L_{\mathrm{MO}}$ (m)
1	8–12
2	12–20

4	60

convective and mechanical turbulence with altitude for the case of an unstable to near neutral daytime atmosphere.

The dominant term in the vertical velocity fluctuation has scales which are a monotonically increasing function of height. As $-L_{\mathrm{MO}}$ increases, this function becomes approximately linear. The magnitude of the scale is independent of stability for $z>-0.7L_{\mathrm{MO}}$.

Horizontal velocity fluctuations obey mixed-layer scaling. The scale of the horizontal fluctuations is determined by the height of the mixed layer and is nearly constant, as a function of altitude, in the planetary boundary layer. These scales will be larger than the vertical velocity scales for unstable measurement conditions.

The temperature fluctuations are closely related to the vertical velocity fluctuations and are expected to obey Monin–Obukhov scaling. Since the temperature fluctuations are caused by vertical velocity fluctuations acting on the temperature gradient, the temperature fluctuation scale is expected to increase monotonically with altitude under unstable conditions.

The variance of the wind speed will also be determined by fluctuations in both the horizontal and vertical. Examining the theoretical variance in the surface layer, the variance in the vertical wind component is expected to increase slowly with height for unstable conditions as a function of z/L_{MO}:

$$\sigma_w \propto [1-3(z/L_{\mathrm{MO}})]^{1/3}. \tag{47}$$

The larger L_{MO}, the slower the variation. The variances of the horizontal components should be constant in the unstable surface layer. Above the surface layer, all wind variances should decrease as the altitude approaches the top of the planetary boundary layer.

The temperature variance in unstable air is a more rapidly decreasing function of height in the surface layer than the variance of the vertical wind velocity. Johnson *et al.* (1982) use the form

$$\sigma_T \propto [1-16(z/L_{\mathrm{MO}})]^{-1/2}. \tag{48}$$

[Note that Eq. (48) corrects an error in Eq. (2) of Johnson *et al.* (1982).] This implies, for example, that at $-L_{\mathrm{MO}}$ the variance should be one-fourth of that close to the ground. Above L_{MO}, the variance in temperature should decrease as $(z/L_{\mathrm{MO}})^{-1/3}$.

A summary of the average results of measurements made at Bondville Field Station in Illinois serves as indicators of typical results. This summary represents typical measured values of turbulence strength and scale at a location that has good fetch. A rougher terrain with poor fetch would have values of L and $\langle\mu^2\rangle$ that would be slightly larger near the ground. The variation of these variables with height for poor fetch would probably be similar to these results at heights away from the ground, but there are no data to confirm this.

(a) Variation of scale.

For overcast, light wind conditions (implying a shallow PBL),

$L\approx 1.0$ m @ 1 m to $L\approx 7.0$ m @ 33 m.

For sunny, windy conditions (implying a deep PBL),

$L\approx 1.0$ m @ 1 m to $L\approx 12.0$ m @ 33 m.

The variation of L with height is approximately linear.

(b) Variation of strength.

Sunny, light wind (<2 m/sec) conditions: $\langle\mu^2\rangle\approx 5\times 10^{-6}$.

Sunny, moderate wind (2–4 m/sec) conditions: $\langle\mu^2\rangle\approx(9\text{–}10)\times 10^{-6}$.

Sunny, strong wind (>4 m/sec): $\langle\mu^2\rangle\approx(15\text{–}25)\times 10^{-6}$.

Overcast, light wind conditions: $\langle\mu^2\rangle\approx 3\times 10^{-6}$.

Overcast, moderate wind conditions: $\langle\mu^2\rangle\approx(8\text{–}9)\times 10^{-6}$.

Overcast, strong wind conditions: $\langle\mu^2\rangle\approx(15\text{–}25)\times 10^{-6}$.

There is very little variation of $\langle\mu^2\rangle$ with height through 10 m. Above 10 m, $\langle\mu^2\rangle$ may be slightly increasing, as determined by the wind speed variance.

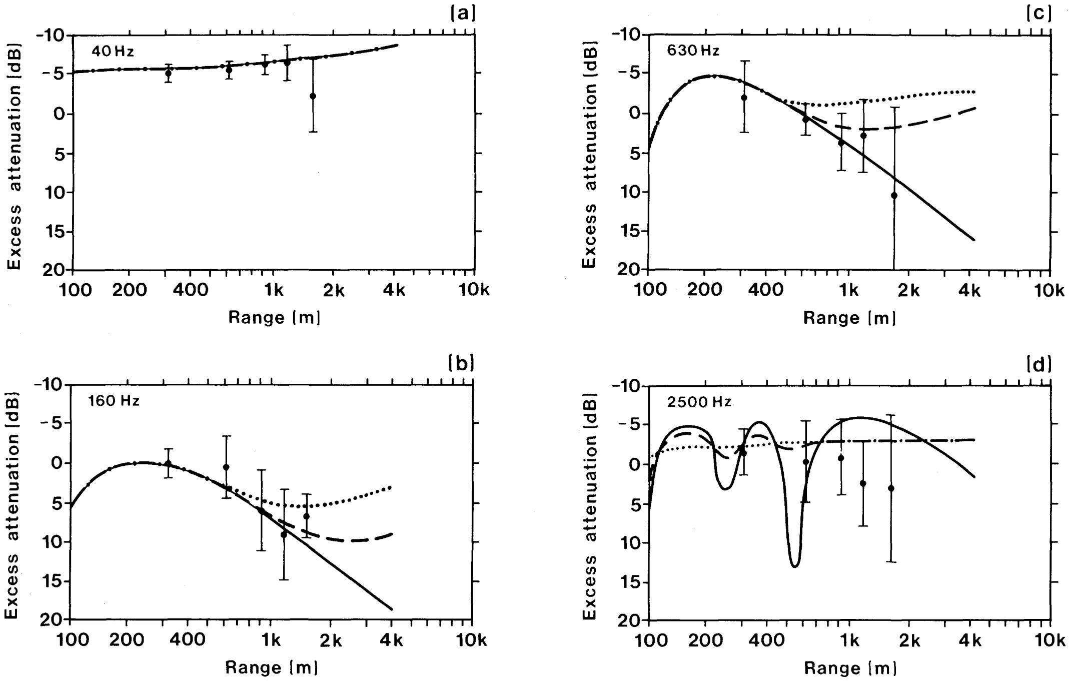

FIG. 23. Excess attenuation vs horizontal distance for 40, 160, 630, and 2500 Hz. The data are the points with error bars. The data at 1550 m are limited since wind noise reduced the sample size. The solid lines are the excess attentuation prediction for a nonturbulent atmosphere. The dashed lines are predictions for $L_0 = 1.0$ m, $\langle\mu^2\rangle = 3\times10^{-6}$, and the dotted lines are for $L_0 = 1.0$ m, $\langle\mu^2\rangle = 15\times10^{-6}$.

Figure 23 displays the variation in excess attenuation with distance for four frequencies measured at Bondville Field Station, Illinois. The source is a set of eight speakers on top of a tower at a height of 31 m. The receivers were 1.2 m high. The data displayed are the average of eleven 15-min measurements of excess attenuation selected as representing a nearly homogeneous atmosphere. These sets had a logarithmic sound speed gradient between -0.11 m/sec and 0.11 m/sec and the standard deviation of the gradient was less than 0.05 m/sec. The predicted quiet-atmosphere excess attenuation with distance for the average ground impedance condition is also displayed in Fig. 23 as the solid lines. These calculations display the expected asymptotic decay of excess attenuation at $1/r^2$ for large distances. The transition to $1/r^2$ depends on frequency, source height, and impedance.

The data for 160 and 630 Hz behave more coherently than was expected. The 40-Hz data and calculation display little variation from coherent behavior and will not be discussed further. The 2500-Hz data, on the other hand, display near incoherent behavior at all ranges.

Calculations based on the extremes of the variance of the index of refraction are displayed as the dashed lines in Fig. 23. These results are calculated for a scale length of 1 m, typical of the scale lengths measured at 1-m height. It is observed that the turbulence effects are less than would be observed for ground to ground propagation for the same scale length. Further, the calculation indicates a larger difference in the coherent and turbulent results than was measured.

For ground to ground propagation, in a quiet homogeneous atmosphere, there is cancellation between the direct wave and plane-wave reflected wave and only the lower-amplitude ground wave is measured. Turbulence reduces the coherence between the equal-amplitude waves, and therefore increases the amplitude of the resultant wave.

2.6 Nonlinear Effects

Large-amplitude waves and impulses will give rise to nonlinear propagation effects. If we consider an impulse as shown in Fig. 4, the point on the pressure wave form corresponding to maximum pressure will travel more rapidly than points of lower pressure according to the relation

$$\Delta v = c[(\gamma+1)/(\gamma-1)][(p/P_0)^{(\gamma-1)/2\gamma}-1], \tag{49}$$

where Δv gives the speed at which a point on the pressure wave form with pressure p travels in excess of the $p=P_0$ point; Δv may be positive or negative. The amount the positive phase of the wave form lengthens can be found from

$$\Delta L = \int_{t_0}^{t} \Delta v \, dt'. \tag{50}$$

The term Δv is a function of time, since from Eq. (49), Δv depends on p/P_0, and $\Delta p/P_0 = (p - P_0)/P_0$ decreases as r raised to a negative power depending upon the spreading law involved, which in turn depends on t. The relationship between r and t is not simple, since

$$r = vt + r_0 \tag{51}$$

and $v = c + \Delta v$, which is a function of (p/P_0) from Eq. (49).

As the wave propagates, the wave steepening predicted by Eq. (49) will tend to transfer energy from low frequency to high. Since atmospheric absorption increases approximately as the frequency squared, these high frequencies will be rapidly attenuated. The overall rate of decay of the wave form, then, will depend upon how rapidly low-frequency energy is transferred to high frequencies which in turn depends upon the amplitude of the acoustic pressure.

One indicator of this wave steepening versus high-frequency attenuation competition is the shock rise time discussed earlier. Referring to Fig. 24, we can see that the rise time decreases as the over-pressure increases. Since the rise time is a measure of the highest frequencies in the impulse, the small rise time (high frequency) associated with high amplitude shows that nonlinear steepening is replacing energy more rapidly for high amplitude waves.

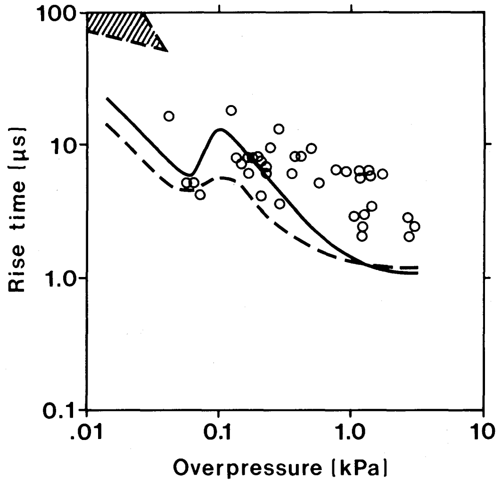

FIG. 24. Experimental and computed rise times. The hatched area and circles represent experimental data from Ref. 1. The solid line was computed for $T=305$ K, relative humidity 90%. The dashed line was computed for $T=293$ K, relative humidity 50%.

Harmonic waves are affected by nonlinearity in slightly different ways. Rather than pulse lengthening, harmonic waves exhibit subharmonic generation. As the subharmonics grow (they are attenuated less than the harmonics), they can produce harmonics and subharmonics until, provided the original amplitude was great enough, the harmonics and subharmonics will completely fill the frequency spectrum and appear as noise.

2.7 Infrasound Propagation

The primary mode of propagation for infrasound at long ranges is by multiple hops; each hop is typically 250 km. This process results from temperature inversions in the upper atmosphere (altitudes of 50–120 km) and reflections at the earth's surface. Referring to the section on absorption, we find that at low frequencies absorption is very small; hence long propagation paths are allowed. The surface impedance is very large at low frequencies so very little energy is lost to the surface on each hop. After a few hops, surface-generated infrasound is constrained to a channel and spreads cylindrically rather than spherically. Empirically it is found that (ANSI, 1983)

$$p \sim R^{-n} \text{ with } n \cong 1.1. \tag{52}$$

Infrasound propagation depends strongly on winds in the atmosphere which change seasonally. As a result, propagation is more effective toward the east in the winter when atmospheric winds tend to blow in that direction. The velocity of propagation for infrasound also varies seasonally with wind and temperature of the primary transmission channel. As shown in Fig. 14, the local sound velocity can rise dramatically at high altitudes but the fact that the waves bounce back and forth between the surface and the upper transmission channel increases the effective propagation distance. Therefore, infrasound velocities are typically a little less than the speed of sound near the earth's surface.

2.8 Numerical Techniques

The conditions for which ray tracing is applicable are

1. $\lambda n' \ll n^2$ where n' is the rate of change in the index of refraction n, and λ is the acoustic wavelength;
2. $\lambda(\ln A)' < 1$ where $(\ln A)'$ is the rate of change in the logarithm of the acoustic amplitude; and
3. $(\lambda/2\pi R)^{1/3} < \theta$ where R is the propagation range and θ is the grazing angle.

Note that each condition becomes increasingly difficult to meet as λ increases (low frequency). Two common sources of low-frequency sound are explosions and rotary wing aircraft.

Air pressure waves from very energetic explosions [the Mount St. Helen's eruption (Reed, 1987), for example] travel through the upper atmosphere and are refracted slowly so that n' is always very small. In these events, ray tracing routines accurately predict quiet zones relatively near the sources and very dramatic damage much further away due to refractive focusing. Low-flying helicopters do not produce sufficient energy to result in detectable sound levels after reflection by the upper atmosphere. The received sound depends, primarily, on index of refraction gradients near the ground surface. In this case, n' can be quite large. For such cases ray tracing can lead to poor predictions of long-range sound propagation and a numerical solution to the wave equation becomes necessary.

Full wave solutions take a variety of forms. The most accurate is a finite element solution. For propagation distances greater than a few meters, such algorithms take many hours of supercomputer time. Most computations involve modified ray tracing routines, the parabolic approximation, or the fast field program. At long ranges, corrected ray tracing routines are typically more time consuming than the other two approaches so ray tracing is generally limited to cases where extensive modifications are not required (sources nearly overhead or an almost neutral atmosphere). Of the remaining two approaches, the PE (parabolic equation) has the capability of including the largest number of effects but is least developed. At very long ranges, the FFP (fast field program) has an advantage in run time but can still consume several minutes on a minicomputer.

For purposes of this contribution, only the FFP will be described in detail (Raspet *et al.*, 1985). The problem considered is sketched in Fig. 25. In the space $0<z<z_{n-1}$, there exist $n-1$ liquid layers. A time-harmonic point source of constant pressure is located at the lower interface of layer S with cylindrical coordinates ($r=0$, $z=z_S$). The problem at hand is to determine the pressure at the observation point located at the lower interface of layer D with coordinate ($r=r$, $z=z_D$).

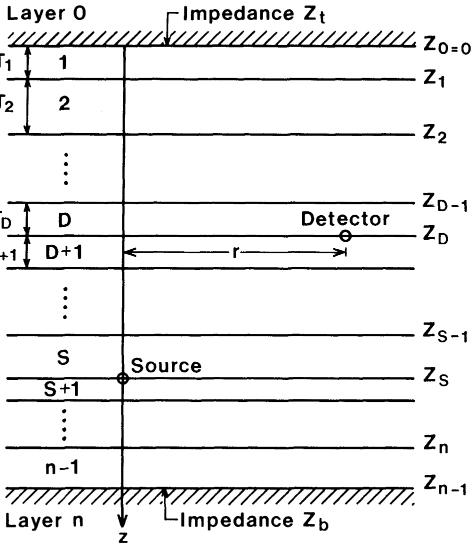

FIG. 25. Liquid layered medium with source and detector bounded by impedance surfaces.

In a typical layer m, the acoustic field is described by pressure $p_m(r, z)$ and a vertical particle velocity $\dot{w}_m(r, z)$. Both of them are expressed in terms of the familiar Fourier–Bessel transform

$$\begin{bmatrix} p_m(r, z) \\ \dot{w}_m(r, z) \end{bmatrix} = \int_0^\infty \begin{bmatrix} p_m(k, z) \\ \dot{w}_m(k, z) \end{bmatrix} J_0(kr)dk. \quad (53)$$

Here, the transform variable k can be interpreted as the propagation constant. Two surface-impedance boundary conditions are to be enforced at $z=0$ and at $z = z_{n-1}$.

At a surface $z=a$, the surface impedance in the transform domain is defined by

$$Z(k) = \text{sgn}\,\frac{p(k,z=a)}{\dot{w}(k,z=a)}, \quad (54)$$

where

$$\text{sgn} = \begin{cases} +1 & \text{if } \dot{w} \text{ moves into impedance surface,} \\ -1 & \text{if } \dot{w} \text{ moves away from the surface.} \end{cases}$$

For the configuration in Fig. 25, sgn$=-1$ if $a=0$ for top impedance Z_t, and sgn$=+1$ if $a=z_{n-1}$ for bottom impedance Z_b. It is assumed that the space above $z=0$ is a liquid half-space, i.e.,

$$Z_t = \omega\rho_0/(k_0 - k^2)^{1/2}, \quad (55)$$

where, for $m=0,1,2,\ldots,n$,

ρ_m = density of layer m in kg/m^3,

c_m = acoustic wave speed in layer m in m/s,

$k_m = \omega/c_m$ = wave number in layer m in m^{-1}.

Use the exp($+i\omega t$) time convention; then (54) assumes the following values:

$$Z_t(k) = \begin{cases} +|Z_t(k)|\,(\text{resistive}) & \text{if } k_0 > k, \\ +i|Z_t(k)|\,(\text{inductive}) & \text{if } k_0 < k. \end{cases}$$

The surface impedance Z_b at the bottom surface has already been described.

An integral solution for the pressure $p(r) = p_D(r, z=z_D)$ at the detector's location can be written as

$$\frac{p(r)}{p_0} = (-i)\int_0^\infty F(k)J_0(kr)dk, \quad (56)$$

where

$$F(k) = \frac{2k}{\omega\rho_s}\,[(D_D)_{21} - Z_t(D_D)_{22}]\left(\frac{(D_s)_{22}(D_{21}+Z_bD_{11}) - (D_s)_{21}(D_{22}+Z_bD_{12})}{(D_{21}+Z_bD_{11}) - Z_t(D_{22}+Z_bD_{12})}\right); \quad (57)$$

p_0 = source pressure at a unit distance away in a homogeneous medium.

In Eq. (57), we have used propagation matrices

$$D_s = d_s d_{s-1} \cdots d_2 d_1,$$

$$D = d_{n-1} d_{n-2} \cdots d_2 d_1,$$

where d_m is a 2×2 matrix with elements given by

$$(d_m)_{11} = (d_m)_{22} = \cos P[\xi_m(z_m - z_{m-1})],$$

$$(d_m)_{12} = (i\xi_m/\omega\rho_m)\sin P[\xi_m(z_m - z_{m-1})],$$

$$(d_m)_{21} = (i\omega\rho_m/\xi_m)\sin P[\xi_m(z_m - z_{m-1})],$$

$$\xi_m = \sqrt{k_m^2 - k^2},$$

D_{12}, for example, is the (1,2) element of matrix D.

Now consider the evaluation of the integral involved in Eq. (56). Of primary interest is the far field solution, i.e., the solution when the observation point is far away from the source. To this end, $J_0(kr)$ can be rewritten as

$$J_0(kr) = \tfrac{1}{2}\,[H_0^{(1)}(kr) + H_0^{(2)}(kr)]. \quad (58)$$

The component involving the incoming wave factor $H_0^{(1)}(kr)$ does not contribute significantly, and can be neglected. Thus, Eq. (56) is approximated by

$$\frac{p(r)}{p_0} \approx \frac{1}{2i}\int_0^\infty F(k)H_0^{(2)}(kr)dk. \quad (59)$$

Two further approximations are used in (59), namely,

1. for the far field, $H_0^{(2)}$ is replaced by its asymptotic expansion:

$$H_0^{(2)}(kr) \sim (2/kr)^{1/2} e^{-i(kr-\pi/4)}, \quad kr \to \infty;$$

2. the range of integration is truncated at $k = k_{\max}$. The final expression suitable for numerical evaluation is

$$\frac{p(r)}{p_0} \approx \frac{1-i}{2\sqrt{\pi r}} \int_0^{k_{\max}} \frac{F(k)}{\sqrt{k}} e^{-ikr} dk, \quad r \to \infty, \tag{60}$$

which is the normalized pressure at a distance r from the source.

Next consider the numerical evaluation of (60) by the fast Fourier transform. To this end, four parameters are required:

$k_{\max}$ = maximum horizontal wave number in integration range,

N = number of steps of integration,

k_0 = starting point of integration,

r_0 = minimum range.

The integral in Eq. (60) is approximated by a summation:

$$\frac{p(r_{n+1})}{p_0} = (\Delta k) \frac{1-i}{2(\pi r_{n+1})^{1/2}} \times \sum_{m=0}^{N-1} \left(\frac{F(k_{m+1})}{k_{m+1}^{1/2}} e^{-imr_0 \Delta k} \right) \times e^{-i2\pi mn/N}, \tag{61}$$

for $n = 0,1,2,\ldots,N-1$, where

$$\Delta k = (k_{\max} - k_0)/(N-1), \tag{62}$$

$$\Delta r = 2\pi/N(\Delta k), \tag{63}$$

$$k_m = k_0 + m(\Delta k), \quad m = 0,1,2,\ldots,N-1,$$

$$r_n = r_0 + n(\Delta r), \quad n = 1,2,3,\ldots,N.$$

Consider the case that c decreases from 335 m/s at the ground to 327 m/s at 8-m height. This is a sample model of shadow zone propagating with a noninfinite negative gradient up to 8 m. The source and the detector heights are 1 and 4 m, respectively. The detector is located in the shadow zone when $r > 71$ m. Regions near the ground are approximated by 16 layers of 0.5-m thickness. For source frequency $f = 40$ Hz, the pressure versus range curve calculated by FFP is shown in Fig. 26 (solid line). The quantity

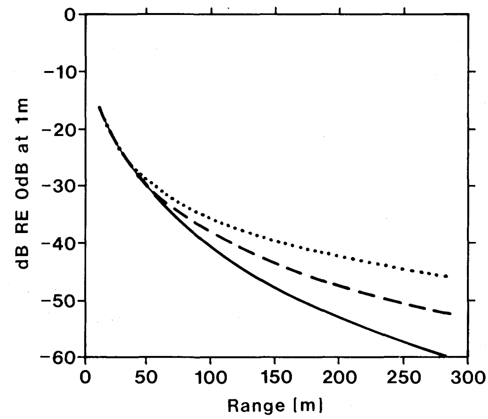

FIG. 26. Normalized pressure vs range for the inhomogeneous half-space sketched in Fig. 25 at a frequency of 40 Hz. In the diagram the dotted line is for the homogenous case, $s = 0$, the dashed line is for $s = 1.567 \times 10^{-3}$ m^{-1}, and the solid line is for $s = -2.985 \times 10^{-3}$ m^{-1}.

$$s = \Delta c / c \Delta h \tag{64}$$

is a measure of the speed of sound gradient. The curve for a homogeneous atmosphere ($c = 335$ m/s for all heights, $s = 0$) is shown by the dotted line. Much larger attenuation is predicted for the inhomogeneous case due to the upward refraction of the sound. In the region $r < 71$ m this reduction in level is principally caused by the reduction in grazing angle; beyond 71 m the detector is in the shadow zone and receives only diffracted sound energy. For ranges greater than 71 m, a simple ray trace treatment would predict infinite attenuation. In Fig. 26, a third curve is shown corresponding to an intermediate gradient $s = -1.567 \times 10^{-3}$ m^{-1}. As expected, this curve falls between the other two.

3. APPLICATIONS

Applications of atmospheric acoustics are quite varied. For purposes of this article only two will be considered. The first is the use of acoustics to determine the state of the atmosphere. Acoustic sensing of the atmosphere takes advantage of the fact that acoustic propagation is very sensitive to atmospheric conditions. The second, and most widespread, application is for prediction of noise levels. In addition to the nature of the source and propagation path discussed to this point, the receiver must be considered. When the receiver is a human listener, human perception of sound becomes an important factor. Based upon a knowledge of the source and transmission path, the sound level at the receiver can be accurately predicted. Human response to that sound, however, is much less predictable.

3.1 Acoustic Sensing of the Atmosphere (Brown, 1987)

The invention of the echosonde (also called the sodar), which McAllister patented in 1972, added a powerful tool for atmospheric research and for applications to forecasting especially in the atmospheric boundary layer. McAllister combined improved antenna design with the use of the facsimile recorder patented by Marti in 1919, which shows graphically the turbulent structure in the boundary layer. The use of the echosonde has become so widespread that results derived with it have become a ubiquitous part of the environmental impact studies required in many countries around the world. In its more complex form—the Doppler echosonde—the instrument can provide measurements of mean winds, sea breezes, and the flows in and out of valleys. An outgrowth of the instrument, called the echometer, shows promise of providing vertical profiles of mean temperatures as well. The monostatic echosonde relies on backscatter (scattering angle $\theta_s = \pi$) from a field of turbulence-driven temperature fluctuations. The bistatic echosonde ($\theta_s \neq \pi$) includes separated transmitter and receiver, with a signal that results from both temperature and velocity fluctuations. A usable return signal from a transmitted pulse in the monostatic geometry requires both a gradient in the temperature and a turbulent velocity field to shift air parcels to different positions, where the parcels will assume different actual temperatures T from their neighbors and produce a random field of refractive index fluctuations.

The equations of fluid mechanics, together with two assumptions valid in acoustic remote sensing, that the turbulence remains a nonzero-vorticity and incompressible field that produces no sound, while the acoustic wave remains a vorticity-free longitudinal compression field that produces no changes in the turbulence, lead to the governing acoustic remote-sensing equation. If the turbulence "eddy" sizes (here, an eddy represents a Fourier space component, not a physical swirl or blob) lie within the inertial range (tenths of meters to tens of meters), and Taylor's "frozen turbulence" hypothesis* holds, the "single scatter," or Born, approximation is valid. Then, the scattering cross section σ_s (in reciprocal meters) as a function of scattering angle θ_s becomes

$$\begin{aligned}\sigma_s(\theta_s) = {} & 1.52 k_0^{1/3} \cos^2(\theta_s) \\ & \times [0.13 C_n^2 + \cos^2(\theta_s/2) C_v^2/(4c^2)] \\ & \times [2 \sin(\theta_s/2)]^{-11/3}, \end{aligned} \qquad (65)$$

with k_0 the initial wave number, C_v^2 the structure parameter for velocity fluctuations ($\mathrm{m}^{4/3}\,\mathrm{s}^{-2}$), and C_n^2 the structure parameter for refractive index fluctuations ($\mathrm{m}^{-2/3}$) given by

$$\begin{aligned} C_n^2 = {} & C_T^2/4T_0^2 + 2(0.307) C_{eT}/4P_0T_0 \\ & + (0.307)^2 C_e^2/4P_0^2, \end{aligned} \qquad (66)$$

where subscript e refers to water vapor, and T to temperature, fluctuations (C_T^2 and C_{eT} are in $\mathrm{K}^2\,\mathrm{m}^{-2/3}$ and $\mathrm{K\,N\,m}^{-8/3}$, respectively). One should note that a single fluctuation would have negligible effect on the scattered wave. However, the nonzero correlation and cross-correlation distances for turbulence velocity, vapor pressure, and temperature fluctuations imply a quite different kind of interaction than that from a field of randomly spaced point scatterers. Therefore, wavelets scattered from nearby regions can interfere constructively and destructively to produce a partially coherent scattered wave resulting from the integration of many wavelets over a nonzero region of space. The same physics underlies the importance of the spatial Fourier transform decomposition of the random fluctuation field.

A typical monostatic echosonde employs a single antenna for both transmission and reception, with an electronic switch to alternate between the two. The antenna includes a high-power pressure transducer (similar to those used in airport public address systems)

---

*Taylor's "frozen turbulence hypothesis" maintains that temporal changes in local meteorological parameters caused by turbulence are related to spatial changes through the mean wind.

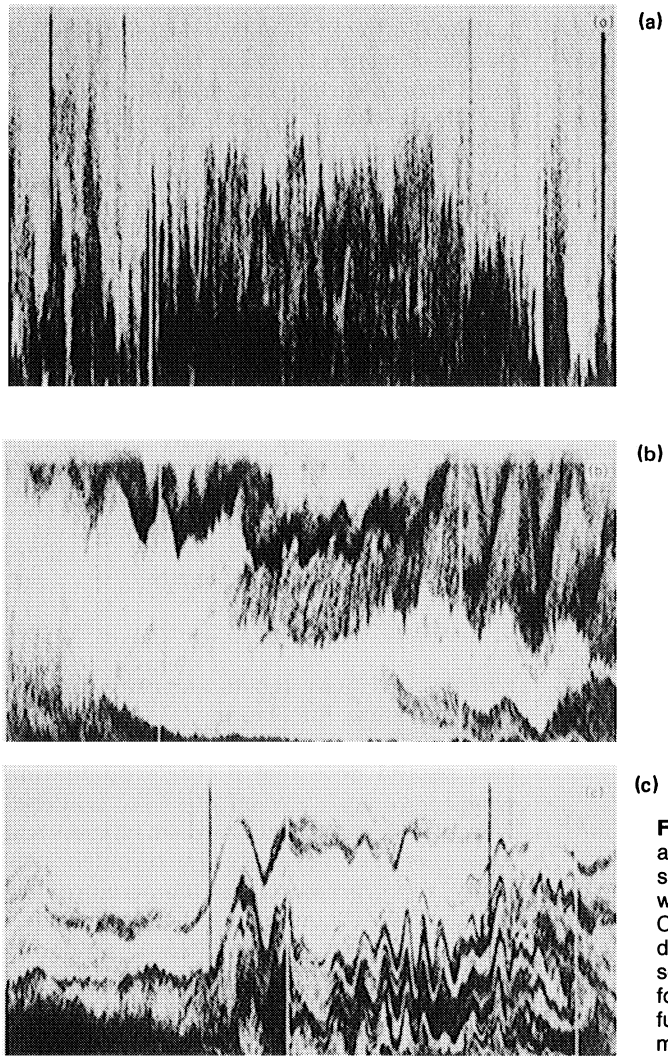

FIG. 27. Echosonde records of the boundary layer. Vertical scale: 0–500 m; horizontal scale: time, increasing to the right; vertical white streaks are hour markers. (Courtesy of C. W. King.) (a) Daytime thermal plumes; (b) decreasing ground layer (below) and descending inversion (above) in early evening, followed by triggering of internal waves; (c) fully developed internal wave activity after midnight.

together with an exponential feed horn (for impedance matching) mounted at the focus of a parabolic dish, with the entire assembly enclosed in a shield, or "cuff," made from plywood lined with an acoustic foam that includes a lead-sheet septum. The cuff provides substantial side-lobe suppression and, if the sides flare, an increase in the effective aperture of the antenna. Typical antennas achieve angular beamwidths of 8°–10°. The reason for using the same antenna for reception rather than a more sensitive microphone lies in this narrow beamwidth and the resulting much greater signal-to-noise ratio.

Figure 27 shows a sequence of boundary layer structures over a typical diurnal period. (Time in the figure moves from left to right.) The top of the figure corresponds to an altitude of 500 m; vertical thin white stripes represent hour markers. Figure 27(a) shows a typical unstable, daytime record of thermal plumes carried through a vertical echosonde beam by the mean wind. Such plumes result from the conductive random heating of air near the ground, itself heated by solar radiation. Randomness may result from variations in surface albedo and from the presence of clouds. Figure 27(b) shows the boundary layer in the late afternoon and early evening. The decrease and then disappearance of solar radiation and the consequent cooling of the ground brings about the vanishing of the thermal plumes, a concurrent creation of a ground-based shear layer that on a finer time scale would show a "herringbone" structure, and the slow descent of an elevated inversion previously off the top of the record. Near its end, the figure shows the beginning of internal gravity wave activity. In Fig. 27(c) a series of large-scale internal gravity waves dominate the record. Especially noteworthy, the particle displacement double amplitude (peak to peak) reaches values of the order of 300 m. In the descending part of the cycle such large displacements require a horizontal outflow near the ground that would appear similar to wind gusts, except for the regularity of their return with the period of the waves.

Although the bistatic configuration has many other uses, its greatest value lies in vertical profiles of Doppler measurements of mean winds. Figure 28 outlines the geometry of one leg of such a system. (With two horizontal legs at right angles to each other and the addition of a vertical Doppler measurement, one can map the entire three-dimensional wind field at all heights within the echosonde range.) A number of different arrangements have shown various advantages and drawbacks. The following describes a particular design that seems one of the more flexible and dependable and has the advantage that the vertical narrow receiver "pencil beam" rejects much of the noise coming in on low-elevation paths from road traffic, distant aircraft, and residential areas. The typical transmitter antenna uses a "fan beam" geometry, one that sprays an initial pulse over a range of angles. Time-gating of the received signal then gives a Doppler value at each desired height. Other configurations use a set of three monostatic echosondes pointing in three different directions, allowing greater simplicity in the hardware but producing greater errors when the atmosphere lacks horizontal homogeneity because of the separations between the three different scattering volumes. The wind velocity will be denoted by a vector **w** or a Mach vector defined as $\mathbf{m}=\mathbf{w}/c$. For the monostatic Doppler echosonde, when **m** is directed along the beam, and with no refraction, the frequency shift Δf satisfies

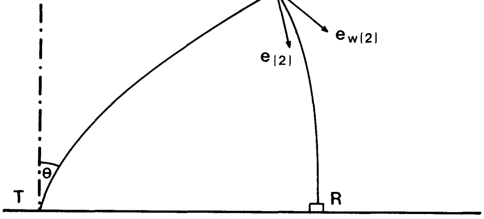

FIG. 28. Geometry for Doppler wind measurements. Transmitter *T* and receiver *R*. Scattering volume center *S* at height *z*. Other symbols defined in the text.

$$\Delta f/f=\pm 2m, \tag{67}$$

where the plus sign holds when the wind blows toward, and the minus sign away, from the antenna, and $m=|\mathbf{m}|$. For the bistatic system, shown in Fig. 28 (together with some simplifying assumptions, such as horizontal stratification and negligible vertical wind or cross wind) the horizontal component of the Mach vector m_x, with $m_x = \pm|m_x|$, and with an obvious choice of sign, satisfies

$$\Delta f/f=-m_x \sin\theta+(m_x \sin\theta)^2. \tag{68}$$

Frequently, an average over, say, 20 min will cancel the effect of any vertical wind; that is, one can consider it zero. However, a complete horizontal wind measuring system may often face conditions where cross winds on one leg or the other become important, or some other simplifying assumption no longer holds.

Researchers prefer various methods for determining the frequency shift Δf from the raw data, especially to cope with the ubiquitous presence of noise. In the frequency domain, many use the FFT (fast Fourier transform), at the same time trying to measure or estimate the spectral contribution of the noise. However, the FFT requires a fairly powerful computer. In the time domain, the CXCV (complex covariance) method provides good data with a much less expensive microprocessor but requires careful choice of sampling frequency and filter bandpass; a choice of sampling frequency such that the Nyquist frequency remains near the filter half-power point minimizes aliasing.

With the increasing amount of inexpensive computer memory becoming available, echosonde designers now have the choice of turning to completely coherent signal processing, for example; averaging the signal in both amplitude and phase, and, thus, reducing random noise to a negligible problem. The noise of rain hitting the receiving antenna makes echosonde observations impossible during a storm. In contrast, the temperature-measuring echometer, by virtue of the (here necessary) coherent processing, operates successfully through a rain squall, producing data in close agreement with those from a nearby *in situ* thermometer on a tower. No obvious reasons exist that would rule out similar coherent processing of echosonde signals to obtain a large increase in signal-to-noise ratios.

The boundary layer can have either an "open" structure for the unstable case, acting as a pathway for fluxes of momentum, heat, and water vapor to reach higher levels and perturb mesoscale processes, or a "closed" structure for the stable case, acting as an impenetrable container disconnected from large-scale events. In the first case, information on the structure may have an impact on future weather-prediction methods. In the second, boundary layer data should assist in predicting the strength and duration of air pollution events. Many of the parameters needed, however, derive from higher-order measurements that have a slightly shaky theoretical basis, and experimental values of unknown precision. Thus, they represent work still in progress, on the leading edge of the research in acoustic remote sensing.

Among other parameters, dependable measurements of mean temperature profiles $T(z)$ still elude researchers. One method, called RASS (radio acoustic sounding system), uses an acoustic pulse containing of the order of 50 phase fronts to reflect a radar signal coherently back to a receiver. With an acoustic wavelength equal to one-half the radar wavelength, strong returns arrive from altitudes throughout the boundary layer. The Doppler shift in the radar return derives—with a correction for mean vertical wind w_z—from the speed of the acoustic waves.

When an elevated inversion lies above an unstable atmosphere near the ground, the height z_i of the inversion becomes a useful parameter. The upper part of the boundary layer, the well-mixed layer, as its name implies, has very little fluctuation in temperature except in the thermal plumes and thus shows no echosonde returns elsewhere, even if (velocity) turbulence exists. Within the inversion the atmosphere remains stable, that is, without turbulence, even though the temperature T changes, and thus again the echosonde shows no returns. However, the rising air in the plumes has a tendency to overshoot and, before descending, entrain air with a different temperature from the bottom of the inversion in its turbulent motion. As a result echosonde facsimile records frequently show a dark elevated band corresponding to this entrainment layer above the region of thermal plumes. Comparisons with radar or FM-CW radar seem to support good agreement between their measurements of the base of an elevated inversion z_i and the echosonde measurement of the height of the bottom of the dark band produced by an entrainment layer.

3.2 Perception of Sound

Measurements and measures associated with atmospheric acoustics are typically related to the hearing response of the human ear. Such a treatment is especially applicable when dealing with acoustic noise and noise control. The loudness level is defined as the sound pressure level of a 1000-Hz tone that sounds as loud as the sound in question (see ACOUSTICS, PSYCHOLOGICAL). The unit of loudness is the phon. The famous Fletcher–Munson equal-loudness contours shown in Fig. 29 give an indication of the loudness level at different sound pressure levels. Note that a sound pressure level of 70 dB at 25 Hz has the same loudness as a 10-dB tone at 1000 Hz.

When measuring noise in the atmosphere, it is common to express the level in dBA, dBB, or dBC. A sound level meter with these ratings has a frequency response given in Fig. 30. The A-weighted curve approximates the hearing response shown in the previous figure for relatively low sound pressure levels ($\sim$40 dB). The B weighted curve is applicable at higher levels (80–90 dB). C-weighted sound levels show less frequency compensation and, therefore, are a better measure of sound pressure level.

Measures of noise are designed to give an indication of human response. Typically, the

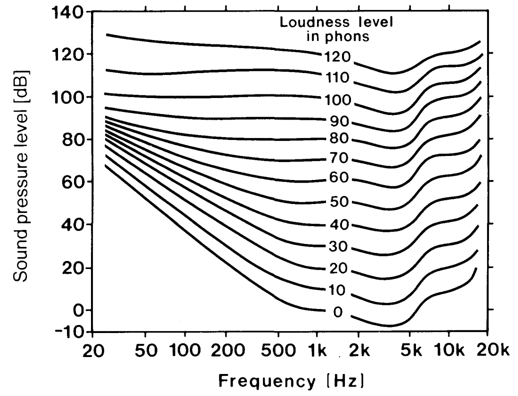

FIG. 29. Equal-loudness contours for pure tones by Fletcher and Munson. (American Standard for noise measurement, Z24.2-1942.)

goal is to reduce annoyance. Since different types of sound present different annoyances at the same C-weighted instantaneous level, a variety of noise measures have been advanced. Some of the more commonly used are perceived noise level (PNL), sound exposure level (SEL), and day-night sound level (L_{dn}).

In contrast to the A level, the perceived noise level weighting function is based upon subjective assessment of the noisiness of the various frequency components of the signal, rather than upon *loudness* considerations. There is more emphasis on the upper portion of the noise spectrum (2000–4000 Hz) in this weighting function than in the A-weighting function. The perceived noise level, in units of PNdB, has been used for many years in the U.S. as a measure of aircraft noise.

Subjective tests indicate that human response to noise is not only a function of the maximum level, but of the duration of the signal and its temporal variation. Time-related changes may range from a sound level constant over time, as produced by a continuously operating machine, to the typical haystack-shaped time history produced by an aircraft flyover, to the constantly varying noise level perceived near highways.

Historically, several methods have been used to introduce time characteristics. With recent advances in electronics and instrumentation technology, there are now instruments which can integrate, or sum, noise signals as a function of time. (Integrated noise levels are a measure of the physical energy in the noise signal.)

Significant evidence indicates that two signals with equal sound energy will produce the same subjective response. For example, a noise with a constant level of 85 dB occurring for 10 min would be judged equally as annoying as an 82-dB noise signal lasting for 20 min, i.e., one-half the energy lasting for twice the time period. This is known as the "equal energy" principle. In practice, the integration process is often replaced by a summation of levels occurring at one-half second intervals over the upper 10 dB of the noise signal.

Integration of the A-weighted noise level over the period of a single event (such as an aircraft flyover) gives the sound exposure level, in dB. The day-night average sound level (referred to as L_{dn}) is obtained by energy-averaging noise levels over a 24-hour period, with a 10-dB penalty to nighttime noise levels. The day-night average sound level can be applied to all sources of noise. For discrete event noise sources, such as aircraft operations, L_{dn} may be computed by decibel summation of noise levels occurring during daytime and nighttime periods (with the nighttime penalty). Areas subjected to L_{dn} in excess of 75 are useful only for selected commercial applications. Areas of a 70–75 L_{dn} may be used for a wider variety of commercial applications while areas impacted by 65–70 L_{dn} may be used for most applications including residential with proper sound treatment. Below 65 L_{dn} some treatment may be required for uses requiring a quiet background.

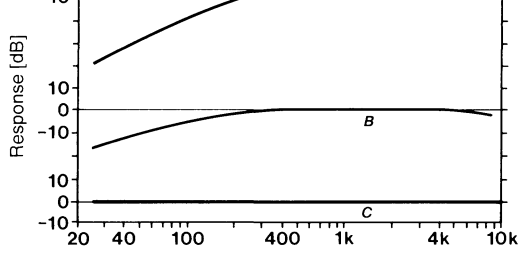

FIG. 30. Frequency-response characteristics taken from the American Standard for sound-level meters, Z24.3-1944.

Combining perception with propagation efforts described earlier provides practical guidelines for predicting community objections to different types of noise sources. In most cases involving community noise (Makarewicz, 1987), the source and receiver heights are much smaller than the source–receiver separation so $|z|\cos\theta_i \ll 1$. For this geometry, the A-weighted mean-square sound pressure at distance d can be given as

$$P_A^2 = \widetilde{P}_A^2[S(\sigma_e,\mu,\beta d)/d^2], \qquad (69)$$

where $\widetilde{P}_A^2$ is the A-weighted mean-square sound pressure for the direct wave, σ_e is the effective flow resistivity of the surface, β is the absorption coefficient α divided by the frequency f, and μ is a parameter which describes the source spectrum $[P(f) = P(0)\exp(-\mu f)]$. Far away from a source ($d \gg 500$ m), $P_A^2 \sim d^{-7}/1$ m which suggests that the A-weighted sound level will decrease at a rate of 21 dB per doubling of distance. In practice, turbulence does not allow complete cancellation of direct and reflected waves so such a rapid falloff is not expected. Nonetheless, atmospheric absorption and surface effects combine to give very rapid attenuation of sources close to the horizon.

GLOSSARY

(For complete definition of commonly used acoustical terms see American National Standards Institute, ANSI S1.1-1960 [R 1976])

Absorption Loss: That part of the transmission loss due to the dissipation or conversion of sound energy into other forms of energy.

Admittance: Inverse of impedance.

atm: One standard atmosphere of pressure $= 1.01 \times 10^6$ dyn/cm$^2 = 1.01 \times 10^5$ Pa $= 1.01 \times 10^5$ N/m^2.

Attenuation Coefficient: Logarithmic rate of change in sound pressure (dB/unit length or neper/unit length).

Creeping Wave: Dominant term in an approximate solution (applicable at long ranges) for sound diffracted into a shadow zone.

Diffracted Wave: One whose front has been changed in direction by an obstacle or other inhomogeneity in a medium.

Echo Sounder (Acoustic Sounder): A device which measures atmospheric conditions by sending and receiving acoustic pulses.

Excess Attenuation: Attenuation in excess of 6 dB/doubling of distance (+dB means added loss).

FFT: Fast Fourier transform.

Impedance: The complex ratio of the sound pressure to the particle velocity. The specific impedance, the ratio of impedance to impedance of air, is generally used.

Infrasound: Sound at frequencies less than 20 Hz.

Insertion Loss: The increase in transmission loss caused by the addition of a barrier.

Mach Number: Ratio of speed to local speed of sound.

neper: Unit of level when the logarithm is on the Naperian base.

Nyquist Frequency: Highest frequency allowed in a digitally sampled signal.

Octave Band: Band of frequencies extending from $f_c/\sqrt{2}$ to $\sqrt{2}\,f_c$, where f_c is the center frequency in Hz.

Pascal: mks unit of measure for pressure (1 N/m^2).

Radio Sounder: Similar to echo sounder but the acoustic wave is monitored with a radar system.

rayl: Unit of measure for impedance; 1 mks rayl $= 1$ kg/m^2 s $= \frac{1}{10}$ cgs rayl.

Rayleigh Waves: Surface waves associated with the free boundary of a solid such that a surface particle describes an ellipse.

Refraction: The process by which the direction of sound propagation is changed due to spatial variation in the speed of sound.

Scattering: Acoustic scattering is the irregular reflection, refraction, or diffraction of sound in many directions.

S/N: Signal-to-noise ratio typically measured in dB.

Sound Pressure Level: 20 times the logarithm to the base 10 of the ratio of the pressure to a reference pressure (conventionally 20 μPa).

Standard Temperature and Pressure: (STP) 273 K, 1 atm. Note that in atmospheric physics the standard atmosphere at sea level (288 K, 1 atm) is commonly used.

Transmission Loss: Decrease in sound pressure level between two points measured in dB re 20 μPa.

Turbule: A single element of turbulence defined in a statistical sense.

Ultrasound: Frequencies above 20 kHz.

INTRODUCTION

Atmospheric physics deals with the application of physical laws to the study of the structure, composition, and motion of the atmosphere. It forms the basis for, but is not limited to, the study of weather and climate (see METEOROLOGY; WEATHER FORECASTING); for this reason, a major goal of the discipline is to develop an understanding of atmospheric behavior that is good enough to allow predictions of the evolution of the atmosphere over time scales from days to decades, on spatial scales from a few kilometers to the whole globe.

Attempts to understand the effects of the atmosphere on man's environment date back to the origin of science itself. At the present time, considerable attention is being focused by the public, politicians, and media on fears that the habitability of the Earth is being altered as an inadvertent side-effect of increasing industrialization. As a result, atmospheric physics is one of the most rapidly growing and widely discussed areas of applied physics at the present time.

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

In the simplest physical terms, atmospheric science is basically the study of a relatively thin, radiatively heated and cooled layer of mixed gases on a large, rapidly rotating sphere with an uneven surface and with chemical activity and all three phases of water present. Because it deals with basic processes, atmospheric physics as a field is not restricted to the single example of the Earth. Eight bodies in the solar system are known to have substantial atmospheres and exhibit structure and behavior analogous to that on the Earth. Information about these derived from astronomical observations and space experiments can be used to make powerful tests of theories and models of atmospheric systems.

The three main cornerstones of the discipline are the subfields of atmospheric radiation (that is, electromagnetic radiation from the sun and terrestrial infrared radiation, and their quantum interactions with atmospheric molecules), geophysical thermodynamics, and gas-phase chemistry, especially photochemistry. The coupling between the various processes in these categories is extensive and important, and progress with a theoretical understanding of atmospheric processes, as well as attempts at prediction (weather and climate forecasting), depends to an increasing extent on vast computer models. The experimental side of the field is now dominated by the development of increasingly large and complex optical instruments, radiometers and spectrometers, deployed in space on satellites. Such experiments produce formidable quantities of raw data, and processing and analyzing the information from satellites also call for a very high level of computing power and sophistication.

Thus the field of atmospheric physics unites many areas of basic physics and engineering to address a topic of great complexity and relevance to society.

1. FUNDAMENTALS

1.1 Definitions

Atmospheres are the envelopes of gas that surround a planet or large satellite. In the case of the Earth, the atmosphere forms a very thin skin, of the order of 100 km in depth, and has a mass of 5.27×10^{18} kg, about one-millionth that of the solid body. This amount of gas is sufficient to exert a mean pressure p_0 of $1.013\,25\times10^5$ pascals (often called 1 atmosphere) on the surface. Other common units of pressure are those based on the *bar*, which is defined to be equal to 10^5 Pa; atmospheric pressures are most frequently quoted in millibars (mbar). The pressure falls off with height according to the formula

$$p=p_0\exp\left(-\int_0^z \frac{1}{H}dz\right), \tag{1}$$

which is easily derived from the perfect gas law and the equation of state. In Eq. (1), the quantity H, the height in which the pressure falls by a factor of e^{-1}, is called the *scale height* (strictly the *pressure* scale height, since other scale heights are sometimes defined; for example, that describing the change with height of the abundance of a species that is not uniformly mixed). H is equal to RT/Mg (M=mean molecular weight, R=gas constant, g=acceleration due to gravity) and so H varies with the temperature T and humidity of the air, but is typically about 8 km. In the approximation H=const, Eq. (1) reduces to $p=p_0e^{-z/H}$, and height is proportional to $\log_e$(pressure). The latter is often a convenient vertical coordinate in atmospheric calculations and sometimes known as the pseudoheight.

1.2 Origin and Evolution of the Atmosphere

The Earth's atmosphere is believed to be of secondary origin (Henderson-Sellers, 1983). This means that the gases surrounding the solid planet at the time it condensed were lost to space at an early stage and the present atmosphere subsequently formed as a result of outgassing from the crust. This process was augmented to an unknown degree by the infall of icy material as comets. The primitive atmosphere thus formed would have had a composition quite different from that which exists today, consisting primarily of carbon dioxide, methane, ammonia, and water vapor with no free nitrogen or oxygen. The large proportion of nitrogen now present arose as a consequence of the photodissociation of ammonia into nitrogen and hydrogen. The latter gas is so light that it can escape from the Earth even at the present time, whereas most heavier gases are gravitationally trapped now that the Earth is cooler and the Sun less active. Most of the methane was oxidized to form carbon dioxide and water vapor, although enough is produced (for example, by the decay of vegetable matter) to leave a substantial admixture in the atmosphere to the present day. Free oxygen exists as a consequence of the presence of life in the form of plants, which convert carbon dioxide into oxygen by photosynthesis. Thus, we owe the present state of the atmosphere to a series of complex and dynamic processes. There is evidence that the atmosphere is not entirely stable but continues to evolve (Sec. 8), perhaps towards a state less well suited to human comfort and survival.

2. ATMOSPHERIC STRUCTURE

2.1 Thermal Structure and Nomenclature

The various regions of the atmosphere are named for their temperature structure (Fig. 1). In simplified terms, these regions exist for the following reasons. Much of the electromagnetic radiation emitted by the Sun and reaching the Earth is at wavelengths in or near the visible part of the spectrum. These are not strongly absorbed by the atmosphere and so, unless there are clouds to scatter the photons and reflect a portion of the radiation back to space, most of the energy reaches the ground where it is absorbed. The lower atmosphere is then heated by the ground and will become unstable against convection if a layer nearer to the ground is warmer than that above it by a sufficient amount (calculated below) to become less dense in spite of the vertical pressure gradient. Convective instability exists in the lowest 10 km or so of the atmosphere, which is known as the troposphere ("turning region"). The upper boundary is the level where the overlying atmosphere is of such a low density that a substantial amount of radiative cooling to space can occur in the thermal infrared region of the spectrum. At this level, called the *tropopause*, radiation cools rising air so efficiently that the temperature tends to become constant with height and convection ceases. The tropopause varies in height over about 6 km with latitude, being highest (around 16 km) in the tropics, where solar heating is greatest, but it is generally quite a sharp feature in the temperature profile everywhere.

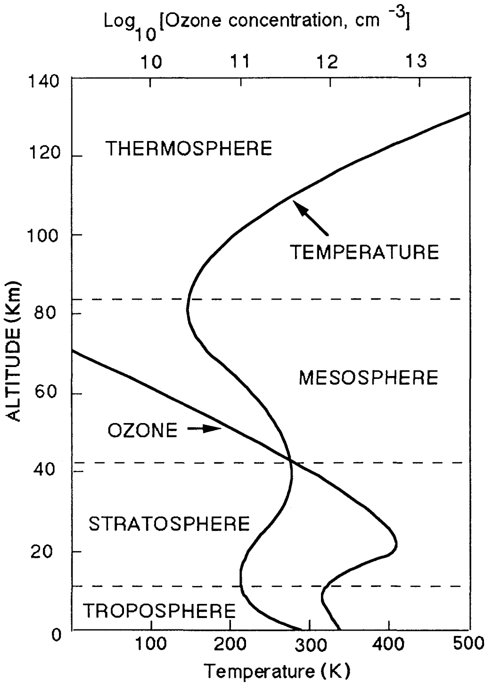

FIG. 1. Standard temperature and ozone profiles, showing the naming of the regions. After NASA (1986).

Assuming that hydrostatic equilibrium applies, then

$$dP = -g\rho\, dz. \tag{2}$$

Furthermore, if we assume that there is no net exchange of energy between a parcel of air and its surroundings, then the specific heat at constant volume c_v, temperature T, pressure P, and volume V are related by

$$c_v\, dT + P\, dV = 0. \tag{3}$$

Using the perfect gas law $PV = RT/M$ (R = gas constant per mole, M = molecular weight) and the relationship $c_p - c_v = R/M$ (c_p = specific heat at constant pressure), we find that the temperature gradient with height dT/dz is given by

$$\frac{dT}{dz} = -\frac{g}{c_p}. \tag{4}$$

This gradient, called the *lapse rate*, is constant and, since c_p is equal to about 1000 J kg^{-1} K^{-1}, equal to approximately 10 K km^{-1}

for dry air. For moist air, dT/dz is less and can be as small as 3 K km^{-1}. A useful average value for Earth is 8 K km^{-1}. Figure 2 shows a realistic temperature profile together with the steeper profile that would exist if there were no vertical convection.

The lapse rate above the tropopause, where convection stops, tends to zero (i.e., constant temperature with height) because there is no longer enough absorption above the layer to stop emitted photons reaching space. Then each layer is heated by radiation from the optically thick atmosphere below and cooled by radiating to space; to first order, height is no longer important. This region is called the stratosphere (it is stratified in the sense that density decreases monotonically with height, and therefore the layers do not try to move up or down through each other as in the troposphere).

If the stratosphere is modeled as an optically thin slab of (vanishingly small) emissivity ϵ, its temperature T_{strat} can be related to the effective radiative, or equivalent blackbody, temperature of the Earth, T_{Earth} (see Sec. 8.2). The stratosphere is heated from below by a flux proportional to $\epsilon T_{\text{Earth}}^4$ and cooled by identical fluxes in the upward and downward directions, each proportional to $\epsilon T_{\text{strat}}^4$. Thus we must have $\epsilon T_{\text{Earth}}^4 = 2\epsilon T_{\text{strat}}^4$ whence

$$T_{\text{strat}} = \frac{T_{\text{Earth}}}{2^{1/4}} = \frac{250}{2^{1/4}} \approx 210 \text{ K}. \tag{5}$$

Although these simple arguments suggest that the stratospheric temperature remains constant to a great height, in fact it is observed to increase above about 20 km (Fig. 2) as a consequence of the absorption of solar ultraviolet radiation by photochemically produced ozone in the stratosphere (Sec. 3.3). Ozone absorbs in the Hartley band, which forms a continuum from 0.2 to 0.3 μm. Below 70 km, virtually all of the energy absorbed is converted to heat.

The ozone concentration in the stratosphere peaks near 25 km (Fig. 1), but a calculation of the heating rate at height z where $\rho(z)$ is the absorber amount,

$$c_p \rho(z) \frac{dT(z)}{dt} = \int_{0.2}^{0.3} \frac{dF_\lambda(z)}{dz}\, d\lambda, \tag{6}$$

where

$$F_\lambda(z) = F_\lambda(\infty) \exp\left(- \int_z^\infty k_\lambda \rho(z) dz \right)$$

is the flux of radiant energy, and k_λ the absorption coefficient at wavelength λ, finds that this peaks at a height of about 50 km. The temperature is also maximum at this level, which is known as the *stratopause.* Above the stratopause, the temperature declines again, reaching an absolute minimum at the *mesopause* near 85 km. The pressure here is only a few microbars. With such low densities of gas above, very energetic solar photons in the extreme ultraviolet range, and particles too, penetrate into the region, causing ionization and dissociation and releasing kinetic energy. The heating thus produced causes the temperature to increase rapidly with height, leading to the name *thermosphere.*

Between the tropopause, where large-scale vertical convection ceases, and the mesopause, the atmosphere remains fairly well mixed by turbulence produced by a variety of instabilities in wave motions and the mean flow (Sec. 5.2). At a fairly small distance up

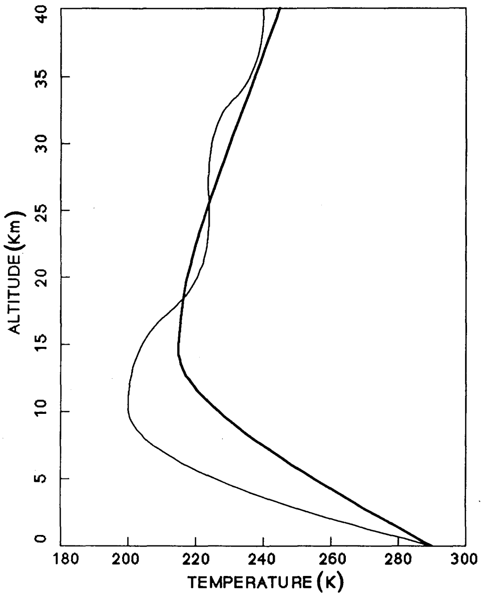

FIG. 2. Atmospheric temperature profile calculated assuming only radiative processes (light line), compared to the observed mean global profile (heavy line). After Kuhn (1985).

into the thermosphere, around the 100-km altitude level, diffusion takes over as the dominant process, and the atmosphere starts to separate into its lighter and heavier components. For many practical purposes, this level (the *homopause*) may be considered to be the effective top of the atmosphere.

2.2 Clouds and Precipitation

Substantial clouds of water droplets are usually confined to the lowest scale height of the atmosphere (0 to 8 km), although very thin "noctilucent" clouds have been observed as high as the mesopause (85 km). Clouds fall into many different classifications, but nearly all are formed by some version of the same basic process: convection upwards of moist air and subsequent condensation of water droplets or ice crystals around dust nuclei (Mason, 1974).

A typical cloud droplet is about 10 μm in diameter, while a typical raindrop is 100 times larger, i.e., contains as much water as a million cloud particles. The process by which cloud droplets grow is basically diffusion and condensation of water vapor until they reach about 30 μm diameter, then collision and coalescence, until they eventually rain out.

In addition to their obvious importance in meteorology and the terrestrial water cycle, clouds play an important role in controlling the global climate by scattering, absorbing, and emitting radiation. They interact strongly with both incoming solar and outgoing thermal (planetary) radiation, and so are an important component of the atmospheric greenhouse (Sec. 4.3). Because the radiative-transfer properties of clouds depend on variable and relatively inaccessible quantities such as the number density and size distribution of particles, their role is a particularly difficult one to quantify in climate models (Sec. 8).

3. ATMOSPHERIC COMPOSITION

3.1 Principal Constituents

Table 1. Composition of clean dry air near the surface.

Species	Mixing ratio (by volume)
Nitrogen, N_2	0.780 83
Oxygen, O_2	0.209 47
Argon, Ar	0.009 34
Carbon dioxide, CO_2	0.000 35
Neon, Ne	18.2×10^{-6}
Helium, He	5.2×10^{-6}
Krypton, Kr	1.1×10^{-6}
Xenon, Xe	0.1×10^{-6}
Ozone, O_3	0.4×10^{-6}
Hydrogen, H_2	0.5×10^{-6}
Methane, CH_4	2×10^{-6}
Nitrous oxide, N_2O	0.3×10^{-6}
Carbon monoxide, CO	0.1×10^{-6}

Table 1 shows the composition of dry air, the basic reasons for this particular mixture having been outlined above (Sec. 1.2). The amount of water that is present in addition to these noncondensible species varies, but can be as high as a few percent. Some of the other species, particularly ozone, are also very variable even in nonpolluted environments.

3.2 Trace Gases, Pollution, and Photochemistry

In addition to the principal gases nitrogen and oxygen and the common *minor* constituents argon, methane, carbon dioxide, and water vapor, the atmosphere contains a number of important *trace* constituents. Many of these are of anthropogenic origin, that is to say they are produced by industrial processes of various kinds at the surface. Well-known examples are the oxides of nitrogen (which are present naturally, but are being enhanced by production from artificial fertilizers and automotive and aircraft engines) and the chlorofluorocarbons used as refrigerants and in various other ways (see AIR POLLUTION: COMPONENTS, CAUSES, AND CURES). Gases such as nitrous oxide (N_2O) and trichloromonofluoromethane (CCl_3F) are source molecules for stratospheric concentrations of products produced by photochemistry in the stratosphere, for example, nitric oxide (NO) and chlorine oxide (ClO). Many other trace species have been observed or postulated to exist that have key roles in important atmospheric chemical processes, for example, those that maintain the ozone layer (Sec. 8.1). Some of them are shown in Fig. 3.

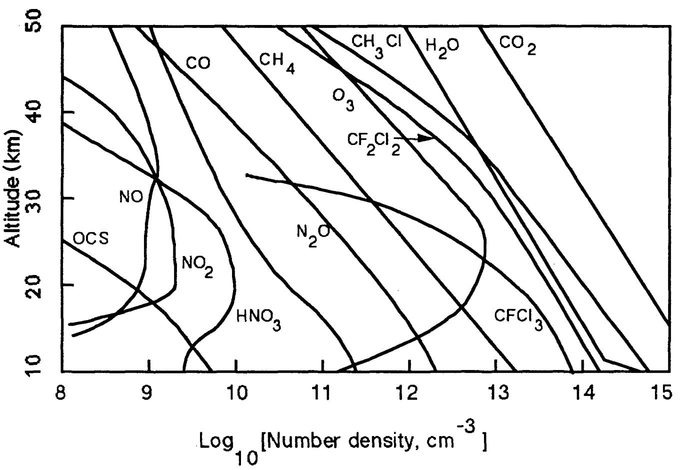

FIG. 3. Some atmospheric minor and trace constituent abundances. After NASA (1986).

3.3 The Ozone Layer

The importance of the ozone layer in determining the temperature structure has been mentioned above (Sec. 2), and its contribution to global habitability, by reducing the amount of energetic ultraviolet radiation that reaches the surface, is well known. Ozone is a very unstable molecule, and the amount that is present at any place and time depends on a balance between production and loss mechanisms. In their simplest form, as stated originally by Chapman, the equations may be written (Brasseur and Solomon, 1986)

$$\begin{aligned} &O_2+h\nu=O+O, \\ &O_2+O+M=O_3+M \end{aligned} \qquad (7)$$

for production, where M is any molecule, usually nitrogen, acting as a collision partner to conserve momentum, and

$$\begin{aligned} &O_3+h\nu=O+O_2, \\ &O+O_3=O_2+O_2, \\ &O+O+M=O_2+M \end{aligned} \qquad (8)$$

for destruction. To obtain reasonable agreement with measurements of the ozone abundance as a function of height, the Chapman scheme has to be augmented to include the effects of catalytic reactions involving trace constituents such as oxides of nitrogen and chlorine. Even then, the amount of ozone varies substantially, not only with latitude and season (as a consequence of the changing solar zenith angle and variations in the circulation of the atmosphere) but also in an apparently random fashion. Research driven by the current concern about ozone depletion (Sec. 8.1) is made complicated by the existence of these large natural fluctuations, many due to causes that are as yet imperfectly understood.

3.4 The Ionosphere

The atmosphere contains substantial numbers of charged particles, especially at those levels (in the mesosphere and above) where dissociation of molecules most frequently occurs (Rees, 1989) (see IONOSPHERE). The ionized fragments, mainly positive ions (of which the most abundant are NO^+ and O_2^+) and free electrons, collect into layers which, particularly in the days before communications satellites, were intensely studied for their effects on radio propagation. The distribution of electrons and the names given to the various regions of the ionosphere are shown in Fig. 4. Since most ions are singly charged and charge neutrality applies overall, the number of ions is approximately equal to the number of electrons at each level.

4. RADIATIVE TRANSFER IN THE ATMOSPHERE

4.1 Solar Radiation

As stated above, the most energetic solar photons at UV wavelengths and shorter are removed at various, mostly high, levels in the atmosphere, where they participate in the dissociation and ionization of oxygen and other species. The longer solar infrared wave-

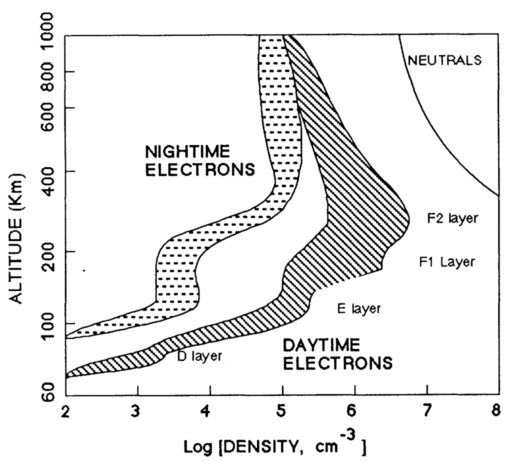

FIG. 4. Middle-latitude electron density profiles in the ionosphere, during the day (shaded area) and at night (stippled area). The areas represent the range of fluctuations due to solar variability.

lengths (1 to 5 μm) are absorbed in some regions of the near-infrared spectrum by molecular vibration-rotation bands, particularly those of water vapor and carbon dioxide. The remainder, radiation at or near visible wavelengths, mainly propagates to the ground unless obstructed by clouds (Fig. 5). On a global average, about 30% of the energy from the Sun is reflected back to space; 25% is absorbed in the atmosphere, and 45% at the ground.

4.2 Thermal Radiation

Because of its low temperature relative to that of the Sun, the Earth's surface re-emits the absorbed energy at a much longer wavelength than it was received (Fig. 6). Some of this thermal infrared radiation is transmitted directly to space by the atmosphere, but at most wavelengths substantially longer than visible the atmosphere is very opaque. Interestingly, the source of this opacity is not, for the most part, the main constituents nitrogen and oxygen, but the minor and trace constituents, especially water vapor, carbon dioxide, ozone, methane, and nitrous oxide. The reason for this is of course the fact that the two homopolar molecules N_2 and 0_2 have no permanent dipole moment and hence no strong vibration-rotation bands in the infrared region. The polar molecules, on the other hand, have a very rich infrared spectra and collectively absorb photons at all wavelengths except in a few small "window" regions, such as those near 12 and near 3.7 μm.

4.3 The Greenhouse Effect

The relative transparency of the atmosphere to sunlight and the great opacity to most infrared wavelengths has the effect of trapping solar energy near the surface. The temperature of the troposphere has to be high enough so that the cooling to space from its upper reaches conserves energy overall; on

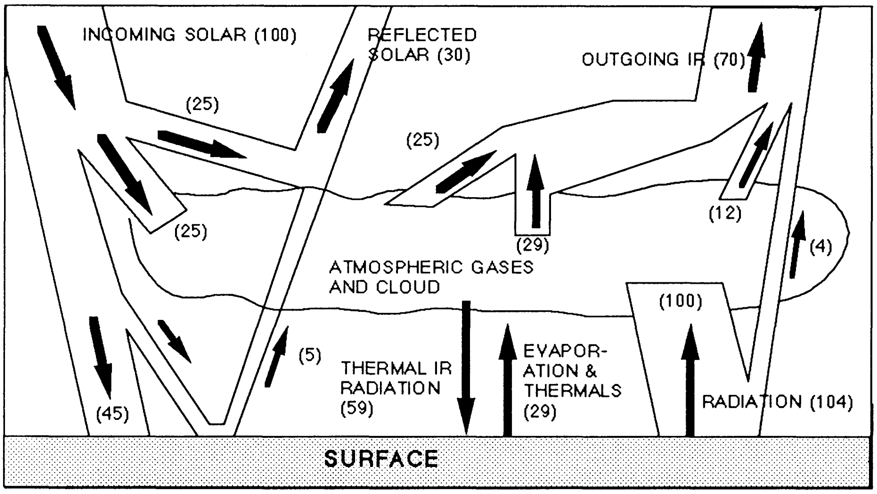

FIG. 5. Contributions of various processes to the energy balance of the atmosphere and surface, in units of percentage of the incoming solar flux.

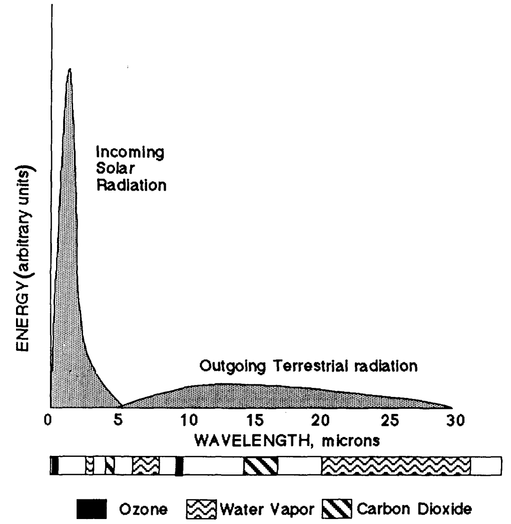

FIG. 6. Simplified emission spectra for the Earth (245 K) and the Sun (5750 K), showing how the energy emitted by these bodies depends on wavelength. Below, the approximate locations in the spectrum of the strongest absorption bands of carbon dioxide, ozone, and water vapor.

the Earth, this has the effect of raising the surface temperature by about 33 K above the equilibrium temperature that would prevail on an airless globe with the same albedo. Needless to say, without this phenomenon, somewhat irrationally known as the greenhouse effect, life as we know it would not be possible on the Earth. Changes in the concentrations of the gases contributing to the greenhouse effect, most notoriously carbon dioxide from industrial processes, are slowly driving the surface temperature up with possibly dire consequences. The physics involved are considered in more detail below (Sec. 8.2).

5. ATMOSPHERIC DYNAMICS

5.1 The General Circulation

The general circulation of the atmosphere is driven principally by pressure gradients that arise as a result of the uneven solar heating of the surface. Because the incoming energy per unit area falls off as the cosine of latitude, the heated air near the surface tends not only to rise, due to convection, but also to move polewards in such a way as to reduce the temperature gradient between equator and pole. The net result is, on the average, a general overturning of the troposphere, with rising motions at low and descending motions at high latitudes (Fig. 7). This *Hadley cell* does not extend all the way to the pole (although it may on Venus; see Sec. 6.1), probably because the rapid rotation of the Earth and the resulting Coriolis forces render such a simple general circulation unstable. A second cell (the *Ferrel cell*) occurs at middle to high latitudes, and a third near the poles, although the main mechanism for the horizontal transport of energy at middle and high latitudes is not a general overturning but instead large-scale wave motions. The relationship between large- and small-scale cells, waves, and flows is an extremely complicated research field (see, for example, Gill, 1982).

5.2 Waves and Turbulence

Atmospheric flows are subject to basic instabilities, generally classified as either *vertical, barotropic*, or *baroclinic* instabilities. An example of the first of these would be the convective instability, which, as discussed above, gives rise to regular overturning motions in the troposphere. Barotropic instabilities are

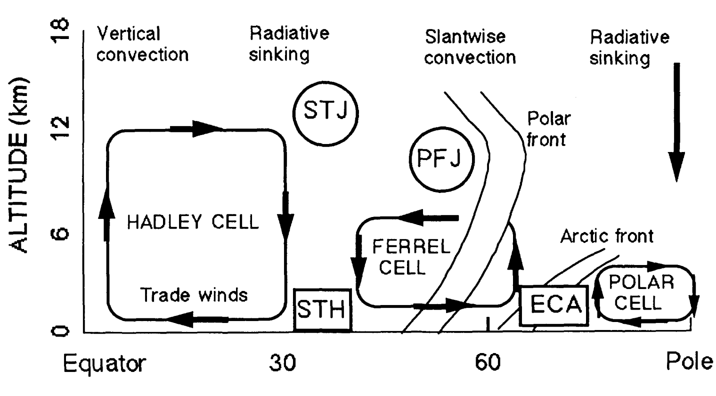

FIG. 7. Schematic features of the general circulation of the atmosphere. STJ = subtropical jet; PFJ = polar front jet; STH = subtropical high; ECA = extratropical cyclones and anticyclones.

those that grow by receiving energy from the mean flow. Baroclinically unstable disturbances extract energy from the horizontal temperature gradient. Both barotropic and baroclinic disturbances can give rise to oscillations in the basic atmospheric fields (temperature, pressure, density, and wind) known as waves. These range in scale from planetary waves, which span the globe in a few wavelengths and are a major factor in the general circulation, to small-scale motions, whose behavior is essentially chaotic, and which mix the atmosphere and act as a frictional term in the equations of motion (see TURBULENT FLOWS). Nonlinear effects in waves can, under certain conditions, roll waves into vortices, some of which become the familiar cyclones seen in weather charts.

Waves in the atmosphere are classified into at least twenty different types (Beer, 1974). Here we consider two prominent examples.

5.2.1 Gravity Waves. These waves arise when parcels of air of different density compared to their surroundings oscillate under the control of buoyancy forces. The motion is therefore at right angles to the direction of propagation. A particular example would be the lee waves that form behind a mountain, as a result of relatively dense air being forced to ascend to cross the obstruction, and then falling freely on the other side. The frequency of the oscillations depends on the wave number k, but for large k tends to the *Brunt–Vaisala* frequency ω, which is given by (Tritton, 1988)

$$\omega = \sqrt{(\gamma - 1) g^2 / c^2}, \tag{9}$$

where g is the acceleration due to gravity.

5.2.2 Rossby Waves. Many of the large-scale features that are seen, for example, in satellite maps of atmospheric temperature fields are *Rossby waves.* These arise as a result of the Coriolis force, which gives rise to a restoring force on an eastward flow that is perturbed, for any reason, away from purely zonal flow. The force on a westward flow is away from the original direction, so westward-propogating Rossby waves are not seen. This explains the absence of planetary-wave activity in the stratosphere in the summer, when the mean flow is predominantly to the west.

5.2.3 Turbulence. The measure of the onset of turbulence is the Reynolds number $\mathscr{R}$, defined as LV/ν, where L is a typical length scale of the motion, V its velocity, and ν the kinematic viscosity. The flow is turbulent if $\mathscr{R}$ exceeds a value of order 10^4. For air at standard temperature and pressure (STP), ν is of the order of $10^{-5}\ \mathrm{m^2\ s^{-1}}$, so the product LV must be as small as 10^{-1} for laminar flow. In fact, typical atmospheric values would be at least 1 m and $1\ \mathrm{m\ s^{-1}}$, respectively, so turbulent flow is common.

In fact, turbulent transfer of heat, minor constituents, and momentum is important at every level in the atmosphere. In the lowest 1 km (the *boundary layer*) it is the dominant process responsible for exchange of these quantities between the land and ocean surfaces and the atmosphere. In the stratosphere, it is found (Andrews *et al.*, 1987) that calculations of the zonal flow and mean meridional motions, which are important for the transport of minor constituents like ozone, resemble reality only if the heat and momentum fluxes due to eddies are incorporated. This is generally accomplished using mixing-length theory, or an empirically determined eddy diffusion coefficient.

6. PLANETARY ATMOSPHERES

The atmospheres of the solar system can be separated into two main classes: those of the terrestrial or Earth-like planets Venus, Earth, and Mars, and those of the outer gas giants Jupiter, Saturn, Uranus, and Neptune. Mercury, Moon, and Pluto, along with most of the satellites of the outer planets, could be considered another class of smaller, virtually airless planetary bodies. Saturn's large satellite Titan, however, possesses a thick Earth-like atmosphere, while Io of Jupiter and Triton of Neptune have very thin atmospheres maintained by active vulcanism.

6.1 The Terrestrial Planets

6.1.1 Composition. Venus, Earth, and Mars are rocky planets with thin *secondary* atmospheres; that is to say, any atmosphere which formed with the planet has been lost, and the gaseous envelopes that now exist were exhaled from the interior at a later date.

Table 2. Surface pressures and fractional abundances (%) in the atmospheres of the terrestrial planets Venus, Earth, and Mars.

	Venus	Earth	Mars
Surface pressure	90 bar	1 bar	0.007 bar
Nitrogen	3.5	77	2.7
Oxygen	~0	20	0.13
Water vapor	~0.01	~1	~0.03
Argon	0.007	0.93	1.6
Carbon dioxide	96	0.035	95
Principal trace gases present	SO_2, CO, Ne HCl, HF	Ne, He, Kr, Xe O_3, CH_4, SO_2, CO, N_2O, H_2	O_2, CO, Ne, Kr, Xe, O_3

Table 2 shows the principal constituents and their relative abundances at the present time.

The composition of Earth's atmosphere is, of course, much modified by the presence of life, and to a lesser extent by the existence of free water on the surface. Neither Mars nor Venus has either feature, and their atmospheric compositions are similar, consisting of carbon dioxide and nitrogen with traces of the rare gases and some photochemically produced species such as carbon monoxide and ozone. Carbon dioxide is a heavy gas and thus easily retained; it is a major product of planetary outgassing and, in the absence of liquid water to promote the production of carbonates, relatively stable. Venus, therefore, has huge amounts of the gas, forming a thick envelope that raises the surface temperature, through the greenhouse effect (Sec. 4.3), to around 730 K. This high surface temperature encourages further outgassing, and active vulcanism on present-day Venus is also a real possibility. Venus has a surface pressure nearly 100 times that on Earth, where most of the originally outgassed CO_2 is now in mineral form. Mars is something of an enigma in having such a low surface pressure, another factor of 100 lower than that on Earth. In part, this might be explained by the relatively small size of the planet, causing vulcanism to end early in its history and making escape of gases to space easier. Another factor is that Mars is cold enough so that CO_2 condenses on the winter pole, a phenomenon that leads to a huge annual swing in the surface pressure all over the planet, which means that some fraction of the atmosphere can be trapped at all times as ice. An additional and, in some models of Mars' evolution, an essential feature is that Mars too may have formed carbonate rocks during an early epoch when the surface was partially flooded. Considerable evidence can be seen in the geological patterns of the surface, which in places on Mars are strongly suggestive of rivers, lakes, and seas. How these were formed and how long they persisted is a matter of much active inquiry and debate.

It is also interesting to consider why it is that Venus and Mars now appear to be so dry compared to Earth. It is thought that on Mars, most of the water that once flowed on the surface still exists on the planet, but now as polar cap ice and lower-latitude subsurface frosts. Venus appears to have lost most of the water it ought to have outgassed along with its carbon dioxide, although a little is still present in the cloud droplets and as vapor. In part, the loss is due to Venus' closeness to the Sun. The high atmospheric temperature and intense ultraviolet fluxes allow greater upward transfer of water vapor, a higher rate of dissociation in the upper atmosphere, and a higher rate of loss to space of the hydrogen atoms produced as a result, compared to the Earth. Here again, however, detailed models suggest that this concept is too simple to account quantitatively for currently observed abundances, and planetary atmospheric water budgets are a research focus.

6.1.2 Clouds. On Venus, three main layers cover the entire planet, occupying the height range from about 20 to 60 km above the surface. The main constituent appears to be concentrated sulfuric acid solution, about 75% H_2SO_4 and 25% H_2O, at least in the uppermost layer where spectroscopy and polarimetry measurements have been made. The droplets there are fairly constant in size, at about 1.1 μm radius; lower down, larger particles up to about 30 μm in radius have been detected by instruments on descending probes. A rather complex, altitude-dependent cloud chemistry, involving photochemical processes, gaseous SO_2 and possibly elemental sulfur, is implied to produce and maintain clouds with this composition and structure.

Mars's atmosphere exhibits a variety of thin clouds at various locations, most spectacularly leeward of the giant volcanoes, which tower up to 25 km above the mean surface height. Clouds of both water and CO_2 ice occur. More important than either of these, in terms of its effect on conditions on the surface, is the load of dust that the atmosphere carries at all times. During storms, this obscures the surface from above, and extends over huge areas, sometimes the entire planet, to heights of 30 km. On Mars, the dust alone exerts a considerable "greenhouse" warming of the surface, as much as 20 K under average conditions.

6.1.3 Dynamics. Venus is a slowly rotating planet (1 Venus siderial day=243 Earth days) and as a consequence the Hadley-type circulation (Sec. 5.1) is more stable than it is on Earth. Cloud motions photographed from spacecraft show equator to pole motions, with velocities of a few m s^{-1} on average, quite clearly; what is less certain is the vertical extent of the cell, and whether or not there are several Hadley cells stacked on top of each other.

The atmosphere as a whole on Venus rotates much more rapidly than the solid planet. This effect, called *superrotation,* is greatest at heights near about 60 km, roughly where the observable cloud patterns lie. At that level, the pressure is about 100 mbar, and the zonal wind (parallel to the equator) is around 100 m s^{-1}, about 50 times faster than the rotation of the surface beneath. Superrotation also occurs in the Earth's upper atmosphere and on the outer planets; it is driven by the transfer of momentum upwards by wave motions. One result is that the poles of Venus are giant vortices, and they have a curious double structure that led to the coining of the term *polar dipole.*

The Martian general circulation is remarkable for its dependence on the surface topography, which is very pronounced, especially for a small planet. As on the Earth, flow over mountains and other structures forces wave motions that propagate and grow, an important part of the mean circulation. Other major factors are the very large day–night temperature contrasts, which can be as much as 100 K, because of the thin air, the variability in dust loading, and the seasonal pressure fluctuation due to the condensation of CO_2 at the winter pole. How these and other processes combine, and how the resulting Martian circulation responds, remain to be fully elucidated.

6.2 The Outer Planets

6.2.1 Composition. The gas giant planets Jupiter, Saturn, Uranus, and Neptune when formed were large enough and cold enough to retain the lighter elements, predominantly hydrogen and helium, which were present in the primordial cloud from which the solar system formed but which were lost to the inner planets. These planets are, in consequence, mostly atmosphere, increasing in density and temperature with depth to very high values, and with the heavy elements concentrated near the core. The composition of Jupiter's atmosphere, the best studied, is shown in Table 3.

As far as is known at present, the elemental abundances in Jupiter are the same as in the Sun, as would be expected if star and planets formed from the same mass and Jupiter retained all of its original material by virtue of its strong gravity field. Most of the elements are combined with hydrogen to form the most stable compound, usually the fully hydrogenated form; for example, most of the nitrogen is found as ammonia, NH_3, and most of the carbon as methane, CH_4. Many other species, in particular more complex hydrocarbons, are present in the thinner

Table 3. Percentage composition of Jupiter's atmosphere.

Hydrogen	86.1
Helium	13.8
Methane	0.09
Ammonia	0.02
Water vapor	0.008
Principal trace gases present	C_2H_2, C_2H_4, CO, HCN, GeH_4, PH_3, C_3H_4, C_3H_8

upper atmosphere where enough solar radiation penetrates to drive photochemical reactions.

6.2.2 Clouds. All of the gas giant planets are cloud-covered, as rising motions from the interior bring air rich in condensibles such as water and ammonia up to cooler levels where they condense. Jupiter is thought to have at least three layers of clouds in the region visible to the outside observer (Fig. 8) and many more below that. The uppermost layer consists of ammonia ice crystals, the one below that of hydrogen sulfide in combination with ammonia as ammonium hydrosulfide, NH_4SH, and the lowest of water. All are bound to have impurities, and the bright coloration of many of the Jovian clouds is testimony to that fact. The so-called chromophores are not yet definitely identified, but various forms of elemental sulfur may contribute to the yellows and browns, while the red spot may be colored by phosphorus produced photochemically from phosphine.

6.2.3 Dynamics. All of the gas giants have internal heat sources (except perhaps Uranus) due most likely to slow contraction of the bodies, either in an overall sense or as a result of fractionation and phase changes in the interiors, with the consequent release of gravitational potential energy. These sources are comparable to the energy arriving from the Sun, and give rise to convective overturning of the atmospheres on a planetary scale. This, and the rapid rotation rates of these large objects, dominate the general circulation, which takes the form of elongated convection cells stretched around the planet in the equatorial direction. The rising branches of the cell have denser, higher clouds, and this gives the planets their banded appearance, most prominent on Jupiter where the clouds form highest in the atmosphere.

After the bands, the most striking characteristics of outer-planet cloud markings are the various spots associated with giant eddies. These come in a variety of colors, sizes, and patterns of behavior and in general are fairly mysterious. One, the Jovian Great Red Spot, is known to have persisted for hundreds of years, at least. On Neptune, a small number of large spots dominates the appearance of the planet with the Great Dark Spot resembling its Jovian counterpart superficially, but

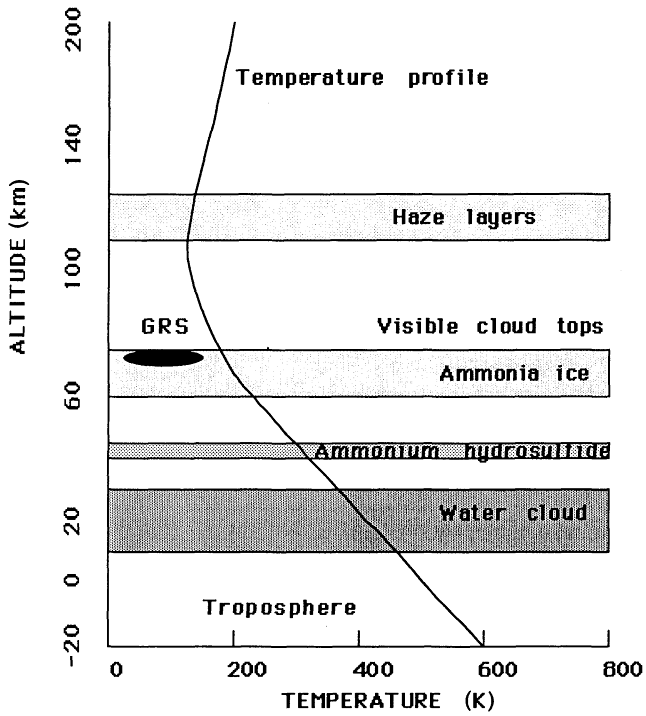

FIG. 8. Inferred structure of Jupiter's atmosphere, based on existing observational data and geochemical models. GRS denotes the Giant Red Spot.

not in detailed behavior. Both are cousins to terrestrial hurricanes but a theoretical understanding of the relationship remains elusive.

6.3 Satellites with Atmospheres

Saturn's Titan has a cloudy atmosphere of nitrogen with a thick layer of orange clouds and a surface pressure of over 2 bars. Why this satellite should be so endowed while, for example, the similarly sized Jovian satellites Ganymede and Callisto are essentially airless is a mystery. The nitrogen on Titan was probably once ammonia that was photochemically dissociated, allowing the hydrogen to escape. The clouds are probably drops of oily hydrocarbons, built up from the photochemical products of methane. It is possible that rain from these clouds has collected on the surface to form an ocean of liquid ethane and other condensible hydrocarbons.

Titan is unique in being the only satellite with an atmosphere that is thick compared to Earth's. Two others, Io (Jupiter) and Triton (Neptune), have thin, transient atmospheres fueled by volcanoes, probably expelling sulfur dioxide and hydrogen sulfide, and nitrogen, respectively. The volcanoes are driven by tidal heating of the interior of the body in both cases, rather than primordial and radioactive heat as with the Earth.

7. ATMOSPHERIC OBSERVATIONS

Although it was one of the earliest subjects of scientific study, our current understanding of the atmosphere of the Earth is mostly quite young, due to the difficulties inherent in obtaining sufficiently extensive and reliable data. To a considerable degree, the current picture, still far from complete, dates back only to the advent of Earth satellites (and computers capable of processing the masses of data that they produce) in the 1960s. Before that, spectrometric instruments on the ground and instruments on balloons and rockets produced isolated profiles of temperature, pressure, and composition, and aircraft explored the lower layers. These techniques are still valued for the high spatial resolution that they afford in studying basic processes, and for their relatively low cost.

7.1 Ground-Based and Airborne Observations

Of the many techniques that have been applied and are still being developed, we mention two classic examples of meteorological instrumentation that are still in daily use.

7.1.1 The Dobson Ozone Spectrophotometer. A worldwide network of about 150 Dobson spectrometers makes daily measurements of total ozone in the atmosphere. It was with this device that the Antarctic ozone "hole" was detected for the first time in the mid-1980s.

The instrument operates by observing the Sun from the ground in the near-ultraviolet part of the spectrum (0.3 to 0.33 μm). Two wavelengths at which ozone absorbs by different amounts are isolated using a diffraction grating and recorded on a photomultiplier detector. A calibrated optical wedge is used to attenuate the longer, less absorbed wavelength, and the wedge position that gives equal attenuation in both channels, together with a knowledge of the solar zenith angle and zero-path brightnesses, is interpreted in terms of total ozone.

7.1.2 The Radiosonde. Radiosondes are packages of inexpensive instruments that are released routinely on small balloons to measure temperature, pressure, humidity, and wind up to heights of about 20 km. Temperature is measured using a fine-wire resistance thermometer, pressure by the deformation of a sealed, flexible capsule, and humidity by the extension of a stressed membrane of a suitable material such as gold-beater's skin. The wind is measured by tracking the balloon during its ascent using radar. Again, a very extensive network in space and time is necessary to provide useful coverage.

7.2 Measurements from Space

Satellites and planetary probes employ infrared and microwave molecular spectroscopy techniques to obtain information about the physical properties of atmospheric gases. This is known as *remote sensing* or, where quantitative measurements of, for example, temperature profiles are concerned, sometimes *remote sounding*. The basic principle of temperature sounding is described in the next section. In applications such as weather forecasting, satellite observations are used to complement surface and balloon data by providing global, frequent coverage. The *in situ* measurements by contrast are sporadic, but have better resolution and often better precision.

7.2.1 Remote Temperature Sounding. The radiance I_λ leaving the top of the atmosphere at a particular wavelength λ is given by the *radiative transfer equation* as

$$I_\lambda = \int_0^\infty B_\lambda(T)\, \frac{d\tau_\lambda(z,\infty)}{dz}\, dz + B_\lambda(T_0)\tau_\lambda(0,\infty), \tag{10}$$

where B is the Planck blackbody function of temperature T at wavelength λ and $\tau_\lambda(z_1,z_2)$ is the transmission of the atmosphere between the two levels z_1 and z_2 at the same wavelength. The second term is the contribution from the surface at temperature T_0. The quantity $d\tau_\lambda(z,\infty)/dz$ is called the *weighting* or *contribution function*, and is usually written $K_\lambda(z)$. The weighting function has a maximum value at the height $z_{\max}$, where the optical depth of the atmosphere is unity, which of course depends on the choice of wavelength. A selection of wavelengths in the wing of a strong absorption band of a species such as carbon dioxide, whose mixing ratio is known and constant up to high levels, allows a family of weighting functions to be calculated with values of $z_{\max}$ ranging from the surface to 50 km or so (Fig. 9). A set of measurements of I_λ can then be turned into a temperature profile by the solution of the set of equations (10). The derived profile is a smoothed version of the actual atmospheric temperature profile, because of the averaging effect of the weighting functions. Some of the detailed structure can be extracted using many spectral channels corresponding to overlapping weighting functions; finding the optimum solution for the profile from a given set of measurements with their associated errors is therefore a complicated matter known as the *retrieval problem* (Houghton *et al.*, 1986).

7.2.2 Vertical Resolution. The vertical resolution of remote sounding measurements is limited by the fact that, in order to get a measurement of I_λ that is not dominated by instrument noise, narrow spectral intervals corresponding effectively to single wavelengths cannot be used in practice. Instead, spectral bands containing many molecular vibration-rotation lines must be employed. This has the effect of further broadening the weighting function relative to that for an idealized, monochromatic observation.

Techniques have been developed, for example using microwave radiometers, that do produce quasimonochromatic weighting functions, but these are still broader (the width at half maximum amplitude is around two atmospheric scale heights, or about 14 km) than desirable for modern atmospheric studies, forecasting, or other applications. This has led to the development of *limb scanning* techniques, in which the instrument views the atmosphere tangentially to the surface and images a thin slab of atmosphere onto the detector. This can improve the vertical resolution to about 2 km, at the expense of poorer horizontal resolution, but tropospheric clouds and hazes generally limit the usefulness of limb scanning to the stratosphere and above.

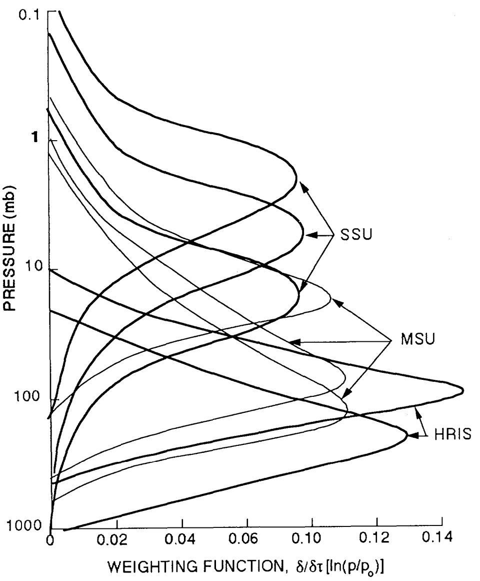

FIG. 9. Weighting function for selected spectral intervals measured by the three instruments that make up the TIROS operational vertical sounder. SSU: stratospheric sounding unit; MSU: microwave sounding unit; HRIS: high-resolution infrared sounder.

7.2.3 Composition Measurements. The transmission function in Eq. (10) is a known function of the vertical profile of the mixing ratio of the emitting species as well as temperature. Once $T(z)$ has been determined using a species of known abundance, measurements in a spectral band of a second species of unknown distribution can be used to obtain its profile. Water vapor or the trace gases such as oxides of nitrogen involved in ozone photochemistry are common targets of this technique. As with temperature, limb measurements improve the vertical resolution when the middle atmosphere is the objective and add the further benefit of a much longer absorbing path, by nearly a factor of 100, when trace constituents are to be measured.

8. CLIMATE AND CLIMATE CHANGE

A knowledge of atmospheric physics can be applied not only to the understanding of the natural state of the environment at the surface and above, but also to considerations of past and future changes in this state. At the present time, there is much concern over changes in the chemical composition of the atmosphere, particularly the stratospheric ozone layer, and changes in the mean temperature due to anthropogenic modifications to the natural "greenhouse" that maintains the status quo. There is also great interest in establishing the physical basis for long-range weather (or short-term climate) forecasting. We consider these topical problems in this final section.

8.1 The Ozone Layer and Ozone Depletion

8.1.1 Production and Loss Mechanisms for Ozone. It was noted above (Sec. 1.2) that the temperature actually *increases* with height above the tropopause and has a maximum value at about 50 km of around 270 K, some 50 K more than the calculated value for an atmosphere without ozone. In fact, it has been known since the early part of the present century that the stratosphere contains substantial concentrations of the triatomic version of oxygen, produced by those photons from the Sun that are at sufficiently short ultraviolet wavelengths (less than about 0.246 μm) to have enough energy to dissociate the oxygen in the atmosphere. The ozone itself also absorbs ultraviolet photons at wavelengths that match its internal energy states; as with CO_2 at longer wavelengths, this ultimately appears as kinetic energy and so warms the atmosphere. Sufficiently energetic UV photons dissociate ozone and produce oxygen again. The amount of ozone that is present at any time depends on the balance between these production and loss mechanisms; so it varies with latitude, height, time of day, and season. This leads to an irregular and variable distribution of ozone around the Earth, with more on the whole at high latitudes. The existence of large amounts of ozone in the stratosphere is important for the biosphere, because its opacity is important for removing ultraviolet radiation that would otherwise reach the ground. This very energetic radiation is harmful to animals and plants.

In addition to the molecular nitrogen that makes up most of the atmosphere, there is a very small amount of nitrogen in its reactive forms, such as the various nitrogen oxides or nitric acid. These come mainly from the surface, from soils containing nitrogen-fixing bacteria, among other sources. Once in the stratosphere—in tiny quantities—they take part in reactions like the following:

$$\begin{array}{l} NO+O_3=NO_2+O_2 \\ \underline{NO_2+O=NO+O_2} \\ O+O_3=2O_2 \end{array} . \tag{11}$$

The importance of this nitrogen oxide or NO_x cycle was not fully realized until the 1970s, because the amounts are so tiny that no one thought nitrogen oxides could possibly be important. The reason why they are important is clear from Eqs. (11)—they are involved in *catalytic* cycles in which the NO_x itself is not consumed.

8.1.2 Anthropogenic Effects. Human activities such as the supplementing of nitrogen-fixing bacteria with artificial fertilizers are increasing the amount of NO_x in the atmosphere. Recently, atmospheric cycles involving chlorine compounds, which mostly start life as Freon propellants in aerosol spray cans or as the working gas in refrigerators and air conditioners, have been identified, and the fact that these also affect the way ozone is created and destroyed has been recognized. More recently still, the importance of hydrogen chemistry through molecules such as H_2O_2 (hydrogen peroxide), which are present in tiny but still important amounts, has been realized (see AIR POLLUTION: COMPONENTS, CAUSES, AND CURES). Stratospheric chemistry is now an extremely complex subject, and realistic attempts to calculate the ozone distribution must include scores of reactions involving dozens of species (Fig. 3).

It is also necessary to realize that all of these reactions, including the catalyzed ones, are very temperature dependent. They also depend indirectly on atmospheric motions, because the ozone and the species with which it is reacting vary considerably in space and time, and the circulation of the atmosphere is very important for moving them around and mixing them up. The intensity of the radiation available is crucial, of course, for both temperature and photochemistry, and varies with altitude and time of day. The heating rate for a given flux depends on the amount of absorbing minor constituent, and so a circular relationship known as the "coupled radiation-chemistry–dynamics (RCD) problem" exists (Fig. 10). This is at the center of most of the problems that the theoreticians in the atmospheric sciences community are tackling at present, including the particularly dramatic, although localized in space and season, problem of the severe depletion of ozone over Antarctica—the so-called ozone "hole." The solution lies in building computer models in which the time-dependent equations of radiative transfer, fluid dynamics, and chemical reactions are all incorporated as accurately as possible and tested against detailed observations.

8.2 The Greenhouse Effect

The role of the greenhouse effect in maintaining the temperature of the Earth's surface may be appreciated by first considering the overall energy balance of the planet (Fig. 11). The effective temperature of the surface of the Sun is about 5750 K, and its distance from the Earth is about 150 million kilometers. Applying the *Stefan–Boltzmann* law, which states that the power E emitted as radiation by any body whose emissivity is ϵ is proportional to the fourth power of its temperature, i.e.,

$$E=\epsilon\sigma(T_{\mathrm{Earth}})^4, \tag{12}$$

where σ is a constant equal to

$5.670\times10^{-8}\ \mathrm{W\ m^{-2}\ K^{-4}}$.

In order for the planet to be in equilibrium overall, E must also be equal to the incoming power, i.e.,

$$E=S\pi R^2, \tag{13}$$

where S is the solar constant, which is defined as the power per cm^2 arriving at the Earth from the Sun. Knowing that the temperature of the Sun is approximately 5750 K, we have (also from the Stefan–Boltzmann law)

$$S=\sigma T^4(R_{\mathrm{Sun}}/D_{\mathrm{Earth\text{-}Sun}})^2 \tag{14}$$

from which we find that S is approximately 1.3 kW m^{-2}. Equating the expressions for E in Eqs. (13) and (14), we obtain the answer $T_{\mathrm{Earth}}=245$ K (approximately). This must be the temperature of a solid sphere the same-size as the Earth at the same distance from

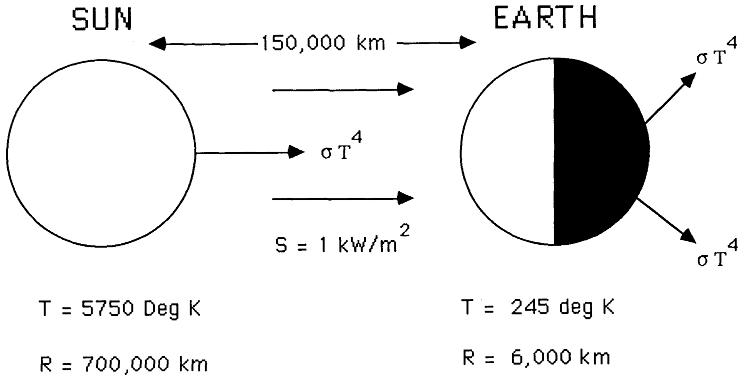

FIG. 11. The overall energy balance of the Earth.

the Sun, but as a value for Earth's surface temperature it is clearly wrong. The reason for the discrepancy is the atmosphere (Fig. 12). The energy from the Sun reaches the surface of the planet because solar radiation consists mostly of photons at visible wavelengths, and the atmosphere is nearly transparent at those wavelengths. The balancing, cooling radiation, however, is in the infrared part of the spectrum because the source is so much cooler, a few hundred degrees instead of a few thousand.

Many of the most abundant minor constituents, such as water vapor and carbon dioxide, absorb *infrared* photons, and do so prodigiously, at most infrared wavelengths (Fig. 6). It also happens that one of the strongest absorption bands of CO_2 covers the wavelength region where emission by typical Earth atmospheric temperatures occur. It is therefore the *atmosphere* that cools by radiating to space, and not the surface, and it is the atmosphere which has the characteristic temperature of 250 K. Of course, the atmosphere will radiate downwards as well as up, so the surface gets an extra σT^4 or 1 W/m^2 in addition to the 1 W/m^2 we get directly from the Sun. By the Stefan–Boltzmann law, this is enough to make the temperature go up to about 290 K, which is much closer to what is observed. The exact solution of the problem involves proceeding from this very simple model to one that includes all of the complex physics of the muitilayer, inhomogeneous atmosphere, with clouds and other factors incorporated (cf. Fig. 5).

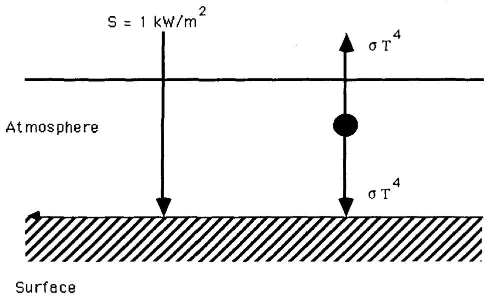

FIG. 12. Energy balance of a single-layer model of the atmosphere.

The above discussion shows how the "greenhouse" effect, caused by minor constituents in the atmosphere, especially water vapor and carbon dioxide, makes the Earth habitable in the first place. The amount of carbon dioxide in the atmosphere is governed by the balance between production, which is mainly by combustion of fossil fuels—coal, oil, and wood—and loss, which is mainly by photosynthesis—trees and other green plants taking in CO_2 and giving off oxygen. Examples of the ways in which human activity is altering this balance are the steady increase in industrial activity, which increases the production of CO_2, and the equally remorseless reduction in the extent of forests, which reduces the rate at which atmospheric CO_2 is recycled.

Figure 13 shows the increase in the abundance of CO_2 that has taken place over the last 100 years or so. A recent discovery is that methane is an important greenhouse gas, too, less so than CO_2 but still significant. The amount of methane in the atmosphere is also, for reasons less well known but probably related to increased agricultural development, going up steadily.

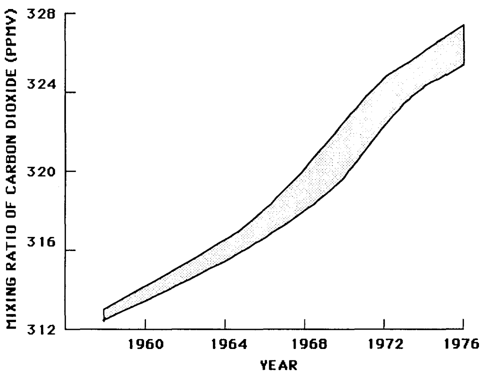

FIG. 13. Range of observed change in CO_2 abundance at various sites. (After Kellogg and Schware, 1981.)

Calculations of the atmospheric energy balance with the amount of CO_2 doubled, which at the present rate will happen in the next century, find that the tropopause will be a few hundred meters higher, and the surface about 3 or 4 degrees hotter. That is a very serious increase indeed and would lead to widespread harmful changes in the environment. For near-equatorial countries, increased desertification would follow; for high-latitude, low countries like parts of Western Europe, the worst problem may be a rise in sea level sufficient to cause extensive flooding of inhabited areas.

8.3 Prospects for Forecasting Climate

General extrapolations of the kind described above are useful for predicting possible modifications to the environment forced by externally imposed changes. A different, but related, problem is the prediction of the natural variability of the climate system, i.e., annual and seasonal fluctuations in the world as we find it now.

Weather forecasting using physical models and data from satellites is now routine, but climate forecasting (predictions of weather averaged over fairly broad space and time scales, but extending months to decades into the future) is at best still some way off. The latest research projects include models of atmosphere–ocean coupling, with which the existence of interactions and fluctuations on long time scales can be investigated. The latest research satellites carry very advanced radiometers of considerable complexity to measure, for example, the tiny amounts (measured in parts per billion in some cases) of reactive gases involved in ozone photochemistry, or the long-term changes in carbon dioxide and methane in the upper atmosphere. Attempts to reproduce the seasonal variation in these quantities are good tests of theoretical models. In due course, long-term trends may be related to temperature and cloud-cover changes to provide an early detection of changes in the climate.

GLOSSARY

Bar: A measure of pressure. 1 bar$=10^5$ pascals. Atmospheric pressures are usually cited in millibars.

Brunt–Vaisala Frequency: A natural frequency of atmospheric gravity waves.

Ferrel Cell: A large-scale overturning of the atmosphere at middle to high latitudes.

Greenhouse Effect: The warming of a planet's surface by the blanketing effect of the atmosphere, resulting from the greater opacity of the atmosphere in the infrared, relative to the visible, part of the spectrum.

Hadley Cell: Large-scale overturning of the lower atmosphere that extends from the equator to middle latitudes.

Homopause: The level at which the atmosphere ceases to be mixed and gravitational separation of species begins. Approximately 100 km altitude.

Ionosphere: Region of the atmosphere containing layers of charged particles; overlaps the upper stratosphere, the mesosphere, and the lower thermosphere.

Lapse Rate: The gradient of temperature with height.

Limb Scanning: A remote sensing technique in which the instrument views the atmosphere tangentially from a satellite.

Mesopause: The level separating the mesosphere from the thermosphere; approximately 90 km altitude.

Mesosphere: The region above the stratosphere, characterized by decreasing temperature with height; approximately 50 to 90 km altitude.

Meteorology: The study of localized atmospheric phenomena ("weather").

Remote Sensing: The technique of measuring atmospheric parameters (temperature, etc.) from a distance, usually from a satellite, using (e.g.) infrared radiometry.

Secondary Atmospheres: Exhaled from the solid body of the planet, as opposed to retained during formation.

Scale Height: The vertical distance in which an atmospheric parameter, usually pressure or density, falls by a factor of $1/e$.

Stratopause: The level separating the stratosphere and the mesosphere.

Stratosphere: The region above the troposphere, approximately 10 to 50 km altitude.

Superrotation: The situation where a region of the upper atmosphere rotates much more quickly than the solid planet.

Thermosphere: The highest region of the atmosphere, characterized by increasing temperature with height.

Trace Constituents: Species present in amounts of a few parts per million or less, often highly variable and chemically active.

Tropopause: The level separating the troposphere from the stratosphere.

Troposphere: The lowest region of the atmosphere, characterized by convective, overturning motions; approximately 0 to 10 km altitude.

Weighting Function: In atmospheric radiative transfer and remote sounding theory, a mathematical function describing the contribution of each height level to the intensity of thermally emitted radiation upwelling to space.

INTRODUCTION

The composition of a planetary atmosphere depends upon the way in which the planet and its atmosphere were originally formed, as well as on physical and chemical processes that continually add some gases to the atmosphere while removing others. Some examples of these processes include volcanic eruptions, chemical reactions at the ground and ocean, and the escape of gases from the top of the atmosphere into space.

The Sun and Earth's atmosphere have been evolving constantly with time. Stellar theory suggests that the early Sun was only 70% as luminous as it is today. Climate theory indicates that if the early Earth's atmosphere had its present composition, the Earth would have existed in permanent glaciation since its beginning and would not yet have thawed out. It has, therefore, been suggested that the early terrestrial atmosphere was poor in oxygen and rich in infrared-opaque gases so that an enhanced greenhouse effect could keep the mean surface temperature above freezing.

The present-day thermal structure of the atmosphere is also determined by how the present atmospheric composition absorbs solar radiation and reradiates it back to space. At today's composition, solar ultraviolet, visible, and infrared radiation are absorbed primarily by molecular oxygen (O_2), ozone (O_3), and water vapor (H_2O). Solar energy in the visible is also absorbed at the ground and oceans. This absorbed solar energy is balanced by infrared radiation to space from the radiatively active atmospheric gases, primarily carbon dioxide (CO_2), O_3, and H_2O vapor. Clouds, however, can influence this clear-sky radiative balance by reflecting solar radiation

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

back into space and also by altering the infrared radiational field. The present-day basic atmospheric structure that is maintained by this radiative balance is described in this article.

In addition to the long-term changes in atmospheric composition because of planetary evolution, there have also been more recent variations. Fluctuations in greenhouse gases (CO_2 and CH_4) have been measured in deep ice cores extracted from the Antarctic ice cap. These ice cores provide a record of atmospheric climate and CO_2 concentration that is representative of global changes over the last glacial-interglacial cycle (160 000 years). CO_2 concentrations as low as 180 parts per million by volume (ppmv) have been derived during the height of the glacial advances about 18 000 years ago (Lorius *et al.*, 1988). The present CO_2 concentration (350 ppmv) is changing rapidly, but this time in response to man's increasing activities (see AIR POLLUTION: COMPONENTS, CAUSES, AND CURES). A doubling of the CO_2 concentration is expected to occur by the end of the 21st century. The greenhouse radiative effect on climate from CO_2 is also being enhanced by increasing concentrations of methane (CH_4), tropospheric O_3, nitrous oxide (N_2O), and chlorofluorocarbons (CFCs). In addition, temperature changes associated with increasing greenhouse gases may also influence water vapor concentration, cloud amounts, and atmospheric structure. The atmospheric structure described in this article applies only to present-day conditions, and it is likely that changes in atmospheric structure will occur in future centuries. Past changes have occurred naturally but projected future changes appear to have a component of man's activities associated with them.

1. GLOBAL MEAN EFFECTIVE RADIATING TEMPERATURE

The Earth is the third planet in our solar system at a mean distance of 1.49×10^8 km from the Sun. It is enveloped by an atmosphere of gases that make our planet habitable by a delicate balance between absorbed solar radiation and radiation emitted to space. The Sun, which has an effective surface temperature of about 6000 K, emits most of its radiation as a blackbody in the wavelength range of 0.2–4.0 μm, including the ultraviolet, visible, and near-infrared wavelengths. The Earth-atmosphere system absorbs part of this energy and is heated by the absorbed radiation at a mean rate of $S(1-a)/4$, where S is the solar irradiance or power per unit area intercepted at the mean Earth-Sun distance (1365–1372 W/m^2), a is the planetary albedo, which is the fraction of solar irradiance reflected by the planet's surface and the atmosphere back to space ($30 \pm 3\%$), and the geometric factor 4 is the ratio of the Earth's surface area to the area of the Earth's disk. The absorbed heating must be balanced by the emission of long-wavelength (thermal or infrared) radiation from the Earth and its atmosphere to space. The rate of cooling is given by σT_e^4, where σ is the Stefan-Boltzmann constant ($\sigma = 5.669 \times 10^{-8}\ W/m^2\ K^4$) and T_e is the effective blackbody radiating temperature of the Earth-atmosphere system. The simplest model of the Earth's climate, considering the long-term average of the global and annual mean temperature (on a time scale greater than a year), is determined from the equilibrium relationship,

$$S(1-a)/4 = \sigma T_e^4. \tag{1}$$

Assuming $S = 1365\ W\ m^{-2}$, $a = 0.3$, yields $T_e = 255$ K (−18 °C). In the absence of an atmosphere T_e is the Earth's global mean surface temperature. However, the value of a that is used does depend on the atmosphere because scattering from clouds and aerosols as well as the properties of the Earth's surface are involved in determining its value.

It is the presence of certain atmospheric gases, such as water vapor, carbon dioxide, and others that are relatively inefficient absorbers of visible solar radiation, but effectively absorb the long-wavelength infrared radiation emitted from the surface, that provides an additional warming of the Earth. These gases absorb, then reradiate both back to the surface, producing an additional warming, and to space, providing the cooling necessary to maintain a radiative balance with incoming solar radiation. The present-day concentration of these so-called "greenhouse gases" raises the effective global mean surface temperature, T_e, from −18 °C to the current observed value of +15 °C. Equation (1) still gives T_e (assuming $a = 0.3 = \text{const}$), but the ef-

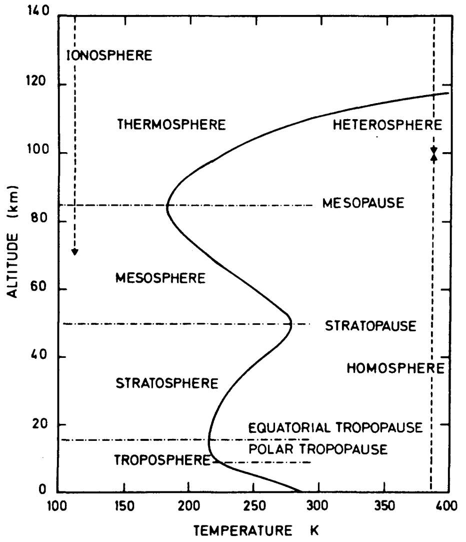

FIG. 1. Thermal structure of the atmosphere from the ground to 140 km. Various atmospheric regions are indicated, as well as the boundaries separating the regions.

fect of the trace gases is to raise T_e to higher values, warming the surface below. Internal heat generated by radioactivity within the planet is a negligible heat source for the atmosphere.

2. MEAN VERTICAL TEMPERATURE STRUCTURE OF THE ATMOSPHERE

In practice, the atmosphere is not in pure radiative equilibrium at a single mean temperature as described above, but varies in all three spatial dimensions as well as in time. Its most fundamental variation, however, is with respect to altitude. The atmosphere has, therefore, been divided scientifically into layers based on the vertical structure of the temperature field. These layers, the troposphere, stratosphere, mesosphere, thermosphere/ionosphere, and exosphere/magnetosphere are separated by boundaries known as the tropopause, stratopause, mesopause, and thermopause. The regions and boundaries, along with a representative vertical temperature profile, are illustrated in Figs. 1 and 2.

The troposphere lies below the first temperature minimum at around 10–15 km, and it is the region where most of the clouds and weather as we experience it exist. The stratosphere lies between this temperature minimum and the temperature maximum around 50 km. The temperature maximum occurs because ozone in this region absorbs solar ultraviolet radiation and heats the atmosphre. Ozone effectively shields the Earth's surface from this harmful radiation. Because the temperature increases with altitude, the atmosphere is stable, forming an inversion layer that confines weather process to the troposphere. Next comes the mesosphere that extends from the 50-km temperature maximum to a temperature minimum around 90 km, the coldest region in the Earth's atmosphere. The thermosphere and embedded ionosphere extend upward from 90 km to several hundred km where the temperature asymptotically approaches a maximum, called the exospheric temperature at the base of the exosphere (Fig. 2). The exosphere lies above the thermopause, and it is so rarefied that the vertical temperature structure remains isothermal because of rapid molecular heat transport. The thermosphere and exosphere are regions where the density is so low that satellites freely orbit the Earth. In recent years the region that includes the stratosphere, meso-

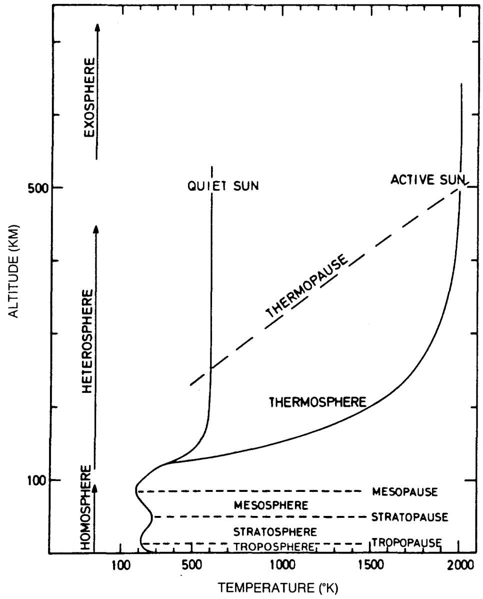

FIG. 2. Mean vertical temperature profile from the ground to the exosphere (from the *U.S. Standard Atmosphere 1976*).

sphere, and the lower thermosphere, between about 10- and 120-km altitude, has been referred to as the "middle atmosphere." This distinction between middle and the lower and upper atmospheres is now widely accepted although there is still frequent reference to the original classification.

The ionosphere (*q.v.*) is a weakly ionized plasma that is embedded within the mesosphere and thermosphere. It is produced by intense solar extreme ultraviolet (EUV) radiation at wavelengths less than 103 nm that ionize the neutral gases in these regions. The magnetosphere (*q.v.*) is a rarefied plasma that coexists with the neutral gases in the exosphere and extends deep into space where it eventually merges with the solar wind. The solar wind is a rarefied plasma that flows radially outward from the Sun into deep space and engulfs the Earth as it passes its orbit. The plasmas contained in both the ionosphere and magnetosphere are strongly controlled by the Earth's geomagnetic field and are subject to electric fields generated by the interaction of the solar wind with the Earth's geomagnetic field.

3. STATIC STRUCTURE OF THE ATMOSPHERE

Atmospheric statics is the study of the relationship between the thermodynamic variables of pressure, density, and temperature, p, ρ, and T, respectively. The atmospheric gases are usually treated as a thermodynamic ideal gas,

$$p=\rho RT, \tag{2}$$

where R is the gas constant, R^*/M, R^* is the universal gas constant, and M is the mean molecular mass.

The vertical profiles of pressure and density, given the vertical temperature profile, shown in Fig. 1, can be determined by the use of the ideal-gas law and the hydrostatic equation. The hydrostatic equation balances the vertical pressure gradient and gravity as

$$dp/dz=-\rho g, \tag{3}$$

where g and z are the acceleration of gravity and the geometric height, respectively. The acceleration due to gravity at sea level, g_0, is 9.806 65 m/s^2. The variation of gravity with altitude follows the inverse-square law of gravitation and for most model atmosphere computations can be determined from

$$g(z)=g_0r_0^2/(r_0+z)^2, \tag{4}$$

where r_0 is the effective radius of the Earth. The *U.S. Standard Atmosphere 1976* gives r_0 as 6356.766 km.

The ideal-gas equation (2) and the hydrostatic equation (3) can be combined to give an equation that describes the vertical atmospheric structure of the atmosphere as

$$\frac{dp}{p}=-\frac{gdz}{RT}=-\frac{dz}{H}, \tag{5}$$

where $H=RT/g$ is called the atmospheric scale height. It represents an altitude difference which corresponds to a reduction by $1/e$ in the pressure or total atmospheric density. The atmospheric scale height is roughly 7 ± 1 km in the lower atmosphere up to about 86 km, but increases rapidly in the thermosphere because of the large increase in temperature and decrease in mean molecular mass. Integrating Eq. (5) gives a simple relationship that describes the vertical structure as

$$p(z)=p_0\exp\left(-\int_{z_0}^{z}\frac{dz}{H(z)}\right), \tag{6}$$

where the subscript 0 denotes that the corresponding values are defined at some reference altitude, z_0, such as sea level. The total number density as a function of altitude can also be derived in a similar manner as

$$n(z)=\frac{n_0T_0}{T(z)}\exp\left(-\int_{z_0}^{z}\frac{dz}{H(z)}\right). \tag{7}$$

The *U.S. Standard Atmosphere 1976* gives the following values for the sea-level temperature, pressure, and density which have been standard for decades:

Temperature, 288.15 K, 15 °C, or 59 °F.
Pressure, 1013.25 mb, 760 mm of Hg, 29.92 in. of Hg, or 1.013 25×10^5 Pa.
Density, 1225.00 g/cm^3 or 0.076 474 lb/ft^3.

The relationship between geometric height, temperature, pressure, and density as given in the *U.S. Standard Atmosphere 1976* is presented in Table 1 and shown in Figs. 1–3. These values are a mean profile of atmospheric structure and should only be consid-

Table 1. Temperature, pressure, and density at various altitudes (from the *U.S. Standard Atmosphere 1976*).

ered as a representative profile since at any given time and location there may be considerable departures from the mean depending upon meteorological conditions.

The air in the standard atmosphere is assumed to be dry. The sea-level dry-air fractional-volume composition of the *U.S. Standard Atmosphere 1976* is given in Table 2. These constituents are generally inert, well mixed throughout the atmosphere by turbulence, and maintain this fractional volume composition up to about 86 km. Above this altitude diffusive separation dominates turbulent mixing, and each species will settle according to its own molecular weight with the heavier species settling out in the lower thermosphere and the lighter species dominating the higher altitudes as shown in Fig. 4.

In addition to these chemically inert species, there are also chemically active trace gases, and the concentrations of some of

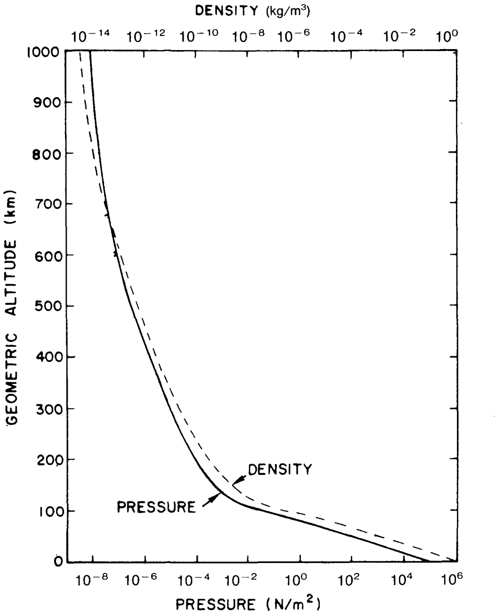

FIG. 3. Total pressure and mass density plotted as a function of geometric altitude (from the *U.S. Standard Atmosphere 1976*).

Table 2. Molecular weight and fractional-volume composition of sea-level dry air (from the *U.S. Standard Atmosphere 1976*).

these gases near the Earth's surface are given in Table 3. These trace gases can vary widely depending upon geographic location, altitude, and time. Several of these gases are increasing as a result of man's activities.

The number density of individual species and the total number density of all species are shown as a function of altitude in Fig. 4. In the lower atmosphere up to the turbopause near 100 km molecular oxygen and nitrogen dominate at relative percentages of approximately 21% and 78%, respectively, with the remaining 1% attributed to the trace gases. Atomic oxygen, produced by photodissociation of O_2 by intense solar ultraviolet radiation in the upper atmosphere, is scarce in the lower atmosphere but becomes the dominant species above about 140 km. Helium becomes dominant above 600 km and finally atomic hydrogen, the lightest gas, which is also scarce in the lower atmosphere, becomes dominant in the exosphere above about 1500 km. The distribution of atmospheric species above about 100 km undergoes large diurnal, seasonal, solar cycle, and geomagnetic storm variations about the mean profile shown here. Below 100 km, these variations are considerably smaller but, nevertheless, are significant. The variations about this mean profile are discussed in a later section.

There are also many other properties that describe standard atmospheric structure, and some of these are listed below.

Table 3. Concentrations of various tropospheric trace-gas constituents near the Earth's surface (from the *U.S. Standard Atmosphere 1976*).

NO_2	1
H_2S	0.05
NH_3	4
SO_3	1
CO	190
0_3	40

3.1 Mean Particle Speed

The mean particle speed V is the arithmetic average of the speeds of all the neutral air particles in a volume element. The analytic expression for V is given by

$$V=(8R^*T/\pi M)^{1/2}, \tag{8}$$

where $\pi=3.141\,5926$, R^* is the universal gas constant, T is the temperature, and M is the mean molecular weight at a specific altitude. The mean particle speed V is plotted in Fig. 5 as a function of altitude. The structure below 100 km properly reflects changes in T because

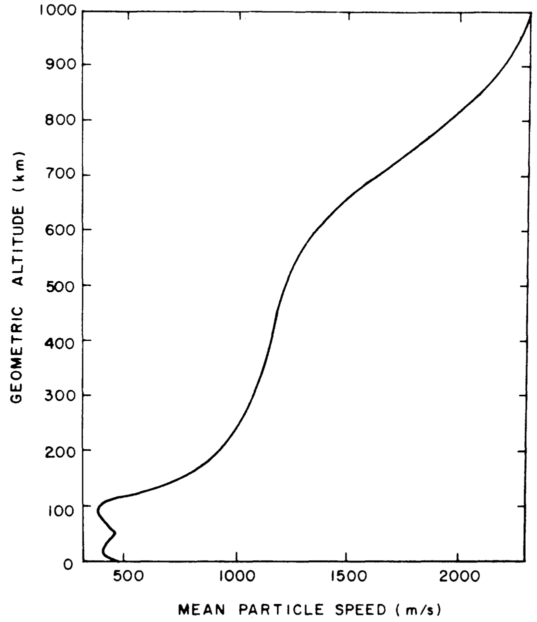

FIG. 5. Mean particle speed as a function of geometric altitude (from the *U.S. Standard Atmosphere 1976*).

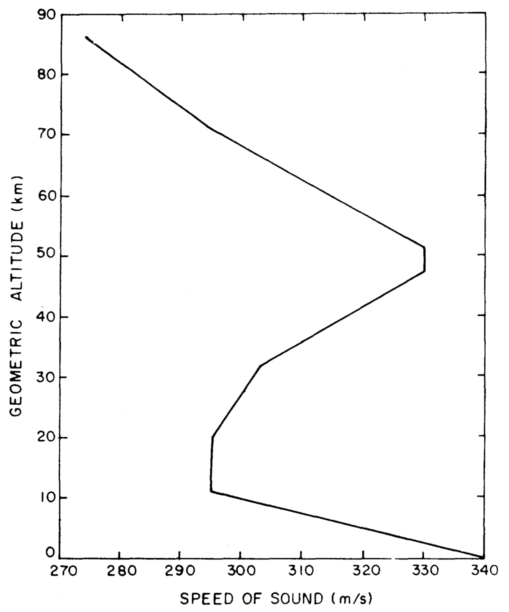

FIG. 6. Speed of sound as a function of altitude (from the *U.S. Standard Atmosphere 1976*).

M is well mixed by turbulence and remains nearly constant with altitude. However, the large increase in the mean particle speed above 100 km results from changes in both *T* and *M*, as molecular species dissociate into atomic species, throughout the thermosphere and exosphere.

3.2 Speed of Sound

The expression for the speed of sound C_s is similar to that of the mean particle speed,

$$C_s = (\gamma R^* T/M)^{1/2}, \tag{9}$$

where γ is the ratio of the specific heat at constant pressure to that at constant volume, 1.40 for air below about 86 km. Above that altitude γ can vary with changing atmospheric composition. The above equation for the speed of sound applies only when the sound wave is a small perturbation on ambient conditions. The attenuation that exists at sea level for high sound frequencies applies to successively lower frequencies as atmospheric pressure decreases and the mean free path increases. For this reason the concept of the speed of sound progressively loses its range of applicability above a certain altitude. The calculated speed of sound as a function of altitude below 86 km is shown in Fig. 6.

3.3 Mean Collision Frequency

The mean collision frequency ν, number of collisions per second, between neutral particles of the atmosphere is a function of pressure, temperature, and molecular weight, as well as of an effective mean collision diameter σ. It is an important parameter for a number of important physical and chemical atmospheric processes, such as collisional quenching of excited species in the high atmosphere. The expression for the mean collision frequency is

$$\nu = 4\sigma^2 np(\pi/MR^*T)^{1/2}, \tag{10}$$

where n is the number density of air and σ the effective collision diameter for an air molecule, 3.65×10^{-10} m^2. The mean collision frequency as a function of altitude in the *U.S. Standard Atmosphere 1976* is shown in Fig. 7.

3.4 Mean Free Path

The mean free path L is equal to the ratio of mean particle speed V to the mean collision frequency ν,

$$L = V/\nu. \tag{11}$$

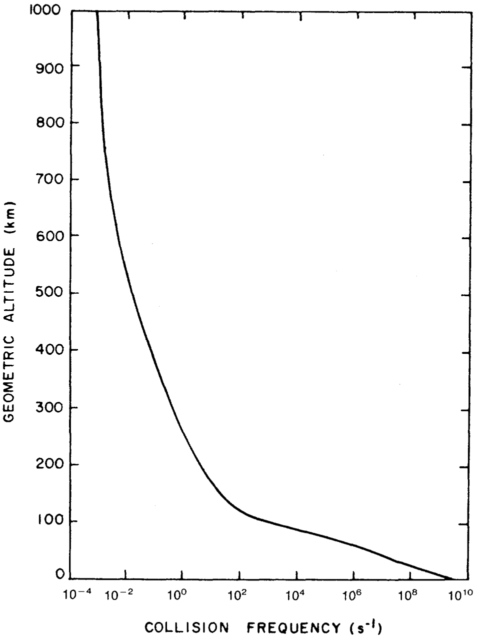

FIG. 7. Collision frequency as a function of geometric altitude (from the *U.S. Standard Atmosphere 1976*).

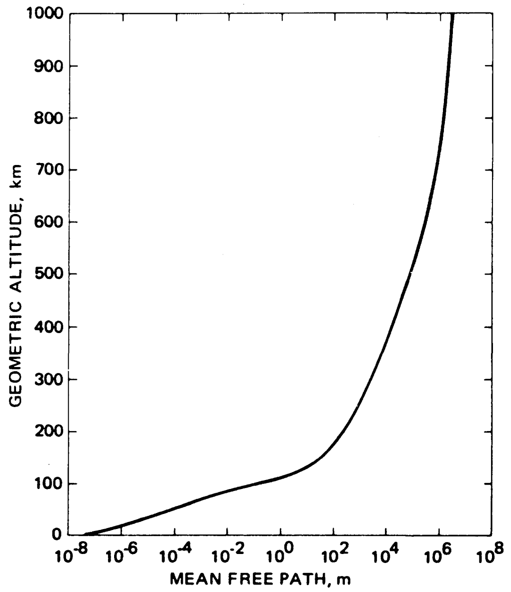

FIG. 8. Mean free path as a function of geometric altitude (from the *U.S. Standard Atmosphere 1976*).

This quantity represents the average travel distance between collisions of neutral particles in any direction for which the total change of number density is small over the mean-free-path length. It is an important quantity in the physical theory of gases. A plot of the mean free path as a function of altitude is given in Fig. 8. The Earth's exosphere is defined as the region above the surface where the mean free path is approximately equal to the local atmospheric scale height, and it occurs near 500 km. This altitude varies considerably with local time, season, and solar activity. Within the exosphere the concept of continuum fluid mechanics breaks down, and air molecules can assume ballistic trajectories or even escape the Earth's gravitational pull and flow outward into interplanetary space.

3.5 Mean Molecular Weight

The mean molecular weight M of a mixture of gases is defined by

$$M=\frac{\Sigma_i n_i M_i}{\Sigma_i n_i}, \tag{12}$$

where n_i and M_i are the number density and molecular weight, respectively, of the ith gas species and Σ_i indicates a sum over all species. Up to about 86-km altitude, turbulent mixing maintains the mean molecular weight at its sea-level value, $M=28.96$ kg/kmol. Above 86 km, diffusive separation and photodissociation of molecular species into atomic species occur, and thus the mean molecular weight decreases with altitude. The mean molecular weight as a function of altitude is shown in Fig. 9.

There are additional mean properties of the atmosphere, such as dynamic viscosity, kinematic viscosity, thermal conductivity, and others, that are not specified here but are given in the *U.S. Standard Atmosphere 1976.*

4. PHYSICAL AND CHEMICAL PROCESSES RESPONSIBLE FOR THE MEAN ATMOSPHERIC STRUCTURE

The physical and chemical processes responsible for establishing the mean structure of the atmosphere are many and varied depending upon the specific atmospheric region. Absorption of solar radiation by the Earth's atmosphere and surface provides the primary energy source, and it is balanced by infrared radiation to space and modulated by

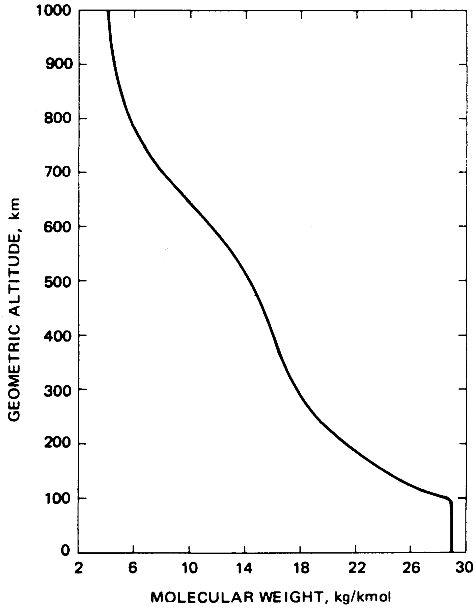

FIG. 9. Mean molecular weight as a function of altitude (from the *U.S. Standard Atmosphere 1976*).

global cloudiness. In this section the basic processes that establish the global mean atmospheric structure are briefly summarized. A more detailed description is given in the article ATMOSPHERIC PHYSICS.

4.1 Solar Radiative Output

The Sun is composed primarily of hydrogen and helium, along with smaller amounts of heavier elements such as iron, magnesium, aluminum, nickel, etc. The temperature in the interior of the Sun is believed to be as high as 2×10^7 K, maintained by a chain of nuclear reactions which convert hydrogen to helium. This energy is radiated to the upper surfaces of the Sun through a series of absorption and reemission processes. Most of the energy reaching the Earth's atmosphere originates from a relatively thin layer of the Sun of about 1000 km in thickness, called the photosphere. Radiation from the photosphere in the visible and infrared follows a blackbody spectrum at an effective surface temperature of about 6000 K as shown in Fig. 10. The visible and infrared portion of the solar spectrum is essentially a continuum emission. Absorption lines become increasingly superimposed on the continuum in the ultraviolet at wavelengths less than 300 nm where departures from the 6000 K blackbody spectrum occur. The longer ultraviolet wavelengths emanate from the Sun's chromosphere, which lies directly above the photosphere, and shorter extreme ultraviolet and x-ray radiation emanates from the Sun's corona, the tenuous outermost atmosphere that is very hot, on the order of several million degrees K. At wavelengths shorter than 140 nm, the emission by hot chromospheric and coronal lines begins to dominate the spectrum. Furthermore, these emission lines are highly variable depending upon the level of solar activity, as shown in Fig. 10. The UV portion of the solar spectrum varies on daily, 27-day solar rotation, and 11-yr sunspot cycles. Also at the extreme ultraviolet (EUV) and x-ray wavelengths, below 50 nm, there are strong enhancements during solar flares and other intense physical processes that occur in the Sun's atmosphere. The variable energetic solar emissions have a pronounced influence on the Earth's atmosphere above about 70 km.

Recent satellite measurements of the total solar radiative output show a variation over an 11-yr sunspot cycle, but it is quite small. The total radiative output of the Sun is about 0.09% larger during sunspot maximum than during sunspot minimum (Willson *et al.*, 1986). Two main components of total radiative output have been identified. Sunspots are

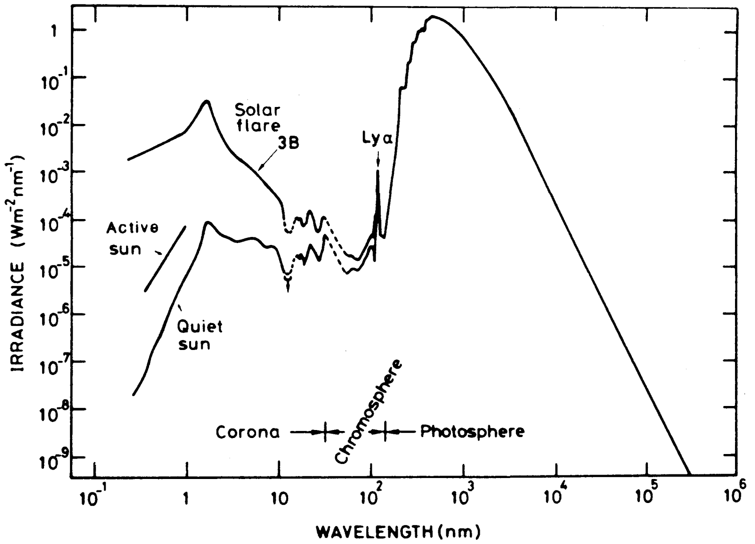

FIG. 10. Spectral distribution of the solar irradiance, and its variation with solar activity. The logarithmic wavelength scale emphasizes the contribution of x rays and extreme ultraviolet radiation (Brasseur and Solomon, 1986). (Copyright by Reidel Publishing Company.)

associated with a decrease in solar radiative output over a solar cycle but it is more than offset by an increase in total radiation from active region phenomena, such as from faculae and plages. Hence there is an increase in total radiative output from sunspot minimum to sunspot maximum. The overall impact of such a small variation in total radiative output on the weather in Earth's lower atmosphere is not well understood at the present time.

4.2 Penetration of Solar Radiation

The mixture of gases at the top of the atmosphere is exposed to the full electromagnetic spectrum of the Sun. As solar photons penetrate into the atmosphere, they undergo collisions with atmospheric molecules and are progressively absorbed and scattered. The probability of absorption by a molecule depends upon the nature of the molecule, its absorption cross section, and the wavelength of the incoming photon.

The Beer-Lambert law describes the absorption of a ray of incident intensity $I(\lambda)$ at wavelength λ, passing through an infinitesimally thin layer of an absorbing gas of thickness ds, as

$$dI(\lambda) = -\sigma_a(\lambda) n_a I(\lambda) ds, \tag{13}$$

where $\sigma_a(\lambda)$ is the effective absorption cross section at wavelength λ in cm^2 and n_a is the number density of the absorbing particle. Integrating Eq. (13) gives

$$I(\lambda) = I_0(\lambda) \exp\left(- \int_s \sigma_a n_a ds \right), \tag{14}$$

where the integral over s is along the path of penetrating radiation.

Solar radiation penetrates the atmosphere at an angle of incidence that depends upon the latitude ϕ, the solar declination angle δ, and the local solar hour angle t. The solar declination, which varies with seasons, is $\delta = \pm 23.5°$ for solstice conditions and 0° for equinox conditions. The local solar hour angle t is 0° for local noon and increases at a rate of 15°/hr in both directions from noon. The cosine of the local solar zenith angle (χ) is given by

$$\cos\chi = \cos\phi \cos\delta \cos t + \sin\phi \sin\delta. \tag{15}$$

For solar zenith angles less than about 70° where spherical and refraction effects are neglected,

$$ds = dz \sec\chi, \tag{16}$$

where ds is the distance along a slant path and dz is an increment in altitude.

If we assume an isothermal (constant temperature) atmosphere, the concentration $n(z)$ varies exponentially with altitude according to a scale height H:

$$n_a(z) = n_a(z_0) \exp[-(z - z_0)/H], \tag{17}$$

where $n_a(z_0)$ is the number density of species n_a at a reference level z_0; then the variation of monochromatic solar radiation with altitude caused by the absorbing gas becomes

$$I(z,\lambda) = I_0(\lambda) \exp[-\sec(\chi) \sigma_a(\lambda) n_a(z) H], \tag{18}$$

where $I_0(\lambda)$ is the intensity at the top of the atmosphere, and $I(z,\lambda)$ is the intensity penetrating down to altitude z. This equation describes the penetration of monochromatic solar radiation of wavelength λ into an atmosphere at a zenith angle χ, with an absorbing species a providing the attenuation. This theoretical derivation was first done by Sidney Chapman in 1931, and it conveniently explains the behavior of layers of ionization in the Earth's ionosphere or photodissociation or photoabsorption in the atmosphere. For multiple species the quantity in the exponential must be summed over all absorbing species a,

$$I(z,\lambda) = I_0(\lambda) \times \exp\left(-\sec\chi \sum_a \sigma_a(\lambda) n_a(z) H_a \right). \tag{19}$$

The optical thickness τ for vertical incidence from space down to an altitude z is defined as

$$\tau(\lambda,z) = \int_z^\infty \sigma_a(\lambda) n_a(z) dz, \tag{20}$$

and the corresponding atmospheric transmission $T(\lambda,z)$ is defined as

$$T(\lambda,z)=\exp[-\tau(\lambda,z)]. \qquad (21)$$

The major absorbing constituents of solar radiation in the atmosphere are N_2, O, O_2, and O_3. The principal absorption of these species occurs at ultraviolet wavelengths with absorption below 127 nm for N_2, 91.1 nm for O, 242.2 nm for O_2, and 1.14 μm for O_3. The depth of penetration, or optical depth, of vertically incident solar radiation as a function of wavelength is shown in Fig. 11. It is the depth at which the incident solar radiation is attenuated by the factor $1/e$. For wavelengths less than 100 nm, radiation is almost completely absorbed by O_2, O, and N_2 above 100-km altitude. Only x-ray radiation at wavelengths less than 1 nm can penetrate below 100 km into the middle atmosphere where it can ionize and dissociate the major species N_2 and O_2. Because these x rays are highly variable and energetic enough to ionize atmospheric species, they are responsible for certain ionospheric perturbations, such as during solar flares. For wavelengths greater than 100 nm, solar ultraviolet radiation can penetrate into the middle atmosphere and photodissociate certain atmospheric molecules. In particular, the solar Lyman-α line at 121.6 nm is very intense and is situated in an optical window where the O_2 cross section is low ($\sim 10^{-21}$ cm^2). Molecular oxygen is the major absorbing species from low wavelengths to near 200 nm. For wavelengths longer than 200 nm, ozone is the major absorber in the lower middle atmosphere. Although ozone absorbs weakly in the visible and even in the infrared, the greater part of the solar photons at wavelengths longer than 310 nm reaches the surface. Solar radiative transfer also includes scattering from gases (Rayleigh scattering), aerosols, and clouds. These affect the planetary albedo and are important to climate.

4.3 Aurora

The solar wind, which is a charged particle (plasma) outflow from the Sun, is another form by which energy is transferred from the Sun to the Earth's upper atmosphere, primarily the thermosphere and ionosphere. Because the solar wind is a plasma (an ionized medium where currents can flow), it is guided by solar magnetic fields that extend outward from the Sun. The electrically charged solar wind is mainly deflected by the

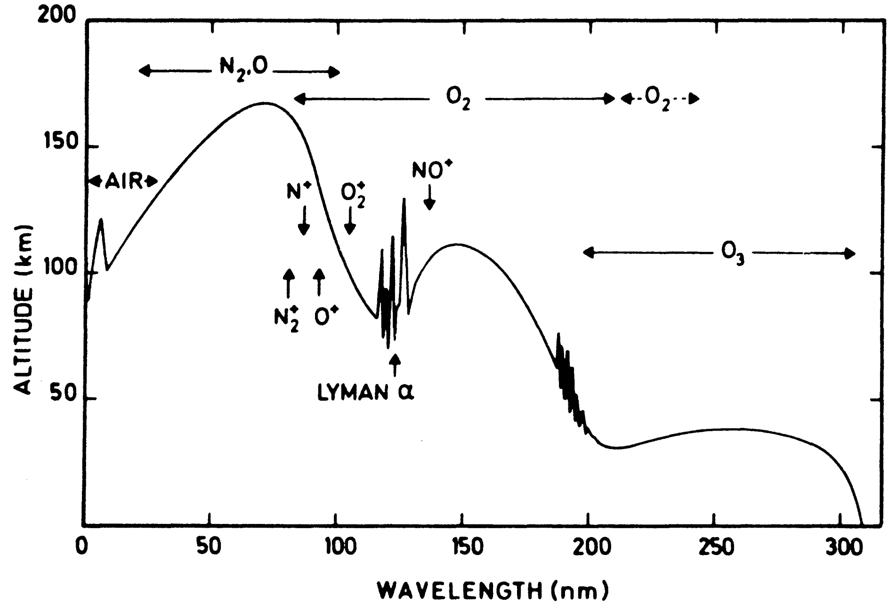

FIG. 11. Depth of penetration of solar radiation as a function of wavelength. Altitudes correspond to an attenuation of $1/e$. The principal absorbers and ionization limits are also indicated (Herzberg, 1965). (Copyright by Prentice-Hall Publishers.)

Earth's own magnetic field, and the bulk of the solar-wind plasma flows around the Earth's magnetosphere into interplanetary space. When the direction of the solar-wind magnetic field is southward, however, complex plasma processes allow a much more efficient coupling with the Earth's magnetic field. Under these conditions a transfer of solar-wind energy is allowed into the Earth's magnetosphere. The solar-wind particles are channeled by the Earth's magnetic field into the high-latitude ionosphere in the magnetic polar caps. The stream of energetic charged particles that flows into the thermosphere and ionosphere collides with the neutral gases and ionizes them, dissociates molecular species, and excites atoms and molecules to higher energy states. These excited atoms and molecules then relax back to their ground states by the emission of photons. The atmospheric glow from atoms above about 100-km altitude is known as the Aurora Borealis in the Northern Hemisphere and the Aurora Australis in the Southern Hemisphere. The energy transferred from the solar wind in the aurora is highly variable and greatly enhanced during geomagnetic storms and substorms. The power from aurora particle precipitation and the Joule dissipation of ionospheric electrical currents associated with the aurora can vary by about 2 orders of magnitude: 10^{10} W for very quiet geomagnetic conditions, 10^{11} W for moderate geomagnetic conditions, and 10^{12} W for brief periods during geomagnetic storms. The bulk of the energy and momentum transfer to the atmosphere in the aurora occurs in the thermosphere and ionosphere, and it is sufficiently large to cause large variations in the thermosphere and ionosphere basic temperature, composition, and wind structure during auroral events.

4.4 Radiative Cooling

The solar energy inputs, described in the previous sections, are balanced by infrared radiative cooling to space, primarily by the 15-μm band of CO_2, but also to a limited extent by the 9.6-μm band of O_3 and the 80-μm band of H_2O in the middle atmosphere and the 6.3-μm band of H_2O in the troposphere. Terrestrial radiation in the infrared region at wavelengths longer than 4 μm dominates the cooling to space. The thermal structure of the atmosphere depends upon an equilibrium between these heating and cooling processes as well as other phenomena, such as production of latent heat in the troposphere and the dissipation of atmospheric waves in the mesosphere and thermosphere. A detailed study of the radiative transfer in the Earth's atmosphere is quite complicated and requires a complete knowledge of the important bands and a compilation of a large body of infrared spectroscopic data. Infrared radiation is discussed in detail in the article on ATMOSPHERIC PHYSICS.

In recent years it has become evident that other radiatively active trace gases, such as methane (CH_4), nitrous oxide (N_2O), and the chlorofluorocarbons, released by anthropogenic activity can interfere with the present-day radiative balance of the atmosphere. Furthermore, the projected rate of increase of these gases into the 21st century indicates that they will become increasingly more important in establishing the mean structure of the entire atmosphere. A list of some of the important infrared atmospheric bands in the Earth's atmosphere is given in Table 4.

4.5 Global Average Heating and Cooling Rates

A calculation of the global average radiative heating- and cooling-rate components in the atmosphere from the surface to 100 km is shown in Fig. 12. The most important radiatively active gases in the atmosphere are O_2, O_3, CO_2, and H_2O vapor. Absorption of solar UV radiation by O_2 and O_3 is responsible for strong radiative heating in the lower thermosphere and in the region of the stratopause. This is balanced, in part, by infrared cooling by CO_2 and to a lesser extent by O_3. Infrared emission in the troposphere, due mainly to H_2O vapor, is partially offset by absorption of solar radiation by H_2O vapor in the near infrared. These are the main heating and cooling mechanisms responsible for the mean atmosphere structure to an altitude of about 100 km. In equilibrium, the differences between radiative heating and cooling rates are balanced by other physical processes such as turbulent transport or release of latent heat.

Above 100 km, the physical and chemical processes responsible for the mean atmospheric structure change dramatically. Virtually all solar photons at wavelengths less than

Table 4. Important infrared atmospheric bands for maintaining the structure of the Earth's atmosphere (World Meteorological Organization, 1982).

Trace gas	Band	Band center (cm^{-1})	Band intensity ($cm^{-2}\ atm^{-1}$) (296 K)
CO_2	ν_2 (15 μm)	667	≈220
CO_2	ν_3 (4.3 μ)	2348	≈2440
O_3	ν_3 (9.6 μm)	1041	312
H_2O	rotation	0–1650	1306
H_2O	ν_2 (6.3 μm)	640–2800	257
CH_4	ν_4 (7.66 μm)	1306	134
N_2O	ν_1 (7.78 μm)	1285	218
N_2O	ν_2 (17 μm)	589	24
$CFCl_3$	ν_4 (11.8 μm)	846	1813
$CFCl_3$	$\nu_1+2\nu_2$	1085, 2144	679
CF_2Cl_2	ν_8 (10.9 μm)	915	1161
CF_2Cl_2	ν_1 (9.13 μm)	1095	1141
CF_2Cl_2	ν_6 (8.68 μm)	1152	777

200 nm are absorbed by the major constituents of the thermosphere, O, O_2, and N_2. The infrared cooling mechanism operating in the thermosphere (5.3-μm emissions from NO, 15-μm emissions from CO_2, and 63-μm emissions from O) are relatively weak and not sufficient to balance the heating rates to maintain radiative equilibrium. The thermosphere is therefore cooled by downward molecular heat conduction above about 140 km and by downward eddy (turbulent) heat conduction to the vicinity of the mesopause where ir cooling becomes sufficiently large to radiate the excess energy to space. The cooling by molecular thermal conduction in the vertical is given by

$$C_m=\frac{1}{\rho C_p}\frac{\partial}{\partial z}\left(K_m\frac{\partial T}{\partial z}\right), \tag{22}$$

where z is the altitude, T is the temperature, K_m is the molecular thermal conductivity coefficient, ρ is the density, and C_p is the specific heat at a constant pressure. Downward thermal conduction implies that the temperature increases with altitude, giving a positive temperature gradient. Therefore, temperature increases with altitude throughout the thermosphere. The molecular thermal conductivity coefficient becomes so large in the upper thermosphere and the heating rate so small, because of the very rarefied atmosphere, that the temperature becomes isothermal at a value called the exospheric temperature.

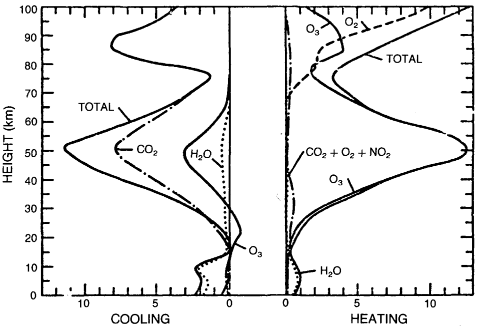

FIG. 12. Components of the global average radiative heating and cooling rates from 0 to 100 km (K/day) (London, 1980).

In the lower thermosphere and upper mesosphere, eddy heat conduction caused by turbulent mixing is an important heat transport mechanism. The cooling by eddy thermal conduction in the vertical is given by

$$C_e=-\frac{1}{\rho C_p}\frac{\partial}{\partial z}\left[K_e\left(\frac{\partial T}{\partial z}+\frac{g}{C_p}\right)\right], \tag{23}$$

where K_e is the eddy thermal conduction coefficient and g is gravity.

5. LATITUDINAL STRUCTURE

The basic vertical structure of the atmosphere was described in the previous sections. The next most important description of structure is its variation with latitude, since there are large seasonal variations in atmospheric properties.

The latitudinal distribution of atmospheric structure is established primarily by the latitudinal distribution of the net heating rate. The net heating rate is the difference between heating rates caused by absorption of solar radiation and the infrared cooling rate from the terrestrial atmosphere. A calculation of the zonally averaged net heating rate, as a function of altitude and latitude for solstice conditions, is shown in Fig. 13. There is net heating in the middle-latitude summer hemisphere and net cooling in the middle-atmosphere winter hemisphere. If the atmosphere were in radiative equilibrium, the temperature structure of the atmosphere would reflect this net heating pattern. The zonally averaged temperature structure of the atmosphere from the ground to 100 km as a function of latitude for solstice conditions is shown in Fig. 14. The bulk of the middle atmosphere is in solar radiative equilibrium, but there are certain atmospheric regions, such as the lower stratosphere and the upper mesosphere, that are far from radiative equilibrium. In these regions the temperature pattern differs considerably from the net heating pattern.

In the troposphere, the maximum temperatures occur in the summer hemisphere tropics with a general decrease in temperature toward both poles, the winter hemisphere being much colder than the summer hemisphere. This pattern follows the net heating rate structure in the troposphere. In the lower stratosphere, between 15 and 30 km, the latitudinal temperature structure reverses. Now the equatorial lower stratosphere is colder than either the summer or winter polar regions. The cold equatorial lower stratosphere occurs because of dynamical effects. The formation of clouds and precipitation in tropical regions is accompanied by the release of latent heat of vaporization providing the energy needed to drive upward motions near the tropopause. Upward motions cool adiabatically, and in the tropical regions above the clouds it is sufficiently strong to overcome radiational heating, thereby maintaining the cold tropical tropopause. Sinking motions in the polar regions produce adiabatic warming.

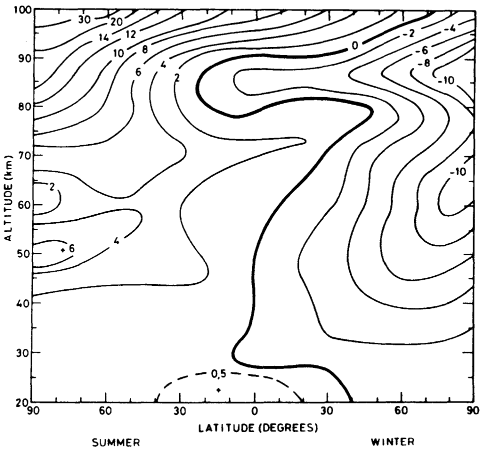

FIG. 13. Total net radiative heating rate associated with the absorption of ultraviolet radiation by ozone and molecular oxygen, and cooling by carbon dioxide (K/day) (London, 1980).

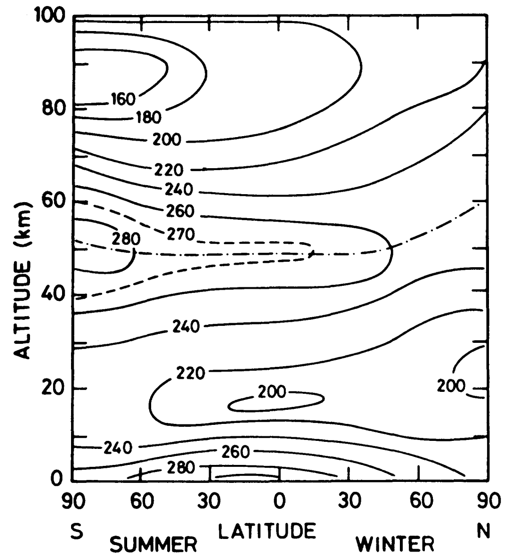

FIG. 14. Latitudinal temperature structure of the atmosphere from 0 to 100 km. The dash-dotted curve represents the height of the stratopause (London, 1980).

The large radiative heating rates in the summer hemisphere stratosphere and lower mesosphere are responsible for the temperature structure of these regions. These regions of the atmosphere are in near radiative equilibrium and they reflect the pattern of net heating. The temperature structure of the upper mesosphere, however, is opposite to what one would expect from the heating rates shown in Fig. 13. The summer upper mesosphere is cold, where the net heating rate is largest, and the winter upper mesosphere is warm where the net heating rate is negative, indicating strong cooling. The source of energy for maintaining the reverse latitudinal temperature gradient from what one would expect from radiative equilibrium appears to be momentum transfer from breaking gravity waves that are sufficiently large to drive a reverse circulation. The upper mesosphere thus acts much like a refrigerator, where momentum transfer from breaking gravity waves drives a circulation that results in the summer mesopause being colder than the winter mesopause.

The mean zonal wind distribution of the atmosphere from the ground to 100 km is shown in Fig. 15. In the troposphere the mean winds are directed eastward (westerly, in meteorological terms) with jets appearing at midlatitudes. The winter jet is about a factor of 2 larger than the summer hemisphere jet. In the middle atmosphere, the zonal winds are eastward (westerly) in the winter hemisphere and westward (easterly) in the summer hemisphere.

Above 100 km in the thermosphere, the basic latitudinal structure displays considerable variability because of the high variability associated with the EUV component of the Sun's radiation that is absorbed in this region. Large amounts of solar-wind energy are also deposited in the high-latitude thermosphere through auroral processes, sometimes locally exceeding the absorbed solar radiation. This makes the thermosphere a dynamically active region with large variations about its global mean state.

The latitudinal variations of temperature and mean mass at 300 km for equinox and solstice conditions are shown in Fig. 16. The zonally averaged temperature and mean mass both have maximum values in the summer hemisphere and minimum values in the winter hemisphere during solstice. At equinox the temperature and mean mass latitudinal variations are small. The enhancements at high latitude are caused by a small auroral heat source for quiet geomagnetic activity. The mean mass varies considerably during solstice because the composition of the atmo-

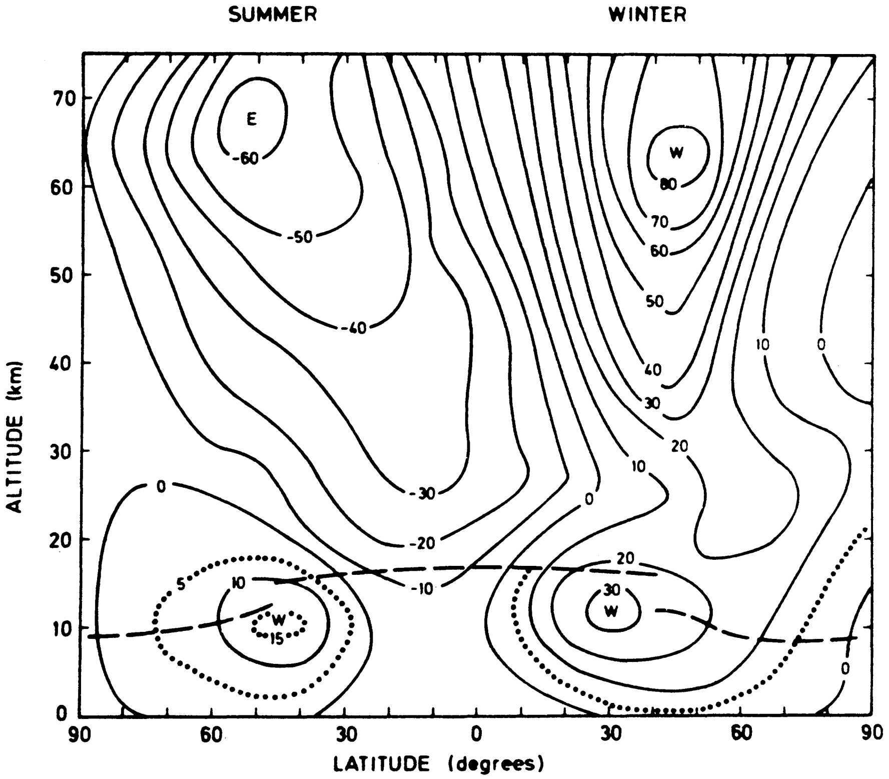

FIG. 15. Mean zonal wind distribution in the middle atmosphere. The contours represent zonal wind speed in m/s. Positive values are eastward (westerly in meteorological terms) and negative values are westward (easterly) (Murgatroyd, 1969). (Copyright by the Royal Meteorological Society.)

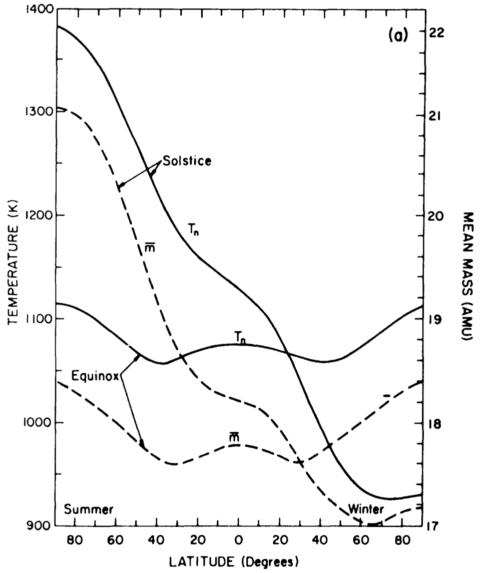

FIG. 16. Latitudinal distribution of the neutral gas temperature and mean mass at an altitude of 300 km in the thermosphere. Equinox and solstice conditions are shown (Roble, 1977).

sphere also varies. Atomic oxygen is the main species at this altitude and it has only a small latitudinal variation; however, both N_2 and 0_2 contribute to the mean mass. In the summer hemisphere the molecular species such as N_2 and 0_2 are enhanced whereas they are suppressed in the winter hemisphere. Because these species are heavier than atomic oxygen the enhancement causes the mean mass to increase to 22 in the summer hemisphere whereas in the winter hemisphere it is only 17.

6. ATMOSPHERIC RESPONSE TO SOLAR VARIABILITY

Solar variability affects each of the atmospheric regions in a different manner. The largest responses occur in the upper atmosphere and the effects become progressively smaller at lower altitudes.

6.1 Thermosphere Response to Solar Variability

The solar EUV and UV radiation at wavelengths less than 200 nm that affect the thermosphere cannot be measured from the ground because it is all absorbed in the upper atmosphere. However, it was shown about 10 years ago that the solar EUV and UV output is closely related to the magnitude of the solar decimeter radio emission at a wavelength of 10.7 cm, which can be measured from the ground with radio telescopes. Since the thermosphere responds dramatically to the solar heat source, the global mean temperature of the thermosphere can be expressed as a function of the solar radio emission. The notation for this function is $F_{10.7}$. During solar minimum the Sun is relatively quiet, and solar $F_{10.7}$ values are typically 80×10^{-22} W/m^2 Hz. Near solar maximum, values of $F_{10.7}$ are 160×10^{-22} W/m^2 Hz or greater with the largest value observed near 400×10^{-22} W/m^2 Hz. The magnitude of the solar EUV output roughly doubles between solar minimum and maximum, and there is also considerable day-to-day variation. Figure 17 illustrates how the global mean temperature profile of the thermosphere responds to the solar $F_{10.7}$ index. During the solar minimum typical exospheric temperatures are 600 K, increasing to 1200 K near the solar maximum. In addition to the temperature variations, the entire thermosphere expands outward with increasing solar heating. For example, the atmosphere density at 500 km can vary by almost 3 orders of magnitude over a solar cy-

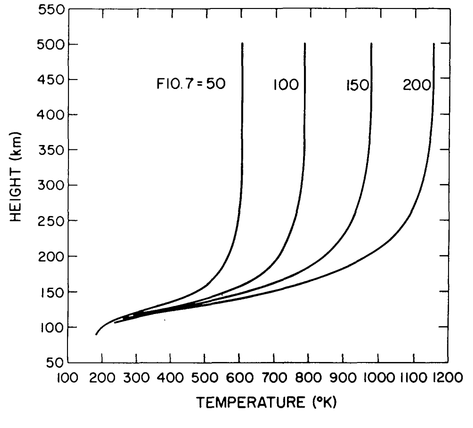

FIG. 17. Global mean neutral gas temperature in the thermosphere as a function of the solar decimeter radio emission at 10.7-cm wavelength ($F_{10.7}$). The solar decimeter radio emission $F_{10.7}$ ($\times 10^{-22}$ W/m^2 Hz) is an indicator of the solar extreme ultraviolet radiation output (Roble, 1977).

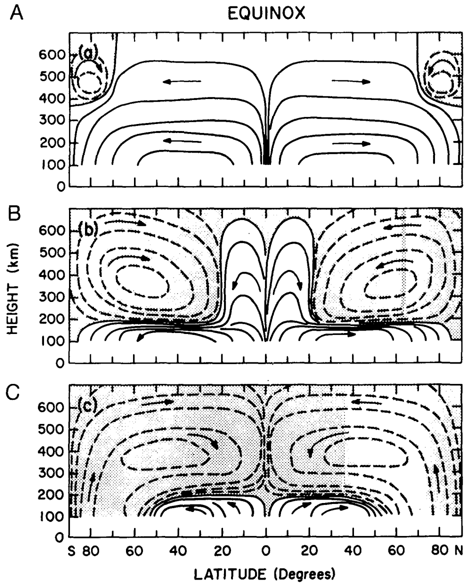

FIG. 18. Schematic of the zonal mean meridional circulation in the Earth's thermosphere during equinox conditions for various levels of auroral activity: (a) extremely quiet auroral activity (10^{10} W), (b) average auroral activity (10^{11} W), and (c) auroral storms (10^{12} W). The contours illustrate the mass flow and the arrows indicate the direction of the motion. Stippling indicates regions of reverse circulation (Roble, 1977).

cle, and this increase in thermospheric density can have an important influence on the drag experienced by orbiting satellites.

The circulation during equinox is shown in Fig. 18, where the mass flow is illustrated schematically, indicating the cellular motion of the thermosphere between 80 and 500 km. Figure 18(a) shows the circulation during very quiet geomagnetic conditions: upward motion occurs over the equatorial subsolar point with a poleward flow in both hemispheres to high latitudes where sinking motion occurs. The small reverse circulation at high latitudes is caused by a small auroral heat source. During average geomagnetic activity the size of the equatorial circulation is larger, as shown in Fig. 18(b). Below about 150 km the strong solar UV heating still maintains a poleward flow; however, above that altitude the flow is equatorward to about 20° latitude. During sizable geomagnetic storms, the equatorward circulation increases greatly, extending right down to the equator, as shown in Fig. 18(c). The circulation below 150 km is also affected by the auroral heating. Thus, it is evident that the mean motions within the thermosphere are in a constant state of agitation, depending on the magnitude of the auroral heat source that varies daily.

The situation is similar during solstice. There is a surplus of energy in the summer hemisphere and a deficit in the winter hemisphere, by comparison with the global mean values. Under geomagnetically quiet conditions, the asymmetry in solar heating drives a summer-to-winter circulation as shown in Fig. 19(a). In Fig. 19(b), the auroral heat source reinforces the solar-driven summer-to-winter circulation in the summer hemisphere but forces a reverse circulation in the winter hemisphere. The two cells converge in the midlatitude winter hemisphere. Below 150 km the summer-to-winter circulation is maintained at all latitudes. As the magnitude of the auroral heat source increases during geomagnetic storms the circulation is equatorward in both hemispheres above 300 km with an asymmetry at lower altitudes. Thus even during solstice conditions the auroral heat source has a strong influence in controlling the circulation and basic structure of the thermosphere (Roble, 1977).

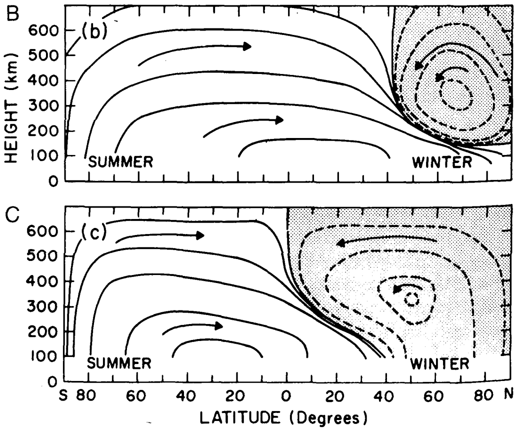

FIG. 19. Same as Fig. 18 but for solstice conditions (Roble,1977).

6.2 Middle-Atmosphere Response to Solar Variability

Solar UV radiation affects a variety of physical and chemical processes in the middle atmosphere. The response of ozone to solar UV variability has been detected by satellites. Near 70 km, it is found that ozone is immediately depleted by short-term increases in solar UV radiation. An apparent mechanism for the ozone depletion is an increase in odd hydrogen production as a result of an increase in the photodissociation of H_2O vapor by solar Lyman-α radiation. The odd hydrogen, defined as the sum of chemically active hydrogen species ($H+OH+HO_2$) catalytically destroys ozone. The response of mesospheric temperature to short-term solar UV variability has also been identified in data sets. There is an approximate 0.3 K increase for a 1% increase in solar UV radiation centered near 205 nm with a small phase lag (Keating *et al.*, 1987).

Temperature and ozone are oppositely correlated throughout the lower mesosphere and upper stratosphere. Temperature-sensitive chemical rate coefficients that control the amount of ozone present at any time are responsible for this effect; as temperature increases ozone decreases and vice versa. Ozone can also be destroyed by an increased photodissociation by solar UV radiation. In the stratosphere, ozone responds directly to changes in solar UV radiation with a phase lag of 0.5 days. Deeper in the atmosphere near 20 km it responds directly but it has a 2-day phase lag. Zonally averaged models of the middle atmosphere have also been used to demonstrate the response of the middle-atmosphere chemistry and dynamics to solar variability over the 11-yr sunspot cycle (Garcia *et al.*, 1984).

6.3 Lower-Atmosphere Response to Solar Variability

The lower atmosphere is a highly complex nonlinear system that is subject to a large component of random variability due to its internal dynamics. Even under conditions of constant external forcing, weather and climate will vary. Weather variability arises primarily as a result of instabilities of the mean flow of the atmosphere, and it is determined by the day-to-day evolution of the large-scale synoptic pressure systems that dominate the atmospheric circulation. Climate is simply the statistical average result of averaging the weather over a period of time.

There have been many attempts to correlate the weather with various properties of the Sun. Most correlations have involved sunspots, but others have considered solar-wind magnetic-sector boundary crossings, flares, etc. Generally, these correlations have a tendency to break down after a period of time. But recently, it has been discovered that there is a strong correlation between the solar cycle and high-latitude stratospheric temperature when the data are categorized according to the east or west phase of the quasibiennial oscillation (QBO) of the winds in the equatorial stratosphere (Labitzke and van Loon, 1988). When the QBO winds are westward the polar data are positively correlated with the sunspot cycle while those at middle and low latitudes are negatively correlated. The converse holds true for the eastward wind phase of the QBO. These effects have been found to hold throughout the troposphere and even into the mesosphere. No physical mechanism explaining the observed correlation has yet been found.

The troposphere has a large natural variability that can exist without any change in external forcing. The energy forcing associated with known solar variability is too small, by about 3 orders of magnitude, to perturb the enormous energy of the troposphere. Because of this, Sun-weather relationships have usually invoked some trigger mechanism that somehow taps the basic energy of the flow and forces an atmospheric response to solar activity.

There appears to be more evidence suggesting possible Sun-climate relationships (Reid and Gage, 1988). Climate energy-balance models all tend to show that the sensitivity of the global climate response to solar variations is an important function of the period of forcing, because of couplings between the ocean and atmosphere. The thermal lag in the models suggests that any climate response to solar irradiance variations on an 11-yr sunspot cycle is small but the response increases on longer time scales. A more effective response is obtained on the timescale of the solar Gleisberg cycle of sunspot activity ($\sim$80–90 yr) and from simulations of the Maunder minimum, an 80-yr period of little or no sunspots from 1645 to 1715 AD that corresponded with the little ice age in Europe and elsewhere.

7. ELECTRICAL STRUCTURE OF THE ATMOSPHERE

The atmosphere is an electrically conducting medium because of the presence of positive and negative ions and electrons. The principal sources of ionization in the atmosphere include

1. ionization by galactic cosmic rays that bombard the atmosphere,
2. photoionization by solar x rays and solar EUV radiation at wavelengths less than about 130 nm,
3. ionization by energetic electrons and protons that bombard the Earth in the aurora,
4. radiation from radioactive substances in soil, and
5. radioactive gases produced by the decay of 4.

In the atmosphere below about 80 km, the net production rate of small ions and electrons, q, is balanced by complex ion chemistry and can be approximated by assuming chemical equilibrium,

$$q = \alpha n_{\pm}^2, \qquad (24)$$

where α is the volume recombination coefficient and $n_{\pm}$ represents the number density of equal positive and negative ions, respectively. The number density of small positive and negative ions as a function of altitude at various latitudes is shown in Fig. 20. Galactic cosmic-ray ionization is the main ionization source for the production of the ion density profiles. Because the galactic cosmic-ray ions are charged they are influenced by the Earth's magnetic field to an extent that lower-energy cosmic rays are predominantly guided into high magnetic latitudes and only the more energetic cosmic rays penetrate to low and equatorial latitudes. As a result, there is a significant latitudinal variation in the vertical profile shapes.

The electrical conductivity σ of air is defined as

$$\sigma = \sum_i n_i e_i k_i, \qquad (25)$$

where n_i is the number of the ith ion species present, and e_i and k_i are the charge and mobility of the ith ion species, respectively. Two classes of ions are normally present in the atmosphere, small ions of charged molecular species and large, heavier ions of charged aerosols, cloud particles, dust, etc. Small ions, because of the low mass, have higher mobilities than larger ions. The mobility of an ion is its velocity per unit electric-field strength. Near the Earth's surface, $n^+ \cong 6 \times 10^8$ m^{-3}, $n^- \sim 5 \times 10^8$ m^{-3} (the difference due to the electrode effect, a charge separation process near the Earth's surface that resembles a similar process near an electrode of an electronic device), $k^+ \sim 1.3 \times 10^{-4}$ m^2/V s, and $k^- \sim 1.6 \times 10^{-4}$ m^2/V s, yielding a conductivity of about $2.5 \times 10^{-14}/\Omega$ m. The electrical conductivity increases rapidly with altitude, as shown in Fig. 21, for the following reasons:

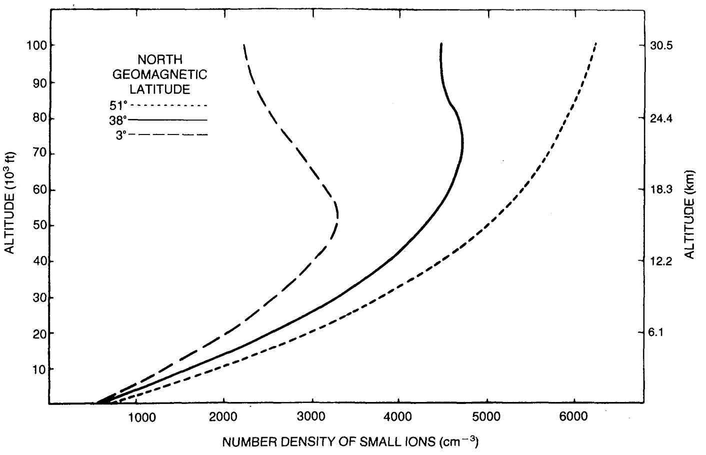

FIG. 20. Number density of small positive or negative ions as a function of altitude computed assuming equilibrium with the galactic cosmic-ray radiation. The variation with latitude illustrates the shielding effect of the Earth's magnetic field (from *Handbook of Geophysics and the Space Environment*, 1985).

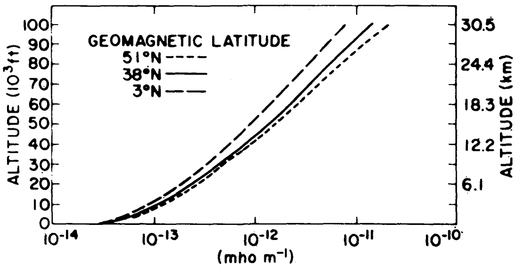

FIG. 21. Total electrical conductivity as a function of altitude for various latitudes (from *Handbook of Geophysics and the Space Environment*, 1985).

1. the mobility of ions increases as the neutral number density decreases,
2. the presence of numerous large aerosols lowers the conductivity of air near the ground, and
3. galactic cosmic-ray ionization, photoionization, and energetic particle ionization increase with altitude.

Investigators in the 18th century recognized that a weak electrification exists as a permanent property of the atmosphere even during fair weather. The Earth's surface was found to be charged negatively and the air charged positively, with a vertical electric field of about 100 V/m existing in the atmosphere near the surface in fair weather. The search for the cause of this electrification was a major investigation for many years. Because the air is electrically conducting, a continuous charging source had to exist. In the 1920s, the British physicist C. T. R. Wilson suggested that currents flowing from thunderstorms were the charging source responsible for maintaining the fair-weather electric field. This hypothesis was based on his observations that beneath a thundercloud negative charge is carried to the Earth's surface and above the thundercloud positive charge flows upward toward the ionosphere. Within the highly conducting ionosphere, the charge is rapidly distributed around the globe, and then it flows down to Earth through the atmosphere in fair-weather regions between thunderstorms as shown in Fig. 22. In the figure, region 0 represents the planetary boundary layer in the troposphere; region 1, the atmospheric region that includes thunderstorms; and region 2, the stratosphere and mesosphere. In the upper portion of the figure, current flows along magnetic-field lines in the ionosphere and magnetosphere. This global circuit can be compared to a giant leaky

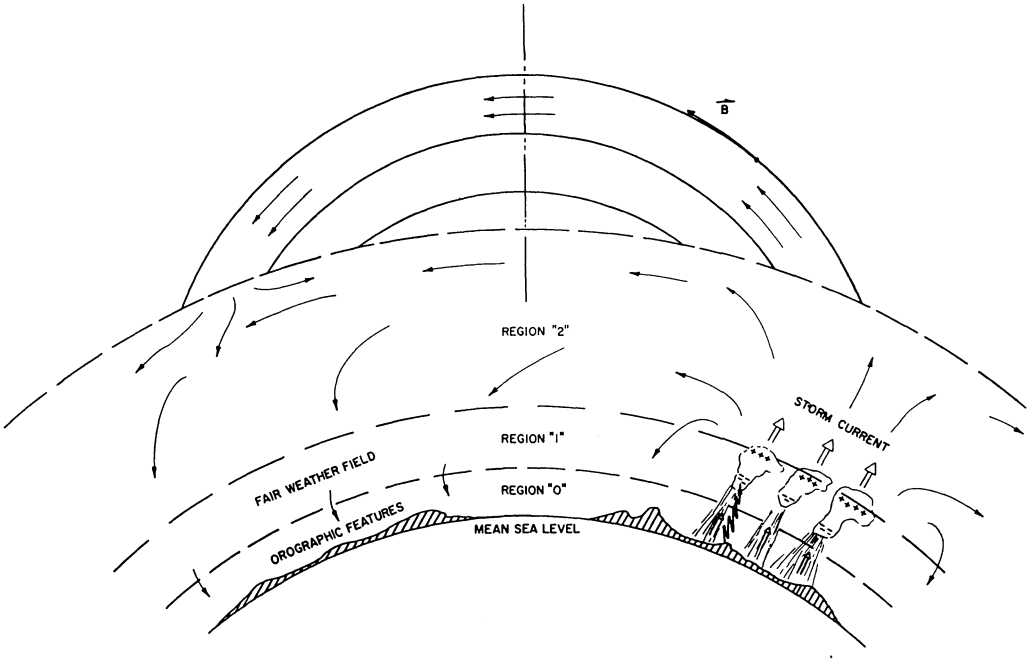

FIG. 22. Schematic of the Earth's global electric circuit (Hays and Roble, 1979). (Copyright by American Geophysical Union.)

spherical capacitor with the highly conducting Earth's surface and the ionosphere representing the plates, the weakly conducting lower atmosphere representing the dielectric in between, and thunderstorms maintaining the charge separation.

The simplest thunderstorm model assumes a quasistatic dipole charge distribution, with positive charge embedded in the cloud top and the negative charge in the cloud bottom. The dipole is immersed in an atmosphere where the electrical conductivity increases exponentially with altitude from the surface to the ionosphere. The 20–100 C of charge that are separated in a thunderstorm maintain large potential differences within spatial regions of the storm. The average current flowing from a thundercloud into the global circuit is typically 1–2 A. Since there are about 1000 thunderstorms operating globally at any given time, about 1–2 kA of current flows continuously into the global circuit. Even though the columnar resistance of the atmosphere is high ($1\times10^{+17}$ Ω/m^2), the columns are coupled in a parallel circuit to give a global resistance of about 250 Ω. Thus, a ground-to-ionosphere potential difference of 250 000 V is maintained by global thunderstorm activity. This potential difference is uniform around the globe because the conductivities of the ionosphere and ground are so high that currents flow freely in these regions to reduce horizontal potential differences.

7.1 Air-Earth Conduction Current

As a result of the potential difference between the Earth's surface and ionosphere, a current is constantly flowing to the Earth's surface. This current is called the fair-weather air-Earth conduction current and is typically $(1\text{–}2)\times10^{-12}$ A/m^2. Since the columnar resistance that controls this current varies depending upon the Earth's orography, higher current densities flow into mountainous areas compared with sea level. There is also a diurnal variation of the surface-ionosphere potential difference and air-Earth current density because of the diurnal variation of global thunderstorm activity. Maximum potential differences and air-Earth current densities occur near 1900 UT when the Sun is heating the South American and African continents and producing copious amounts of thunderstorms. The minimum values occur near 0400 UT when the Sun is heating the Asian sector where thunderstorm activity is lower. A typical diurnal variation is about 10%–20%. The air-Earth current in fair weather is constant with altitude.

7.2 Electric Field

In fair-weather areas the horizontal components of the electric field are small compared with the vertical component. Thus, the atmospheric electric field can be defined as

$$E = -dV/dz\,, \tag{26}$$

where V is the electric potential and z is the altitude. Since the ionosphere is charged positively with respect to the Earth's surface, the electric field is directed downward. Because the air-Earth current is constant with altitude and the electrical conductivity increases exponentially with altitude, the electric field, by Ohm's law, must decrease exponentially with altitude as shown in Fig. 23. Assuming an exponential increase in electrical conductivity with altitude, the basic equations for the atmospheric electric field can be expressed as

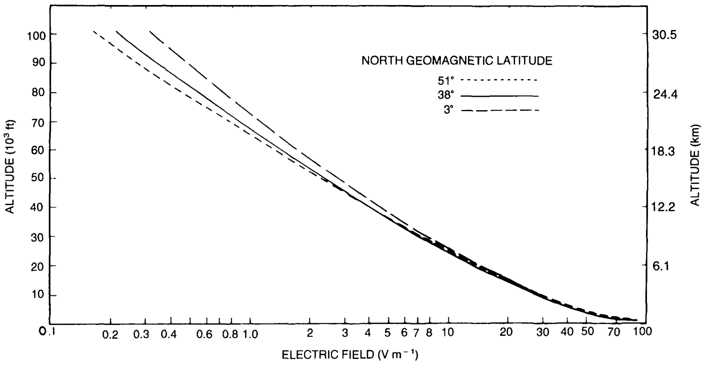

FIG. 23. Vertical electric field as a function of altitude calculated from the electrical conductivity shown in Fig. 21 using Ohm's law and an assumed vertical conduction current of 2.7×10^{-12} A/m^2 (from Jursa, 1985).

$$\sigma(z)=\sigma_0 \exp(2kz), \tag{27}$$

where σ is the electrical conductivity, k is the mobility, and z is altitude. In fair weather there is no charge source and the potential equation is

$$\frac{d^2V}{dz^2}+2k\frac{dV}{dz}=0. \tag{28}$$

Assuming that the potential at the Earth's surface is zero and that the total potential difference between the top of the atmosphere (height H) and the Earth's surface is V_∞, the solution of Eq. (28) yields

$$E=\frac{V_\infty 2k \exp(-2kz)}{1-\exp(-2kH)}=E_0 \exp(-2kz), \tag{29}$$

where E_0 is about 130 V/m at the Earth's surface.

7.3 Space Charge

The space charge density ρ is related to the electric field by

$$\frac{dE}{dz}=-4\pi\rho. \tag{30}$$

7.4 Other Aspects of Global Atmospheric Electricity

The basic atmospheric electric structure in fair weather is generally described by conduction currents flowing in accordance with Ohm's law. There are, however, other sources of current such as

1. convection current, where movement of air carrying charge produces a transfer of charge;
2. displacement current, caused by changes of the electric field with time, $j=\epsilon_0\, dE/dt$, where ϵ_0 is the permittivity of free space;
3. precipitation current, where ions of one sign attached to raindrops fall as rain; and
4. lightning current, where charge, either positive or negative but predominantly negative, is transferred to ground during impulsive lightning strokes.

Besides thunderstorms acting in the lower atmosphere, there are two other upper-atmosphere electrical generators that couple into the Earth's global electric circuit: the ionospheric wind dynamo, where winds flowing in the thermosphere near 100 km generate a horizontal potential difference in the ionosphere of 5–10 kV with 100 000 A flowing horizontally in the dayside ionosphere, and the solar-wind/magnetosphere dynamo that generates a 30–150 kV potential drop across magnetic conjugate polar caps with 1 000 000 A flowing primarily in the auroral zone. Just how all of these current systems in the Earth's global electric circuit interact and respond to solar and auroral variability presents an exciting research challenge in atmospheric science.

8. CONCLUDING REMARKS

In recent years, it has become evident that the trace gases that are being released by man's activities have a potential for altering the detailed structure of the atmosphere and causing possible future climate changes (Bolin *et al.*, 1986). Trace gases such as CO_2, CH_4, tropospheric O_3, N_2O, and CFCs are steadily increasing in the atmosphere. A doubling of the present-day concentration of several of these gases is predicted to occur by the end of the next century. According to the greenhouse theory of climate change, the radiative imbalance caused by trace gas increases will be restored to equilibrium by a warming of the surface-troposphere system. There are many uncertainties concerning trace-gas increases and also with modeling the climate response, but it is generally agreed that the global mean equilibrium surface temperature, due to an increase of CO_2 and other greenhouse gases, is likely to be in the range of 1.5–5.5 °C. This is about the same magnitude as the change of global temperature from the last glacial period to the present interglacial.

The stratosphere is expected to cool by about 10 K in response to a doubling of the CO_2 concentration, because of the enhanced infrared cooling to space. But the stratospheric concentrations of other trace gases, such as CH_4, N_2O, and CFCs, are also increasing at a rapid rate, and these gases are predicted to have an additional influence on the temperature structure, not only because of the effect of blocking thermal infrared radiation, but also because of their ability to destroy ozone through catalytic chemical reactions. Recent calculations have shown that the stratopause will cool from present-day values by −15 to −20 K and ozone will be depleted by −5% to −30% near 40 km by the end of the 21st century (Brasseur and Hitchman, 1988). While ozone depletions at specific altitudes, such as 40 km, are important in determining effects of circulation and temperature profiles, a more important quantity used for policy and determination of biological effects is the percentage depletion of total column ozone. With ozone increasing in the troposphere as a result of man's activities, the change in total column ozone in future years may be small.

The projected CO_2 and CH_4 doublings will also have an effect on the mesosphere and thermosphere. The mesosphere will cool by 10 K and the thermosphere will cool by 50 K. Thus, if the trace-gas releases continue at their projected rate it is expected that the entire atmospheric structure will change somewhat by the end of the 21st century. The present-day atmospheric structure is temporary and quite unique.

GLOSSARY

Chlorofluorocarbons: Man-made chemical compounds that release chlorine in the stratosphere, such as trichlorofluoromethane ($CFCl_3$), or F-11, and dichlorodifluoromethane (CF_2Cl_2), or F-12, and others.

Diffusion: Gas transport due to forces such as pressure gradient and gravity. Eddy diffusion in the atmosphere is the process of transport of gases due to turbulent mixing in the presence of a composition gradient. Molecular diffusion is the net transport of molecules which results from their molecular motions alone in the absence of turbulent mixing; it occurs when the concentration gradient of a particular gas in a mixture differs from its equilibrium value. Eddy diffusion is the most important mixing process in the lower atmosphere, while molecular diffusion becomes significant at the lower pressures of the upper atmosphere.

Electrode Effect: An electrical effect near the Earth's surface where the voltage impressed by the global electric circuit causes a space charge to develop similar to that near an electrode in an electronic vacuum tube.

Galactic Cosmic Rays: High-energy charged particles, primarily protons, that are accelerated by galactic processes and that bombard the Earth's atmosphere and maintain the atmosphere electrically conducting.

Geomagnetic Storm: A period of enhanced magnetic activity caused by intense currents in the auroral ionosphere as detected by ground magnetometers.

Gleisberg Cycle: In addition to the well-known 11-yr cycle in sunspot activity there is a weaker, approximately 80-yr cycle in sunspot activity known as the Gleisberg cycle.

Greenhouse Effect: Certain radiatively active gases in the atmosphere (water vapor, carbon dioxide, ozone) trap infrared radiation emitted by the surface thereby raising the surface temperature of the planet over that which would exist in the absence of an atmosphere.

Ionosphere: The weakly ionized tenuous envelope that surrounds the Earth between about 60- and 1000-km altitude. The charged particles of the region reflect radio waves and are strongly influenced by electric and magnetic fields.

Latent Heat: Energy released when water vapor condenses to liquid water or ice in a cloud.

Magnetosphere: A magnetic cavity in the solar wind that surrounds the Earth and effectively shields the Earth from the continual supersonic outflow of the Sun's ionized upper atmosphere. The charged particles of the region are strongly influenced by electric fields. The magnetosphere overlaps the ionosphere between 60 and 1000 km.

Maunder Minimum: A prolonged period of low sunspot activity that extended from 1645 to 1715 AD.

Mesosphere: That region of the atmosphere which lies above the stratopause (about 47–52 km) and below the mesopause (about 80–90 km) and in which temperature decreases with increasing height; this is the region in which the lowest temperatures of the atmosphere occur.

Odd Hydrogen: A chemical family of active hydrogen compounds such as hydrogen (H), hydroxyl radical (OH), and hydroperoxy radical (HO_2). These form the odd hydrogen or HO_x family ($HO_x = H + OH + HO_2$).

Photochemistry: Chemical processes influenced by sunlight.

Plasma: Gas containing a significant fraction of free electrons and ions.

Quasibiennial Oscillation: An oscillation of the east-west winds in the equatorial stratosphere with an approximate 26-month period.

Radiative Equilibrium: A condition where the thermal structure of the atmosphere is determined by a local balance between heating by absorption of solar radiation and cooling by infrared emission from trace gases.

Solar Cycle: The approximately 11-yr cycle of sunspots.

Solar Flare: A sudden plasma eruption on the Sun that emits a burst of particles that travel outward into interplanetary space.

Solar Wind: Supersonic plasma flow from the Sun.

Stratosphere: The atmospheric shell lying just above the troposphere, characterized by an increasing temperature with altitude. The stratosphere begins at the tropopause (about 10–15 km height) and extends to a height of about 50 km, where the lapse rate changes sign at the stratopause and the beginning of the mesosphere.

Thermosphere: Atmospheric shell extending from the top of the mesosphere to outer space. It is a region of steadily increasing temperature with height, starting at 70 or 80 km. It is below the exosphere and includes most of the ionosphere.

Troposphere: The lowest layer of the atmosphere, ranging from the ground to the base of the stratosphere (tropopause) at 10–15 km altitude depending on the latitude and meteorological conditions. About 70% of the mass of the atmosphere is in the troposphere. This is where most of the weather features occur and where the chemistry of the reactive anthropogenic species released into the atmosphere takes place.

Turbopause: The region of the atmosphere near 100 km where transport by turbulent mixing ceases and transport by molecular diffusion dominates.

13.1
Introduction

The early history of atomic spectroscopy is closely connected with the observation of the sunlight. Wollaston (1802) reported seeing dark lines in the sun's spectrum, but he could not give a satisfactory explanation for them. Fifteen years later, Fraunhofer designed the first grating ruling engines and succeeded in producing transmission gratings with up to 600 grooves per centimeter; he noted the same lines and proceeded to map the dark lines. As spectra produced by gratings, unlike prism spectra, are nearly linear with wavelength, Fraunhofer (1817) succeeded in calculating the wavelength of the dark lines with remarkable accuracy.

During the first half of the nineteenth century, a good deal of experimentation took place with colored flames generated by injecting salts into alcohol burners or oil lamps as excitation sources. Herschel (1823) and Talbot (1826) succeeded to identify alkali metals using this technique. A breakthrough occurred in 1855, when Bunsen designed an efficient burner for coal gas, in which fuel and air were mixed before the mixture was ignited. The new flame was much steadier and gave a higher temperature, making possible a much more efficient study of the emitted spectra.

Soon after, a close collaboration began between Kirchhoff, professor of physics, and Bunsen, professor of chemistry, both at the University of Heidelberg, Germany. Kirchhoff compared the Fraunhofer lines in the sun's spectrum to those obtained in the laboratory, and showed that they arose from the same elements. He explained the reversed appearance of the lines as due to a process of absorption as the emission rays passed through the cooler outer layer of the sun's atmosphere, which caused them to show up dark against the bright background. Kirchhoff (1860) also concluded that absorption occurs only at the same wavelengths as emission, a phenomenon called *resonance*.

Among the most important stages in the development of emission spectroscopy are the first measurements in the ultraviolet (UV) made by Mascart (1864) with a photographic plate, which have later been extended to the low-vacuum UV. Balmer (1885), with his equation for the Balmer series of hydrogen lines, started the search for an explanation for the origin of atomic spectra, which was continued by several

ISBN: 978-3-527-40773-6

other researchers. It was the work of Bohr (1913), with his concept of the "astronomical" atom that placed the origin of spectra on a firm theoretical foundation. Later, Sommerfeld (1916) proposed elliptical orbits and the Schrödinger wave equation finally permitted calculation of the quantum states necessary to describe the energy positions of electrons in atoms. The development of X-ray spectroscopy is mainly based on the work of Barkla, Moseley, and Siegbahn, who received the Nobel price for physics in 1924.

13.2
General Considerations

13.2.1 Atomic Spectra

Atomic spectra are due to radiative transitions of electrons between the ground state and/or excited states of an atom. Three forms of radiative transition are possible: (i) *spontaneous emission* for the transition from a higher excited state to a lower state after the transfer of kinetic or electrical energy to the atom; (ii) *absorption of radiation* with a corresponding transition of a lower state to a higher excited state; and (iii) *induced emission* for the transition from a higher excited state to a lower state after the absorption of external radiation of corresponding frequency (the reversed process to absorption of radiation); the latter is generally referred to as *atomic fluorescence*. Atomic spectra are line spectra and are specific to the absorbing or emitting atoms (elements), that is, the spectra contain information on the atomic structure. An electron in an atom can only absorb and emit energy at well-defined wavelengths, which correspond to the energy difference between the two levels of the transition. Absorption spectra are generally simpler than emission spectra, as absorption usually starts from the ground state of the neutral atom according to selection rules, whereas all kinds of excited states can be reached in thermal and electrical excitation, resulting in a whole series of de-excitation pathways, and a correspondingly greater number of emission lines, as shown in Figure 13.1 for the spectrum of sodium.

Transitions of electrons of the outer shell are found in the spectral range between 100 nm and 1 mm, and are referred to as *optical spectroscopy*; transitions of electrons from inner (K, L, and M) shells are found in the spectral range between about 10 pm and 10 nm, and are referred to as *X-ray spectroscopy*.

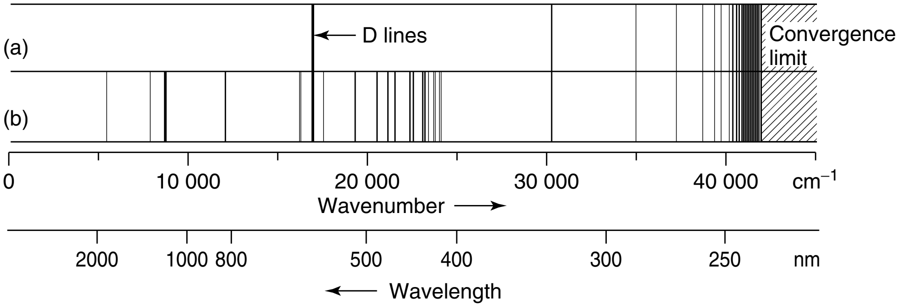

Fig. 13.1 The spectrum of the sodium atom; (a) in absorption and (b) in emission. (From Welz and Sperling (1999), Wiley-VCH, p. 67; reproduced with permission.)

The term *spectroscopy* – at least in atomic spectroscopy – refers to the visual evaluation of spectra using a dispersive system; however, it is also used as the general term for all spectroscopic measurement and observation procedures. The term *spectrometry* refers to the photoelectric measurement and evaluation of spectral radiation units using a dispersive spectral apparatus.

13.2.2
Interferences

The presence of concomitants (matrix) in the test sample can cause interferences in the determination of the analyte. The interference can influence both the attainable precision and the trueness. However, interference only leads to a measurement error if it is not eliminated, or if it is not taken into consideration in the evaluation process, by suitable measures. Such measures can be instrumental, such as background correction, or the choice of a suitable calibration technique, such as the analyte addition technique, or the use of chemical additives.

Interferences in spectrochemical analysis can be classified according to a number of aspects. The various categories are not mutually exclusive but rather complement each other in characterizing the interference. Frequently, the distinction is made between *specific* (for the analyte) and *nonspecific* interferences or between *additive* (the measured signal is increased or reduced by the same value independent of the analyte concentration or mass) and *multiplicative* interferences (the slope of the calibration curve is affected by concomitants). In the following, we shall largely adhere to International Union of Pure and Applied Chemistry (IUPAC) recommendations (IUPAC, 1978), according to which interferences are divided generally into *spectral* and *nonspectral interferences*.

Spectral interferences are due to the incomplete isolation of the radiation emitted or absorbed by the analyte from other radiation or radiation absorption detected and processed by the electrical measuring system. Spectral interferences may be due to (i) direct or partial overlapping of the analytical line with the emission or absorption line of another element; (ii) emission of radiation by concomitants that is not overlapping with the analyte line, but is not separated by the monochromator/polychromator; (iii) emission or absorption of the radiation of the analytical line by gaseous molecules; and (iv) radiation scattering caused by particles in the observation volume. Spectral interferences are always additive interferences; details are discussed with the specific techniques, where the interferences appear to a significantly different degree.

Nonspectral interferences are those that cause an influence on the number of analyte atoms (absolute or per time unit) in the observation volume, and thus on the measurement value. Nonspectral interferences are most conveniently classified according to the place or time of their occurrence. The most common types of nonspectral interferences are (i) *transport interferences*, that is, interferences that occur during the transport of a (liquid) sample from the sample container to the atomizer/excitation source due to the physical properties of the solution; (ii) *solute-volatilization interferences*, which are due to incomplete transfer of the sample into gaseous species, an interference that is typically limited to atomizers/excitation sources of relatively low temperature; (iii) *vapor-phase interferences*, which include all the equilibrium processes that may occur in the vapor phase, such as *dissociation, ionization,* and *excitation interferences*. If an interference cannot be classified because its cause is unknown or it is of complex nature, we speak of a *matrix effect*. Other interferences that are typical for specific atomizers and excitation sources are discussed in connection with these atomizers.

13.3
Optical Atomic Spectroscopy

13.3.1
Basic Principles

13.3.1.1 Physics of Atomization and Excitation

In the atomizer, the sample to be analyzed is dissociated into atoms; the *degree of dissociation* depends on the temperature of, and on chemical reactions within the atomizer. The *ground state* is the lowest energy state of an atom. By absorption of additional thermal, electrical, or optical energy, a neutral atom can be transferred into an excited state or it can be ionized. The *excited state* is unstable; the atom returns to a lower energy state after a lifetime of typically 10^{-9}–10^{-8} seconds. The transitions are limited by selection rules. *Ionization* refers to the complete separation of one or more electrons from an atom, so that the remaining atom becomes electrically charged. The degree of ionization is the ratio between the number of ions and that of the originally present number of atoms of the element under consideration.

If thermal equilibrium is established, the fraction of atoms N_j in an excited stage j can be calculated by statistical mechanics. The fraction of excited atoms at a certain energy level in comparison to the number of atoms in the ground state N_0 is given by the *Boltzmann distribution*

$$\frac{N_j}{N_0} = \frac{P_j}{P_0} e^{-E_j/kT} \qquad (13.1)$$

where P_j is the statistical weight of the selected excited state j, P_0 the statistical weight of the ground state, E_j is the energy of excitation, k is the Boltzmann constant, and T the absolute temperature. In Eq. (13.1), the exponent is inversely proportional to the absolute temperature, which means that the increase in the relative number of excited atoms N_j/N_0 is exponential with increasing temperature. Walsh (1955) calculated the ratio N_j/N_0 for a number of elements at various temperatures, as is shown in Table 13.1. For most of the elements and temperatures, the number of atoms in the ground state N_0 is virtually identical to the total number of atoms N.

Tab. 13.1 Temperature and wavelength dependence of the ratio N_j/N_0 (Walsh, 1955).

Element	Excitation energy eV	Wavelength nm	2000 K	N_j/N_0 3000 K	4000 K
Zn	5.80	213.9	7.29×10^{-15}	5.58×10^{-10}	1.48×10^{-7}
Ca	2.93	422.7	1.21×10^{-7}	3.69×10^{-5}	6.03×10^{-4}
Na	2.11	589.0	0.86×10^{-4}	5.88×10^{-4}	4.44×10^{-3}
Cs	1.46	852.1	4.44×10^{-4}	7.24×10^{-3}	2.98×10^{-2}

13.3.1.2 **Atomic Spectra and Spectral Lines**

Dispersion of the radiation emitted or absorbed by the atomizer/excitation source results in a spectrum that is characteristic of the emitting or absorbing species. Atomic spectra are line spectra; molecular spectra are band spectra that extend over a wider spectral range. A *spectral line* is defined as the monochromatic radiation that is emitted or absorbed at the transition of an atom or ion between different energy states E_1 and E_2. The wavelength λ of the transition is characteristic for the two energy states according to

$$\lambda = \frac{hc}{E_2 - E_1} \tag{13.2}$$

where h is Planck's constant and c is the speed of light. Spectral lines, the radiation of which can be absorbed by atoms in the ground state or that are generated by a transition into the ground state, are called *resonance lines.*

Atomic lines are not strictly monochromatic, but characterized by a distribution of the radiation intensity over wavelength that can be described by a profile function, as is schematically shown in Figure 13.2. The width of an atomic line is usually given as the full width at half maximum (FWHM), or briefly *half width.* The part of the line that is within the FWHM is called the *line core*; the parts that are outside are called the *line wings.* The *natural line width* is the smallest possible line width, which is caused by the residence time of the atom in the involved energy states and the resulting uncertainty of the measurement. The natural width of atomic lines is typically of the order of 0.01–0.1 pm, which is, however, not of practical significance due to the various broadening effects that occur under normal analytical conditions. The most important effects that finally determine the *physical line width* are Doppler and pressure broadening. The *Doppler broadening* is caused by the random movement of the emitting or absorbing atoms; it is proportional to the square root of the temperature and results in a symmetric broadening of the line. *Collision broadening* is caused by collision of the emitting or absorbing atoms with other neutral or charged particles; it depends on the pressure and temperature of the environment and results in an asymmetric broadening. Depending on the mass of the atom and the collision partner this effect may shift the line

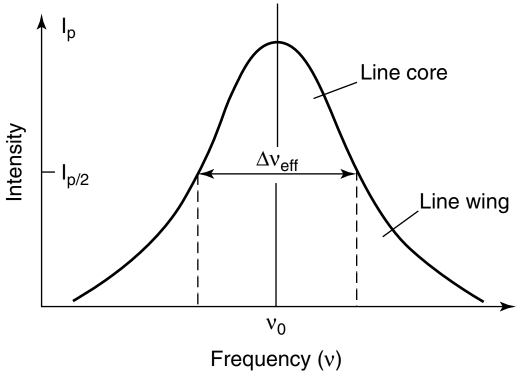

Fig. 13.2 Typical line profile and half width (FWHM, $\Delta\nu_{\text{eff}}$) of a spectral line. (From Welz and Sperling (1999), Wiley-VCH, p. 74; reproduced with permission.)

maximum to lower or higher wavelength, an effect called *Lorentz shift*.

The physical width of an atomic line depends on a variety of factors (besides individual differences in the hyperfine structure). Lines in the vacuum UV are approximately one order of magnitude narrower than lines in the beginning infrared. Lines emitted by low-pressure lamps, such as hollow cathode lamps (refer to Section 13.3.3.2, Radiation Sources for LS AAS), essentially only exhibit Doppler broadening, no Lorentz shifts, and typically have half widths between 0.3 and 1.5 pm. Lines emitted by a high-temperature plasma (refer to Section 13.3.2.1, Plasma Sources) are typically one order of magnitude broader, and the absorption lines in flames are in between with half widths of 1.5–5 pm.

13.3.1.3 **Measurement of Radiation, Calibration, and Evaluation**

The intensity of the emitted or absorbed radiation is measured using a *photoelectric detector* that converts the flux of photons into a flux of electrons using the outer or inner photo effect. The most common detectors are the photocathode detector, commonly denominated as photomultiplier tube (PMT) that uses the outer photo effect and the semiconductor detectors that use the inner photo effect. The latter ones come in a variety of array detectors that are increasingly used in modern equipment.

The measurement of signals in optical emission spectrometry (OES) and atomic fluorescence spectrometry (AFS) is typically done in emission or fluorescence intensity with the dimension counts per second (s^{-1}). In atomic absorption spectrometry (AAS), in contrast, measurement is done in absorbance, A, according to the Beer–Lambert law, which, for AAS, is usually written in the form:

$$A \equiv \log \frac{\Phi_0(\lambda)}{\Phi_{\mathrm{tr}}(\lambda)} = 0.43 N \ell \kappa(\lambda) \quad (13.3)$$

where $\Phi_0(\lambda)$ is the incident radiant power, $\Phi_{\mathrm{tr}}(\lambda)$ is the transmitted radiant power, N is the total number of free atoms, ℓ is the length of the absorbing layer, and $\kappa(\lambda)$ is the spectral atomic absorption coefficient. In addition to the absorbance A, which is typically used for steady-state signals, for example in flame atomic absorption spectrometry (FAAS) the time-integrated absorbance, A_{int} (which corresponds to the area under the absorption pulse), is used for the evaluation of transient signals, as they are typical for graphite furnace atomic absorption spectrometry (GF AAS). Whereas the absorbance is a dimensionless measure, the integrated absorbance has the dimension seconds.

None of the techniques used for atomic spectroscopy is an absolute technique, which means that, for quantitative determinations, all of them require calibration using appropriate *calibration standards*. These could be, in an ideal case, aqueous solutions with a known content of the analyte element, or, in the case of severe matrix effects, have to be reference materials with analyte content and matrix composition close to that of the test sample to be analyzed. A *calibration function* that describes the mathematical dependence of the measured value on the concentration or mass of the analyte has to be established for quantitative determination. The slope of the calibration function is termed *sensitivity*.

Table 13.2 shows the different measurement units, their dimension and the resulting units for the sensitivity of different atomic spectrometric techniques.

Tab. 13.2 Examples for the dimension of sensitivity in different atomic spectrometric techniques.

Technique	Measured quantity		Dimension	Concentration or mass[a]	Sensitivity
OES	Intensity	I	s^{-1}	$mg \cdot L^{-1}$	$L \cdot mg^{-1} \cdot s^{-1}$
FAAS	Absorbance	A	–	$mg \cdot L^{-1}$	$L \cdot mg^{-1}$
GF AAS	Integrated absorbance	A_{int}	s	ng	$s \cdot ng^{-1}$

[a] Other concentration or mass units might be used as well.

This comparison clearly demonstrates that "sensitivity" is not an appropriate parameter to compare the analytical performance of different systems due to the entirely different definitions. In addition, sensitivity is only one aspect, but noise is at least as important. Hence, the comparison of different systems should be on the basis of the signal-to-noise (S/N) ratio exclusively. Appropriate measures of the S/N ratio are the limit of detection (LOD), and the limit of quantification (LOQ), which are usually defined as 3 times and 10 times, respectively, the standard deviation of a blank, divided by the slope of the calibration function. Obviously, LOD and LOQ should be compared for real samples, not only for matrix-free calibration solutions. Another important parameter for OES is the signal-to-background ratio, and the figure for comparison is usually the background equivalent concentration (BEC), that is, the analyte concentration that gives the same signal as the background.

The measurement of the emission intensity, particularly in OES, is subject to relatively great day-to-day variations due to minor changes in the temperature of the excitation source and in detector sensitivity. The measurement of the absorbance in AAS, in contrast, is relatively independent of such fluctuations, firstly, as the number of atoms in the ground state is essentially independent on minor temperature changes (refer to Section 13.3.1.1) and the intensity of the radiation from the primary source has no influence on the sensitivity either, as the absorbance only depends on the ratio $\Phi_0(\lambda)/\Phi_{tr}(\lambda)$. Measurement quantities, such as the characteristic concentration, c_0, the concentration of an analyte that gives an absorbance reading of $A = 0.0044$ in FAAS, and the characteristic mass, m_0, the mass of an analyte that gives an integrated absorbance reading of $A_{int} = 0.0044$ seconds in GF AAS may therefore be used to test the proper function of the equipment and of analytical procedures on a day-to-day basis.

13.3.2
Optical Emission Spectrometry

OES, often referred to as atomic emission spectrometry (AES) – an acronym the use of which has been discouraged by IUPAC because it is reserved for Auger electron spectroscopy (AES) – is the oldest of the atomic spectrometric techniques. A great deal of research has been carried out in this area in the late nineteenth and the early twentieth century, including the design of ever more advanced mono- and polychromators. Modern quantitative methods of spectrochemical analysis using OES, however,

did not begin until about 1925, when the first commercial optical equipment began to be manufactured in Europe and the United States. A photographic plate was used as detector in these instruments, a practice that continued for about half a century.

An optical emission spectrometer consists basically of an atomization and excitation source with a sample introduction system, a wavelength-dispersing system, such as a monochromator or polychromator, and a detector, amplifier, and readout system. The kind of samples that can be analyzed and the elements that can be determined depend mostly on the excitation source.

A liquid sample, when introduced into the excitation source, is submitted to several steps that are shown schematically in Figure 13.3. Initially, the sample aerosol, which is formed by a nebulizer, is desolvated, that is, the solvent is evaporated. The desolvated particles then are vaporized, that is, converted to gaseous species, and finally dissociated in the atomization process. The atoms formed in this process are in equilibrium with their respective excited (neutral) and ionic species, which may also undergo excitation (Boss and Freeden, 1999). In the cases of direct solid sample and gas analysis, some of the above stages might be omitted or altered.

13.3.2.1 Excitation Sources

The role of the excitation source in OES is to transfer the sample into the gaseous state, to dissociate molecular species, and to provide sufficient energy to excite the analyte atoms, promoting the emission of photons that will later be detected.

Electrical Arcs and Sparks Many analytical applications of OES produced their spectra by arc or spark excitation techniques. The historical development in this area is most difficult to document since almost from the start, after observations of the sun's spectrum, the attempt was to use high-energy sources. The first commercial instruments for OES that have been introduced in the first half of the twentieth century also used electrical arcs and sparks for the direct vaporization and excitation of solid samples. This kind of equipment is the working horse in most metallurgical laboratories even today. An *arc* is an electrical discharge that takes place between two or more conducting electrodes. The sample usually stands as one of the electrodes, either as a powder, a solid mixture, or a solution residue.

One of the most common arc types used in OES is the direct current (*dc*) *arc*. The dc arc consists of a continuous discharge of 1–30 A between a pair of metal or graphite electrodes, one of which contains the sample. The dc arc provides good detection power and generates relatively high amounts of neutral (excited) atoms, although it is also characterized by relatively poor precision and by an effect denominated *selective volatilization*, which occurs because the electrodes are only gradually heated by the arc. The consequence is that the most volatile materials vaporize first, which may result in an erroneously high result for volatile analytes. A *spectrochemical buffer* is frequently used to reduce or control the effects of selective volatilization; substances that are typically employed include graphite powder or alkali and alkaline–earth compounds (Ingle and Crouch, 1988; Mika and Török, 1974; Zhou, Zhou and Hou, 2005).

The alternating current (*ac*) *arcs* may be either operated at high (2–4 kV) or low (100–400 V) voltages. Unlike the dc arc, the ac arc is extinguished at the end of each half-cycle, which allows the sampling of different portions of the electrode at each cycle. Compared to dc arcs, ac arcs lead to better precision and more efficient sample volatilization, whereas the sensitivity is usually lower and the analysis of refractory materials may become more difficult (Ingle and Crouch, 1988).

Sparks are intermittent electrical discharges of a few microseconds that occur under application of high electrical potentials. Spark sampling usually consists of two stages: firstly, a low-energy discharge is produced to ionize the noble gas (usually Ar) in the sampling chamber; later, after the conducting plasma has been generated, a high-energy discharge (spark) is induced, causing vaporization of the sample in the location where the spark impacts, where temperatures as high as 50 000 K can be reached (Ingle and Crouch, 1988; Mika and Török, 1974). Spark sources are characterized by relatively high precision, as they are able to vaporize several distinct portions of the sample electrode in successive discharges. Spark-source OES instruments are, however, usually less sensitive than arc and discharge instruments, mostly because the high-peak currents and high-power density in sparks lead to a high degree of single and even multiple ionization of analyte species. In addition, the mass of sample that is vaporized in each cycle is relatively low. Despite those drawbacks, spark sources have been successfully applied to the analysis of samples, such as environmental, geological, and biological materials, but the main focus has been, and is, the analysis of metal alloys (Zhou, Zhou and Hou, 2005).

One of the limitations of arc and spark OES is the need of reference materials with a matrix composition and analyte content as close as possible to the sample for calibration due to the significant matrix effects encountered with these techniques. This requirement might increase the cost of analysis significantly.

Glow Discharges Glow discharges (GDs) have been used in OES since the beginning of the twentieth century. Usually, the sample to be analyzed was filled into a hollow cathode, which was placed inside a quartz tube through which an inert gas (usually Ar) was pumped at low pressure. A voltage potential was then applied between the anode (usually made of graphite) and the hollow cathode, causing electrons to migrate from the cathode to the anode. In their path they collide with Ar atoms, generating positively charged metastable argon species, which are accelerated to the sample holder, held at negative potential. Collision with the sample surface will result in the ejection of atoms and electrons from the sample, a process called *sputtering*. Sputtered atoms collide with metastable Ar atoms or high-energy electrons, and are excited. With relaxation, the photons emitted from the excited species produce a small plasma (GD), which is used for analytical purposes (Pisonero *et al.*, 2006; Angeli *et al.*, 2003; Jakubowski *et al.*, 2007). In the second half of the twentieth century glow discharge optical emission spectrometry (GD OES) became quite popular after Grimm (1968) had proposed several modifications of the setup. He used a flat cathode (the sample) and a ring anode, as shown in Figure 13.4, which significantly facilitated the preparation and change of samples. GD OES is ideally suited for surface analysis and depth profiling, as it produces a crater with a flat bottom, which is in contrast to other ablation techniques. Some typical applications of GD OES include the analysis of thin films (Pisonero *et al.*, 2006; Angeli *et al.*, 2003) and metal alloys (Galindo and Albella, 2008).

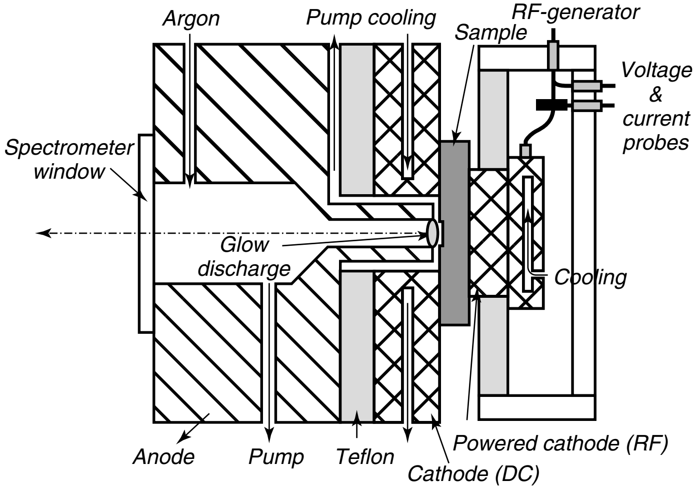

Fig. 13.4 Schematic design of a Grimm discharge lamp for GD OES. (From Hodoroba *et al.* (2001), p. 31; reproduced with permission from Elsevier.)

Flames The simplest excitation source is a *flame*, a mixture of at least two gases, a fuel and an oxidant, and the first burner designed for atomic spectroscopy was the burner of Bunsen. The work that gave principal impetus to flame excitation was that of Lundegårdh (1936). In his method, the sample solution was sprayed from a nebulizer into a condensing chamber and then into an air–acetylene flame. Since spectra produced by flames exhibit significantly less lines compared to those produced by arc and spark emission, simple devices for spectral isolation could be used. Barnes *et al.* (1945) reported a simple filter photometer for alkali metal determinations; instruments of this kind are still in use nowadays, mainly in clinical laboratories, and the technique is often referred to as *flame photometry*.

Flame OES is limited to the analysis of liquid or dissolved/digested samples, and a nebulizer is typically required for sample introduction into the flame. The nebulizer-burner unit might be similar to the design used for FAAS (refer to Section 13.3.3.1, Flame Atomizers) or it might be of the *total consumption* design that makes possible to use oxygen as the oxidant and hence to achieve higher flame temperatures. Among the advantages of flames as excitation sources are their stability and the relatively simple and inexpensive operation. However, the temperatures of flames are, in most cases, not sufficient to promote the excitation of a significant fraction of analyte atoms, as can also be deduced from the data in Table 13.1 (Ingle and Crouch, 1988). The use of flames for OES is restricted to a few isolated applications nowadays.

Plasma Sources One of the most widely used excitation sources in OES nowadays is the *inductively coupled plasma* (ICP), which has been investigated independently by Greenfield, Jones and Berry (1964) in the UK and Wendt and Fassel (1965) in the USA. The ICP is a partially ionized gas (usually argon) that is formed from an electrical discharge inside a quartz torch and maintained by an induction coil to which a radiofrequency (RF) power is applied. The schematic design of an ICP torch, which consists of three concentric cylinders, is shown in Figure 13.5. The main gas flow (usually at flow rates above $15\,\mathrm{l\,min^{-1}}$), which is the main flow responsible for plasma formation, is in the outer cylinder. A secondary gas flow (usually at flow rates of $1-1.5\,\mathrm{l\,min^{-1}}$) runs between the inner and the middle cylinder and is responsible for cooling the torch and maintaining a distance between the plasma and the torch walls. The *nebulizer gas* flows inside the inner cylinder, being responsible for the transport of the sample aerosol to the plasma itself. To initiate the plasma, a discharge takes place, generating Ar ions and electrons. An RF power is then applied to the metallic load coil located in the front part of the plasma torch, originating a magnetic field that maintains the electrons on the torch, promoting their collision with other neutral Ar atoms. The collisions generate more electrons and ionized gas species in a chain reaction, and the otherwise neutral gas becomes a plasma, constituted by neutral atoms, ions, and electrons. Owing to the high temperatures that can be attained in this system (up to about 10 000 K, depending on the plasma region), basically all elements can be excited and even ionized to a great extent in an ICP. The same ICP source can be used with a

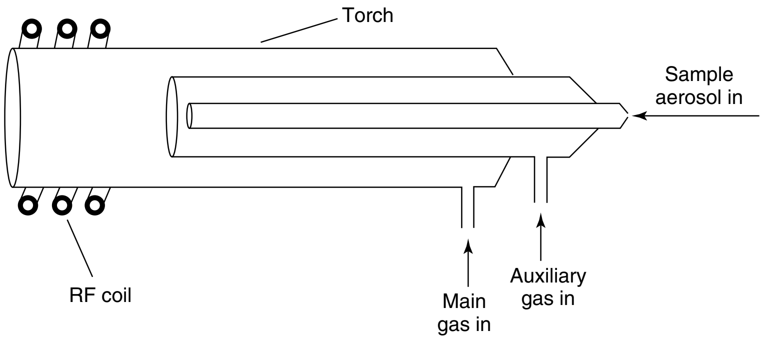

Fig. 13.5 Schematic design of an ICP torch; for details see text.

mass spectrometer, in a technique called *inductively coupled plasma mass spectrometry*, (*ICP-MS*) (Montaser and Golightly, 1992; Becker, 2007).

In inductively coupled plasma optical emission spectrometry (ICP OES), liquid samples are used almost exclusively. They are introduced into the plasma using a pneumatic nebulizer and a spray chamber in order to obtain an aerosol with very small droplet size. A wide variety of different nebulizers and spray chambers have been proposed for ICP OES (Nölte, 2003), but they are not discussed in detail here. The most commonly used one is the Meinhard nebulizer, a concentric nebulizer of very simple design, in combination with a Scott spray chamber, as shown in Figure 13.6. Another frequently used nebulizer is the *cross-flow* nebulizer, where a capillary with a high-pressure gas flow is positioned at a 90° angle with the capillary tip through which the

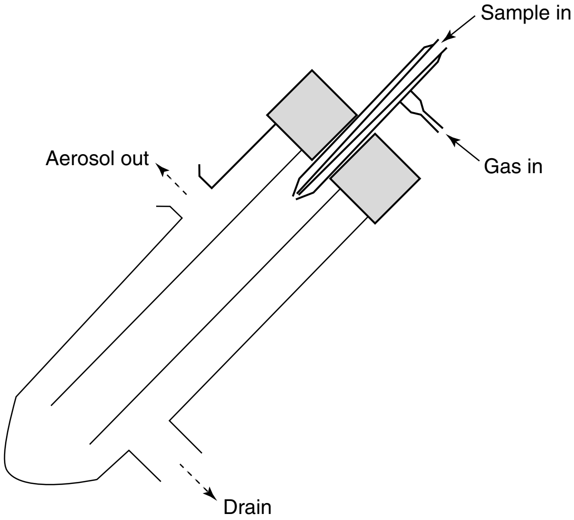

Fig. 13.6 Schematic design of a Meinhard concentric nebulizer in a Scott spray chamber for ICP OES.

sample flows. Both nebulizers have an uptake rate of about 2 ml min^{-1} and are typically operated in combination with a peristaltic pump for sample introduction in order to reduce the effect of viscosity of the solution on the flow rate. As a consequence of the requirement for very low volume droplets in order to maintain plasma stability, the sample introduction efficiency is around 2%, so that most of the aspirated sample is discarded through the drain (Boss and Freeden, 1999).

There are basically two different configurations possible for ICP OES, the *radially viewed plasma* (or side-on), where the ICP is positioned at a 90° angle with the detector, and the *axially viewed plasma* (or end-on), where the ICP and the detector are assembled in the same optical axis. The latter configuration provides higher sensitivity due to the longer path length that is exposed to the detector, although the risk of interference with this configuration is considerably higher (Boss and Freeden, 1999). The major problem in ICP OES, similar to arc and spark OES, is the extremely great number of emission lines that is produced at the high plasma temperatures, which obviously increases the risk of spectral interferences proportionally. Modern simultaneous ICP OES instruments offer computer programs to correct for spectral interferences, measuring the interferent emission at a suitable line, calculating and subtracting its contribution to the emission at the analytical line using a least-squares algorithm.

An alternative for sample introduction in ICP OES is the use of a graphite furnace specially designed to carry the sample aerosol from the graphite tube to the plasma source. This technique is known as *electrothermal vaporization* (ETV), and works under the same basic principles as the graphite furnace technique used in AAS (refer to Section 13.3.3.1, Electrothermal Atomizers). Among its advantages are the higher transport efficiency and the greater tolerance to matrix components, allowing even the analysis of solid samples directly or prepared as slurries. Most ICP OES instruments, however, have difficulties to handle transient signals, which are generated by ETV. As a consequence, the use of ETV devices became more popular in ICP-MS.

Another technique that is occasionally used in ICP OES is hydride generation (refer to Section 13.3.3.1, Atomizers for Chemical Vapor Generation) in order to separate the analyte from the matrix and introduce it into the plasma in the form of a gaseous compound. In this case, the plasma conditions have to be adapted in order to tolerate the hydrogen that is developed during the chemical reaction.

Other plasma sources have also been investigated as excitation sources in OES. The *direct current plasma* (DCP) was the first plasma source described and commercialized. In this system, the plasma is generated when a direct current is established between two fixed electrodes, and the sample aerosol is carried to the plasma region by an argon flow. The *microwave-induced plasma* (MIP) is also an important plasma source. In this case, the plasma is generated by application of microwave power, generated by a magnetron, to a cavity with an inert gas, usually Ar or He (Rosenkranz and Bettmer, 2000). Microplasmas with dimensions of 1 mm or less, usually microwave-induced, generated by high frequency or dc discharges, are a promising field of research in OES, and have been experiencing increasing popularity in the past few years (Foest, Schmidt and Becker, 2006; Broekaert and Siemens, 2004).

Lasers The most recent excitation sources in OES are lasers used in *laser-induced breakdown spectroscopy* (LIBS). In a very simplified definition, Sallé, Mauchien and Maurice (2007) described LIBS as a technique based on the focusing of high-power laser pulses onto a sample surface leading to the generation of a plasma composed of excited species, which emit radiation. Nd : YAG lasers are typically used at 1064 nm, but the results obtained with UV lasers are not significantly different (Fantoni *et al.*, 2008). The technique uses short-pulsed lasers (in the nanosecond range) to induce the dielectric breakdown of a gas located at the laser focal point. The microplasma that is generated as a consequence can reach temperatures as high as 20 000 K, which is sufficient to break chemical bonds present in the sample and to produce excited atoms and ions. The results obtained using LIBS depend on several factors, which include the surrounding gas, sample matrix, and laser parameters, such as wavelength, power density, and pulsing frequency (Rusak *et al.*, 1998; Kennedy, Hammer and Rockwell, 1997). The applications of LIBS for qualitative and quantitative chemical analysis range from depth profile studies (Das *et al.*, 2008) to the analysis of paints (Kim *et al.*, 2007) and meteorites (De Giacomo *et al.*, 2007). Fantoni *et al.* (2008) published a review article about semiquantitative and quantitative analysis using LIBS. Portable LIBS spectrometers have also been described and applied successfully to a number of elements (Harmon *et al.*, 2005; Mohamed, 2008; Goujon *et al.*, 2008).

13.3.2.2 **Spectrometers**

A spectrometer is an apparatus for the conduction and dispersion of the emitted radiation and a system for the measurement of spectral radiation quantities. We distinguish between *sequential spectrometers*, where the radiation of different wavelengths is measured one after the other, and *simultaneous spectrometers*, where the radiation of different wavelengths is measured at the same time, using more than one detector or a single space-resolving detector. The sequential spectrometer uses a *monochromator*; the simultaneous spectrometer uses a *polychromator*. Lenses and mirrors are used for the conduction and collimation of the radiation; prisms and gratings are used for their dispersion. Monochromators have one entrance and one exit slit; polychromators have one entrance slit and no exit slit in case a space-resolving detector is used, or multiple exit slits in case where more than one detector is used. Because of the great number of lines that are emitted in OES, particularly from high-temperature excitation sources, the quality of the spectrometer and the relative freedom from spectral interferences is directly related to its resolving power.

The most popular mounting used for monochromators in OES is the Czerny–Turner mounting, which is shown in Figure 13.7; the Czerny–Turner mounting offers the best correction for coma and astigmatism, and hence the lowest stray light level. Monochromator-based instruments are usually compact, show greater spectral flexibility and allow background correction to be performed more accurately compared to polychromators.

In the case of *polychromators*, we have to distinguish between three different

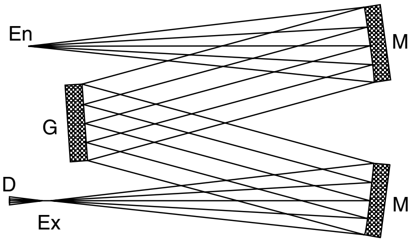

Fig. 13.7 Schematic design of a monochromator in Czerny–Turner mounting with flat grating. (From Welz and Sperling (1999), p. 62; reproduced with permission from Wiley-VCH.)

designs, the classical spectrograph, the conventional prism or grating polychromator, and the echelle grating polychromator. The *spectrograph* used a prism or a grating as the dispersive element, usually in Littrow, Ebert, or Czerny–Turner mounting, and it often had a focal length of several meters in order to obtain high resolution. It had no exit slit and a photographic plate or film as the detector, which recorded the entire spectral range of interest. Spectrographs have played a decisive role in research and routine analysis up to the 1970s, but are no longer in use because of their complexity and the time-consuming evaluation of the photographic plates.

In *conventional polychromators* with a prism or a grating and multiple exit slits, each exit slit is assigned to a specific wavelength (element) and equipped with its own detector, hence making simultaneous multielement determination possible. One of the most popular configurations used for polychromators in OES is the Paschen–Runge mount assembled in a *Rowland circle*, as shown in Figure 13.8. In this system, radiation from the excitation source is conducted toward a concave diffraction grating, and the resolved spectrum is directed to several exit slits located on the opposite side of the circle. An individual detector is associated to each exit slit. Conventional polychromator-based instruments usually have higher sample throughput, although there are restrictions with regard to the number of elements that can be determined, which have to be specified when the equipment is purchased. There are also limitations with respect to background correction, as the lines to be used for correction have to be defined in advance as well, which increases the risk of spectral interferences (Broekaert, 2005; Boss and Freeden, 1999). Simultaneous spectrometers with Rowland circle mounting and a series of space-resolving detectors instead of PMT obviously do not show the above limitations.

Many modern ICP OES instruments use an *echelle grating polychromator* for wavelength dispersion. Echelle gratings are used because of their much higher resolving power compared to conventional holographic gratings. According to the general grating formula

$$R = n\,O \tag{13.4}$$

where R is the resolution, n the number of grating grooves that are illuminated, and O is the grating order. The resolution of conventional holographic gratings, which are generally used in the first order, only depends on the ruling density and the grating size. Echelle gratings, in contrast, exhibit maximum intensity for grating orders around 100. This means that, although their ruling density is typically an order of magnitude lower than that of holographic gratings, their

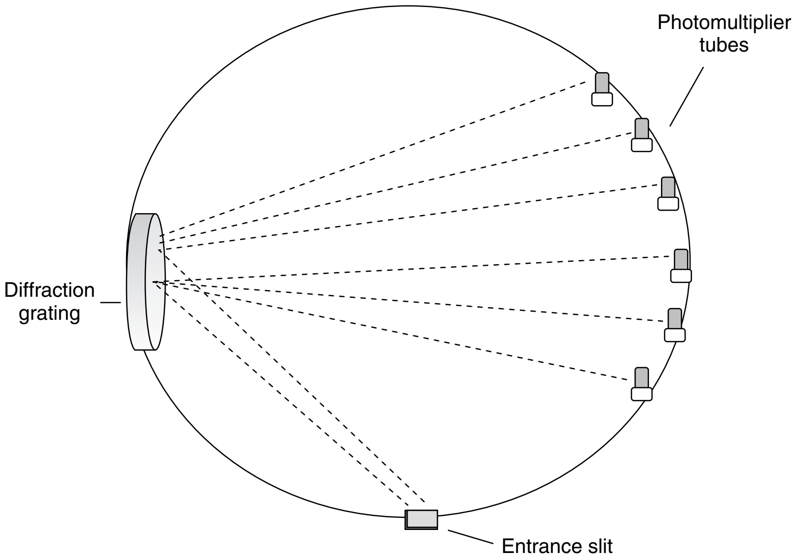

Fig. 13.8 Schematic design of a polychromator in Paschen–Runge mounting, assembled in a Rowland circle with concave grating.

resolution is still an order of magnitude higher. In this case, a second dispersive system, either a diffraction grating or a prism is used and positioned perpendicularly to the echelle grating. The echelle grating separates the polychromatic radiation by wavelength and overlapping spectral orders that are later separated or *cross dispersed* by the second optical component, generating a two-dimensional pattern. Detection of the bi-dimensional spectrum is usually achieved by a solid-state detector, such as a charge-coupled device (CCD) or charge-injection device (CID). A schematic representation of an echelle spectrometer is shown in Figure 13.9.

13.3.2.3 **Detectors**

The intensity of the radiation emitted by excited atoms or ions and separated by the wavelength-dispersing device is measured using a detector. For about half a century, photographic plates and films were used for that purpose in OES; they were increasingly replaced by PMTs in the second half of the twentieth century. In a PMT, an anode, a radiation-sensitive electrode (known as the *photocathode*) and a series of emission cathodes (known as *dynodes*), typically 10–12, are assembled and held at an increasingly positive potential. Radiation that passes the exit slit reaches the photocathode, which will emit electrons upon the impact of photons. The emitted electrons will be accelerated to the first dynode, which will release a greater number of secondary electrons that will be accelerated to the next dynode, where the process is repeated, resulting in a cascade effect. The multiplication of electrons along a PMT depends on the amplitude of the high voltage applied. At the end of the process, an electrical current is generated related to the number of photons that impacted the photocathode.

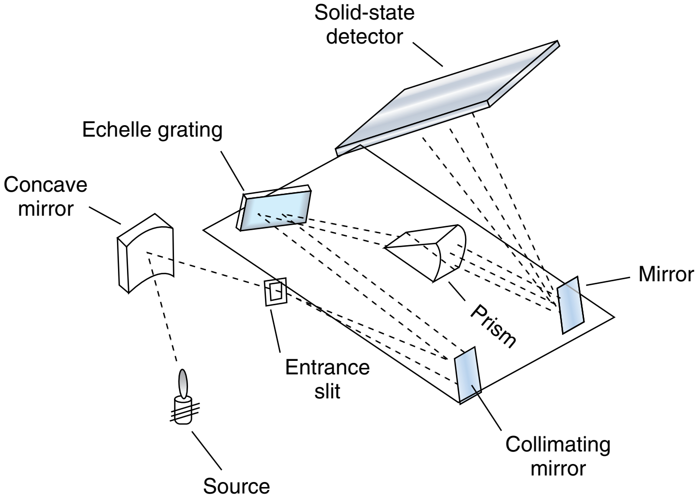

Fig. 13.9 Schematic design of an echelle spectrometer.

Modern echelle grating polychromators are equipped with solid-state detectors, such as CCDs or CIDs, which are based on the light-sensitive properties of solid silicon. In a CCD, the impact of photons generates electrons that are collected and accumulated by positively biased capacitors. The charge packets are transferred in discrete time increments by the controlled movement of potential wells to preamplifier and to the readout. In a linear CCD, the charge is moved in a stepwise fashion from element to element and is detected at the end of the line. A two-dimensional array CCD consists of an assembly of interconnected linear CCDs. The on-chip summing of charges in adjacent pixels along rows or columns is called *binning* (Laqua *et al.*, 1995). In the CID, photons striking the silicon wafer generate positive charges, and these charges are stored below negatively biased capacitor plates. The amount of stored charge is proportional to the intensity of the radiation and to the integration time. When a pixel is selected for readout, the row capacitor associated to it is maintained at a ground potential (zero volts), resulting in the injection of charge into the substrate and in an output signal (Ingle and Crouch, 1988).

13.3.3
Atomic Absorption Spectrometry

After the effectiveness of AAS for atomic spectrometric investigations had been demonstrated by Kirchhoff and Bunsen, the technique was used by other researchers as a qualitative method. Wood (1905) performed the definitive experiments that elucidated atomic absorption by resonance in gases. The absorption of the radiation from a mercury discharge lamp by mercury vapor, which appears as shadow on a screen, became a common experiment in physics lectures in colleges. Woodson (1939) applied the procedure to a quantitative method for the determination of mercury – the first application of atomic absorption to quantitative measurement. Besides these isolated examples, however, OES was preferred as an analytical technique during the first half of the twentieth century. This was to a great extent due to the fact that continuum radiation sources, as they have been used in the nineteenth century, were not really suited for AAS measurements. Particularly with a photographic plate as a detector, it was much easier to detect and measure a small emission, that is, a small increase in the opacity of the photographic layer than a small reduction of a strong emission over a narrow spectral range of a few picometers.

A turning point came in 1955 when Walsh reintroduced AAS to chemical analysis. He recognized the importance of a high-intensity, narrow linewidth source for high sensitivity and suggested the use of hollow cathode lamps (HCL). This way the high resolution that is required for atomic absorption measurements was provided by the line radiation source; in this case, a monochromator of medium resolution could be used, which only had to separate the analytical line from other lines emitted by the source. Walsh also proposed to modulate the HCL radiation and to use an amplifier tuned to the same modulation frequency (Russell, Shelton and Walsh, 1957), so that measurements could be made without interference from flame emission. This concept made AAS highly specific and selective for the element to be determined, but at the same time it limited the technique to the determination of one element at a time. The use of continuum radiation sources for AAS measurement could only be realized toward the end of the twentieth century due to the significant progress in the technology of components and in the design of spectrometers (Harnly, 1999; Heitmann *et al.*, 1996), as is discussed in Section 13.3.3.3.

An atomic absorption spectrometer consists of an atomizer with a sample introduction system and a spectrometer. The latter consists of a radiation source, a monochromator, and a detector, and it usually also contains a device for background correction. As there are fundamental differences between spectrometers for line source and continuum source AAS, these two spectrometer types are treated in separate sections.

13.3.3.1 **Atomizers**

The role of an atomizer in AAS, similar to the excitation source in OES (Section 13.3.2.1), is to transfer the sample into the gaseous state and to dissociate molecular species into ground-state atoms. Ionization of the analyte atoms has to be avoided, as ionic species have a different absorption spectrum and are therefore not available for atomic absorption measurement.

Flame Atomizers Walsh (1955) made use of a premixed, laminar-flow *air–acetylene flame*, similar to that of a Lundegårdh burner to produce atoms in the ground state. This flame, which has a temperature between 2200 and 2300 °C, and can be operated under reducing (fuel-rich) as well as oxidizing (fuel-lean) conditions, allowed the sensitive determination of some 35 elements. It still is the most popular flame used in AAS; however, it is not suitable for the determination of refractory elements and those with high affinity to oxygen. The introduction of the hot (~2700 °C) and reducing *nitrous oxide–acetylene flame*

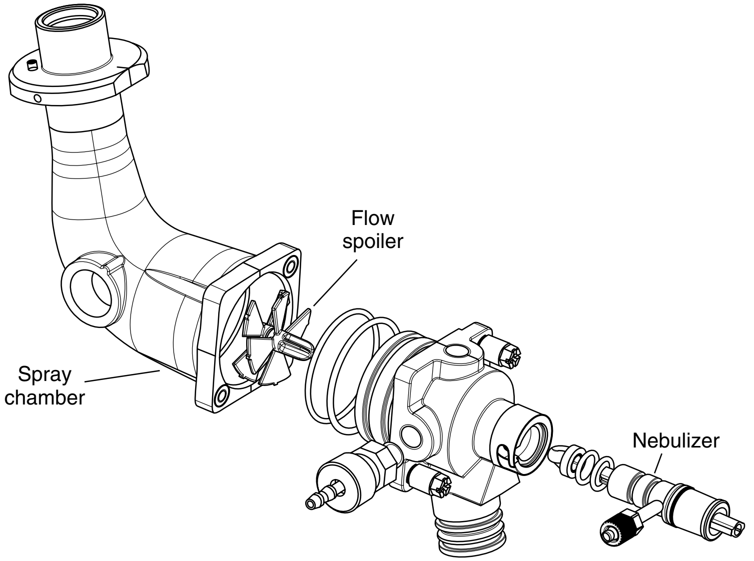

Fig. 13.10 Schematic design of a premix burner for FAAS with concrntric nebulizer, mixing chamber and impact devices. (With kind permission of Analytik Jena AG, Jena, Germany.)

(Willis, 1965) brought the solution for this limitation and added another 30 elements to the list of those that could be determined by AAS. Other gas combinations, such as the *air–hydrogen flame*, found only limited interest for special applications. Flames with oxygen as the oxidant cannot be used in a premix burner due to their high burning velocity; total consumption burners that have reached some popularity in OES have been found unsuitable for AAS (Welz and Sperling, 1999). Next to the temperature it is mostly the chemical environment, that is, the components of the flame gases, that plays a decisive role in the atomization process.

Samples are usually aspirated by a concentric *pneumatic nebulizer*, using the oxidant as the nebulizer gas; the uptake rate of these nebulizers is typically 5–10 ml min^{-1}. The generated aerosol is introduced into a mixing chamber, where it is mixed with the fuel gas and additional oxidant (Figure 13.10). The mixing chamber usually also contains impact devices, such as impact beads and flow spoilers, for postnebulization and separation of big droplets. The ''conditioned'' aerosol that finally reaches the flame typically has a maximum droplet size of <10 μm; only about 5% of the aspirated sample finally reaches the flame. Nevertheless, the amount of sample that is introduced into a flame in AAS is about an order of magnitude greater than that in ICP OES (refer to Section 13.3.2.1, Plasma Sources).

In the flame, the aerosol is submitted to several successive processes, including *desolvation* (evaporation of the solvent), *solute volatilization* (transfer of the dry particles into the gas phase), and *dissociation* of the molecules into atoms (refer to Section 13.3.2.1). The completeness of these three processes is decisive for the absence of nonspectral interferences; however, as the process of dissociation is an equilibrium process, it is sufficient that the same degree of dissociation is reached for the analyte in the sample and in the calibration solution to obtain freedom from interference. Because of its simplicity and freedom from spectral interferences, flame AAS was, to an extent, replacing flame emission spectrometry in the market, except for the flame photometers that were used mostly in clinical laboratories.

The major sources of interferences in flames are transport interferences due to differences in viscosity, surface tension, and so on, between the solution, which result in different aspiration rates and nebulization properties, as well as dissociation and ionization interferences. The former ones can be controlled using the analyte addition technique for calibration, whereas the latter ones can be removed by adding appropriate buffers or releasing reagents (Welz and Sperling, 1999).

Electrothermal Atomizers The term *electrothermal atomization* (*ETA*) refers to an atomizer that is made of a material of relatively high specific resistance, which is heated by application of a high current. Several ET atomizers have been described, differing mainly in the design and in the material from which the atomizer was made. Nowadays, essentially all of the commercially available ET atomizers are made of graphite, although other devices, such as tungsten coils, have also been used successfully (Berndt and Schaldach, 1988; Silva *et al.*, 1996). For simplicity reasons, graphite tube atomizers are discussed exclusively in this section. The GF atomizer has originally been proposed by L'vov (1961) and later been simplified by Massmann (1968); the first commercial atomizer of this type was introduced in 1970. The main advantages of this atomizer are that the entire sample portion that is introduced into the graphite tube is atomized typically within 1–2 seconds and the analyte atoms remain in the absorption volume much longer, resulting in an increase in sensitivity of 2–3 orders of magnitude, compared to flame atomizers (Welz and Sperling, 1999). Another important feature of this atomizer is that not only liquid and dissolved samples can be analyzed but also gaseous and solid samples directly (Welz *et al.* 2007b), resulting in further increase in sensitivity and greatly simplified sample preparation.

A GF atomizer consists of a cylindrical graphite tube, typically 20–25 mm long with a diameter of about 5 mm. A small orifice is usually present, through which the (liquid) sample is introduced. The tube is positioned between two cooled graphite electrodes, and acts as a resistance, reaching temperatures as high as 2700 °C. An inert gas (argon) constantly flows around the tube, protecting it from contact with the outside air and, consequently, from burning at high temperatures. An additional internal gas flow is used to eliminate the solvent and matrix vapors during thermal pretreatment of the sample. A *temperature program* is usually applied, consisting of four essential stages: *drying*, where a sufficiently high temperature is applied to eliminate the solvent; *pyrolysis*, where the intention is to eliminate the matrix components without vaporizing the analyte; *atomization*, where the temperature is increased rapidly in order to promote the formation of the maximum concentration of analyte atoms in the absorption volume. The internal gas flow is normally interrupted in this stage to increase the residence time of analyte atoms in the absorption volume. The last stage is a *cleaning* stage, where all matrix and analyte residues are eliminated prior to the introduction of the next sample.

While the temperature, heating ramp, and hold time of all stages of the temperature program require optimization, the two most critical parameters are pyrolysis and atomization. Firstly, a *pyrolysis curve* is established plotting the integrated absorbance signals obtained at a set atomization temperature against the pyrolysis temperature, which is increased in increments of typically 100 °C. This curve usually exhibits a plateau up to a maximum temperature above which the signal begins to drop, indicating analyte losses in the pyrolysis stage as shown in Figure 13.11(a). Secondly, using the maximum pyrolysis temperature at which no analyte losses occur, the atomization temperature is increased gradually, and at least for the more volatile elements a maximum is obtained, as shown in Figure 13.11(b).

During the first decade after its introduction, GF AAS was considered a technique that is subject to numerous difficult-to-control interferences, which was mostly due to the fact that it was largely unknown how to use the technique properly. Slavin, Manning and Carnrick (1981), based on research of L'vov (1978), introduced the stabilized temperature platform furnace (STPF) concept, which was the key to essentially interference-free GF AAS analysis. The most important components of the concept were (i) atomization of the sample from a graphite *platform* inserted into the graphite (instead of from the tube wall) in order to delay atomization until the tube has reached its final temperature; (ii) integration over the *peak area* of the transient signal (instead of using peak height) in order to compensate for matrix influences on the kinetics of atom release; (iii) use of *chemical modifiers* in order to avoid low-temperature analyte losses due to matrix components. The last topic has been treated in a large number of publications (Tsalev, Slaveykova and Mandjukov, 1990); a mixture of Pd and Mg nitrates, co-injected with the sample, was proposed as a *universal chemical modifier* (Schlemmer and Welz, 1986), and its use has been demonstrated for over 20 elements (Welz, Schlemmer and Mudakavi, 1992). In the meantime, *permanent chemical modifiers* are investigated increasingly, where noble metals, such as Pd, Ir, Ru, or Rh, and carbide-forming elements, such as W, Zr, Th, and Ta, or mixtures of both, are used as a kind of surface coating of the graphite platform to stabilize the analyte for a large number of consecutive determinations.

One aspect that was not included in the original STPF concept, but which turned out later to be another very decisive parameter, was the spatial isothermality of the graphite atomizer. In the original concept of Massmann, which has been adopted by all GF manufacturers in the following years, the graphite tube was contacted at its ends and heated longitudinally. As the contacts were cooled, this resulted in a significant temperature gradient along the graphite tube, which was the reason for condensation of matrix and analyte residues on the cool ends, causing severe background absorption and memory effects. *Transversally heated atomizers* solved this problem and should

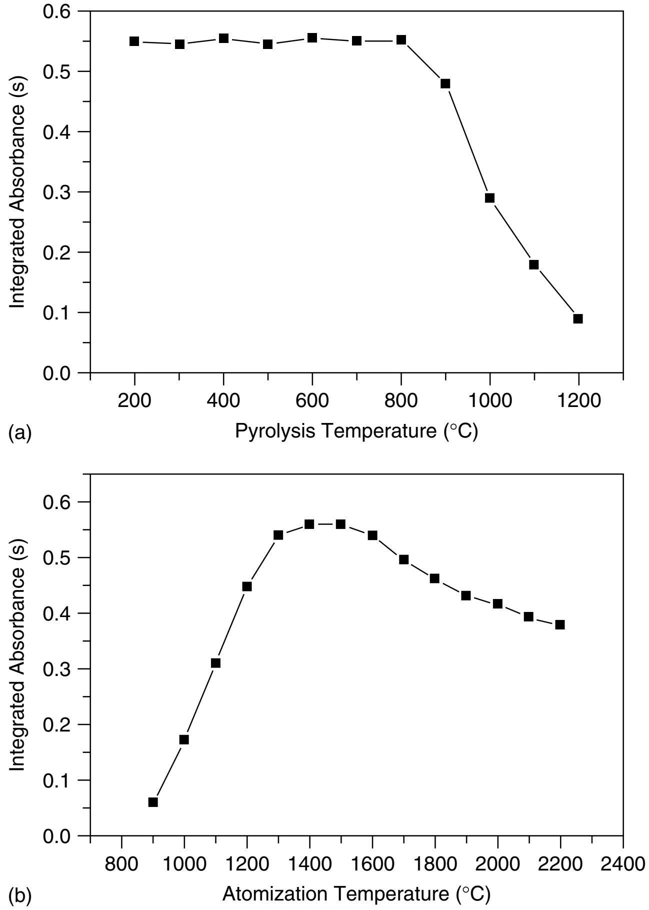

Fig. 13.11 Typical pyrolysis and atomization curves for GF AAS; (a) pyrolysis curve and (b) atomization curve; for details see text.

be preferred over longitudinally heated ones. The schematic design of such an atomizer tube is shown in Figure 13.12.

Atomizers for Chemical Vapor Generation

Chemical vapor generation (*CVG*) is actually a general term for several sample preparation and introduction techniques, where the analyte is converted into a gaseous compound using a chemical reaction. This gaseous compound may then be introduced into different atomizers for atomization and measurement of the absorbance. The two most important techniques are the cold vapor (CV) technique for the determination of mercury and the hydride generation (HG) technique for the determination of elements that form volatile hydrides, mainly As, Bi, Sb, Se, Sn, and Te. In the former technique, mercury (II) is reduced to the element using stannous chloride according to

$$Hg^{++} + Sn^{++} \rightarrow Hg^{0} + Sn^{4+} \quad (13.5)$$

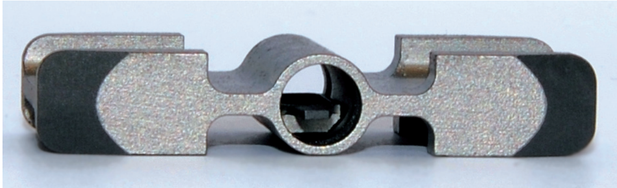

Fig. 13.12 Transversally heated graphite tube for GF AAS. (With kind permission of Analytik Jena AG, Jena, Germany.)

Other reducing agents, such as sodium tetrahydroborate (THB), may be used as well. As mercury is reduced to the element in this reaction, and as mercury has a significant vapor pressure already at room temperature, cold vapor atomic absorption spectrometry (CV AAS) does not need an atomizer. The mercury vapor can simply be transferred to an absorption cell using a flow of gas, where the absorbance can be measured, a procedure that has been described by Hatch and Ott (1968). Alternately, it can be collected by amalgamation on a precious metal, such as gold gauze, and liberated by heating in order to increase the sensitivity. Another way of preconcentrating mercury is in a graphite tube treated with a permanent modifier and atomization using GF AAS. This preconcentration also eliminates interferences due to different release kinetics of the vapor from the solution.

The formation of volatile hydrides of arsenic and a few other elements upon reaction with zinc in acid solution is known as the *Marsh and Gutzeit tests* since the nineteenth century. Holak (1969) proposed this technique for the determination of As by AAS. A major breakthrough came with the introduction of sodium THB as the reducing agent (Braman, Justen and Forebank, 1972), which increased the number of elements that could be determined to eight. The mechanism of hydride formation was, for a long time, believed to be due to "nascent hydrogen," a mechanism that has now been ruled out (D'Ulivo *et al.*, 2004a; D'Ulivo, Onor and Pitzalis, 2004b) In fact, it is due to direct interaction between the analyte and THB, resulting in hydroborane intermediates that will later decompose to generate the volatile species. Another recent advance in this technique is that the number of elements that form volatile compounds with THB has increased to more than 15 (Guo *et al.*, 2004; Sturgeon, Guo and Mester, 2005), although not all of these reactions might be of practical analytical importance.

Initially, the generated hydrides were introduced into a flame for atomization, which, however, did not result in sufficiently high sensitivity. For about two decades, the heated quartz tube atomizer (QTA), an electrically or flame-heated quartz tube has been the preferred atomizer for hydride generation atomic absorption spectrometry (HG AAS), mostly because of its high sensitivity. It took some time until the mechanism of atomization in the QTA was understood, as thermal dissociation could be excluded as the mechanism, because atoms of As, Se, and so on, could not exist at temperatures $<1000\,^{\circ}\mathrm{C}$ thermodynamically. Later, it has been shown that atomization occurs in a cloud of hydrogen radicals that is formed in the entrance part of the T-tube in a reaction between hydrogen that is generated in the reaction of the acid sample solution with THB and traces of oxygen (Dědina, 1988).

The QTA has been increasingly replaced by the GF atomizer over the past decade, mostly because preconcentration in a graphite tube, treated with a permanent modifier, increases the sensitivity and eliminates kinetic interferences due to the release of the hydride from the solution. The major advantage of HG AAS is the separation of the analyte from the matrix, which largely eliminates interferences in the atomization stage. The major problems are interferences in the liquid phase that impede the formation or liberation of the gaseous compound from the solution. These interferences are mostly caused by transition elements of Group VIII and Group I, which are reduced by THB, for example, to the finely dispersed metal that adsorbs and decomposes the hydrides (Welz and Melcher, 1984(a, b, c); Welz and Schubert-Jacobs, 1986). Another problem of CVG is that the analyte has to be present in ionic form and in a well-defined oxidation state, as, for example, only tetravalent selenium and tellurium form a hydride, and in the case of As and Sb the trivalent form reacts faster and gives better sensitivity. This means that CVG generally requires complete sample digestion and a prereduction step in order to give reliable results.

13.3.3.2 Spectrometers for Line Source AAS

In line source atomic absorption spectroscopy (LS AAS), the high resolution required to measure atomic absorption is provided by the radiation source that emits radiation only within the narrow spectral interval that can be absorbed by the analyte atoms. As there is practically only the spectrum of the analyte element emitted by the source, the only task of the monochromator is to isolate the analytical line from other lines emitted by the source.

Radiation Sources for LS AAS The line source used most frequently in AAS is the *hollow cathode lamp* (HCL), a lamp that has been described as an emission source as early as 1916 (Paschen, 1916). However, in order to become applicable for routine use in AAS, this lamp had to be modified significantly (Russell and Walsh, 1959, Jones and Walsh, 1960), and was optimized further in the following years (Manning and Vollmer, 1967). The schematic design of an HCL is shown in Figure 13.13. An HCL is a spectral lamp with a hollow, cylindrical cathode made of, or containing the element of interest; the anode is mostly made of tungsten or nickel. The glass cylinder of the lamp is filled with an inert gas, usually neon or argon, at a pressure of about 1 kPa; for elements that have their main analytical line in the UV range, the front window is mostly made of quartz. HCL often also contain some insulation in order to concentrate the discharge to the inside of the cathode. When a voltage of 100–200 V is applied across the electrodes, a GD takes place in the reduced-pressure gas atmosphere, as described for the GD excitation source (refer to Section 13.3.2.1, Glow Discharges). As a result, the emission spectrum of the element of interest is obtained, and the radiation beam can be directed toward the absorption volume

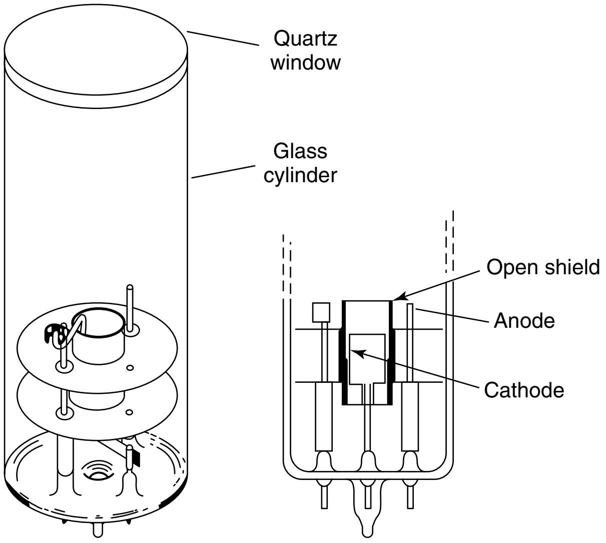

Fig. 13.13 Schematic design of a hollow cathode lamp for AAS. (From Welz and Sperling (1999), p. 107; reproduced with permission from Wiley-VCH.)

in the atomizer, where the absorption process takes place.

For some of the volatile elements, such as Hg, and those that have their main lines in the vacuum-UV range, particularly As and Se, the quality of HCL and their emission intensity are not always satisfactory. In these cases, *electrodeless discharge lamps* (EDLs) might be used with advantage. An EDL consists of a sealed quartz bulb filled with the element of interest (or a compound of it, such as an iodide) and an inert gas. The bulb is placed inside a metallic coil, to which an RF power is applied, generating an ICP discharge. This promotes volatilization of the element inside the quartz bulb; further dissociation and excitation will be induced by the plasma, resulting in the emission of the wavelengths characteristic for the element. The emission intensity of an EDL is typically 20–50 times higher than that of an HCL, resulting in better precision and lower LOD. The disadvantages of this lamp type are the need of an additional power supply and the long warmup times until they reach stable emission.

Other radiation sources, such as diode lasers (Zybin *et al.*, 2005; Hergenröder and Niemax, 1988), have also been investigated with some success, but their use remains restricted to research instruments.

Monochromators for LS AAS The role of the monochromator in LS AAS is to isolate the analytical line from all other lines emitted by the radiation source. Medium-resolution grating monochromators in Czerny–Turner (refer to Section 13.3.2.2) or the simpler Littrow mounting are used most frequently. A particularly important aspect is the *spectral bandwidth,* $\Delta\lambda$, which corresponds to the radiation interval that effectively reaches the detector. The spectral bandwidth is determined by the width of the entrance slit, the *geometric slit width*, s, which controls the amount of radiation that enters the monochromator, and by a characteristic of the dispersing device, the *reciprocal linear dispersion*, $d\lambda/dx$, (dimension: nanometers per millimeter) according to

$$\Delta\lambda = s\frac{d\lambda}{dx} \tag{13.6}$$

The reciprocal linear dispersion depends on the ruling density and the ruled area of the grating; the smaller the numerical value of the reciprocal linear dispersion, the wider can be the geometric slit width in order to obtain a given spectral bandwidth. A wide geometric slit width means that a great amount of radiation can enter the monochromator, resulting in a good S/N ratio. The spectral bandwidth is determined by the spectral environment of the analytical line; it should be chosen as wide as possible, and as narrow as necessary to exclude other lines emitted by the radiation source. Typical values to fulfill this requirement are between 0.2 and 2 nm.

Detectors for LS AAS The role of detectors in AAS is to proportionally convert optical radiation (photons) into an electrical signal; PMT are mostly used for that purpose, although solid-state detectors provide better S/N ratios (for details refer to Section 13.3.2.3).

Spectral Interferences and Background Correction in LS AAS Spectral interferences due to direct or partial *line overlap* are relatively scarce in AAS due to the much smaller number of absorption lines compared to the number of emission lines, particularly in high-temperature excitation sources. However, there are a few well-known examples, such as the overlap of the 213.859-nm secondary iron line with the main analytical line for zinc at 213.857 nm. There is essentially no way to correct for this kind of interference in LS AAS, which means that the determination of Zn in the presence of high iron concentration is always affected by a systematic error.

Other spectral interferences encountered in AAS are *radiation scattering* at particles in the absorption volume, an interference that is mostly limited to GF AAS, and *molecular absorption* due to nondissociated matrix components. The latter has to be classified into dissociation continua, that is, molecules are dissociated by the incident radiation, and electron excitation spectra. In the latter case, we again have to distinguish between electron excitation spectra of diatomic molecules, which exhibit a pronounced rotational fine structure, and those of tri-atomic molecules, the fine structure of which cannot be resolved, so that they appear as broadband spectra.

There is no way to measure only atomic absorption in the presence of any kind of background absorption. In LS AAS, it is necessary, first to measure total absorption and then background absorption, and to calculate atomic absorption by difference in a fast sequential process.

The first system that was proposed to correct for background absorption in AAS used a *deuterium lamp* as a second radiation source in addition to the line source (Koirtyohann and Pickett, 1965). The radiation of the two sources was passed alternately through the flame, typically at a frequency of 50–60 Hz. This system assumed that background absorption is spectrally continuous, at least within the section of the spectrum that is passing the exit slit (0.2–2 nm), whereas atomic absorption occurs only within a very narrow spectral interval (a few picometers). Under this premise, essentially only the background will attenuate the continuum radiation emitted from the deuterium lamp, as atomic absorption represents a fraction of <1% of the spectral interval. The line source, in contrast, will measure total absorption, that is, atomic and background absorption. A "subtraction" of the signal obtained from the D_2 lamp from the signal of the line source will provide the net atomic absorption signal; Figure 13.14 shows a schematic representation of this system.

Background correction with a deuterium lamp is relatively simple and does not add significantly to the cost of the instrument. However, it increases the noise level, as two radiation sources are used, hence deteriorating the S/N ratio and LOD. Although rapidly changing background signals, as they typically occur in GF AAS, could cause artifacts, the system works reasonably well in the case of continuous background absorption. However, the system fails to correct for any *structured background*, such as the electron transition spectra of diatomic molecules that exhibit rotational fine structure. In this case, the deuterium lamp makes an average of the background absorption over the spectral bandwidth, which is in most cases different from the actual background at the analytical wavelength, resulting in over- or under-correction. Deuterium background correction can actually even be the source of errors when the absorption line of a concomitant element is within the spectral bandwidth without overlapping with the analytical line. If this concomitant element is present at high concentration, it can absorb a significant portion of the continuous radiation without absorbing radiation of the line source, resulting in over-correction, which appears as a negative absorbance signal. The emission intensity of deuterium lamps decreases significantly above 350 nm, so that it

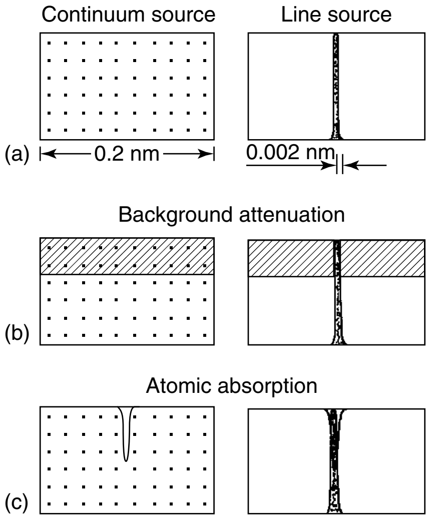

Fig. 13.14 Mode of function of deuterium lamp background correction; (a) the radiant intensity, represented schematically by dots, for the deuterium lamp is distributed over the entire width of the spectral band isolated by the slit (e.g., 0.2–2 nm), while for the line source it is limited to a few picometers; (b) broad-band background absorption attenuates the radiation emitted by both sources to equal degrees; (c) atomic absorption, which is limited to a few picometers, in the first approximation attenuates only the radiation from the line source. (From Welz and Sperling (1999), p. 122; reproduced with permission from Wiley-VCH.)

cannot be used for correction at higher wavelengths.

A more efficient, but also more complex approach for background correction makes use of the *Zeeman effect*, that is, the splitting of electronic levels of atoms (and consequently of spectral lines) under the influence of a magnetic field (De Loos-Vollebregt and de Galan, 1985). The spectral lines split into three components or groups of components: a π component of the same frequency as the original line, and two σ components (σ^+ and σ^-), with slightly higher and lower frequency, as shown in Figure 13.15. In addition to the splitting the components are also polarized, the π components are linearly polarized in a direction parallel to the magnetic field, while the σ components are circularly polarized in a direction perpendicular to the magnetic field. For *Zeeman-effect background correction* (ZBC), an alternating magnetic field is usually applied at the atomizer, and all measurements are made using the line profile emitted by the spectral lamp. The total absorbance (atomic and background) is measured with the magnetic field off, and the background signal is measured with the magnetic field on. In this case, the σ components of the analyte atoms are shifted out of the emission profile of the lamp, and the π components are usually eliminated using a polarizer. Alternately, the magnetic field can be applied parallel to the radiation beam; in this case, the π components become "invisible," so that no polarizer is necessary.

ZBC is almost exclusively used for GF AAS and can be successfully employed for most analytical applications, as it

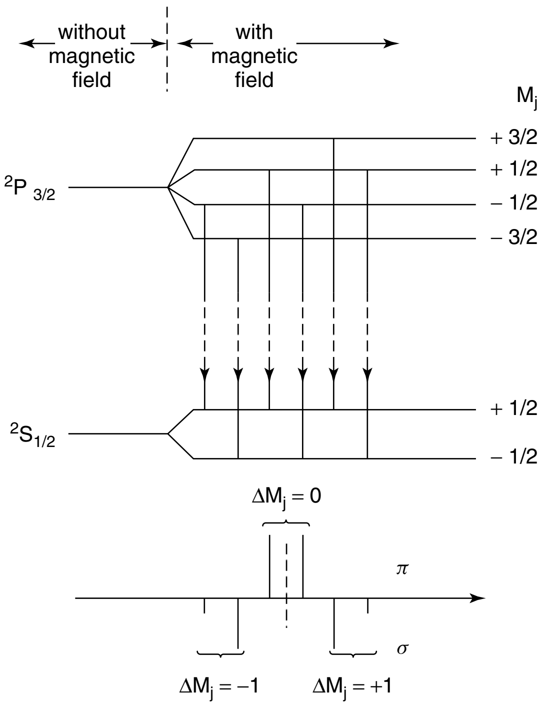

Fig. 13.15 Splitting of the energy levels in a magnetic field with the resulting splitting pattern for the electron transition $^2S_{1/2} \leftrightarrow {}^2P_{3/2}$. (From Welz and Sperling (1999), p. 97; reproduced with permission from Wiley-VCH.)

efficiently corrects for most types of background absorption, including structured background. The only notable exceptions are when the concomitant species, an atom or a diatomic molecule, is also affected by the magnetic field; in this case, the background without and with magnetic field is not the same, which inevitably results in background correction errors. In the case of a near-line coincidence with an absorption line of a concomitant element, the latter obviously also shows Zeeman splitting; in this case, the σ components of the concomitant element might overlap with the emission line even more severely than without magnetic field, causing an even more pronounced spectral interference. The same is true for the spectra of some diatomic molecules, such as the phosphorus suboxide PO (Becker-Ross, Florek and Heitmann, 2000), which also undergo changes in the magnetic field, causing background correction errors.

The sensitivity of AAS instruments with ZBC is lower when compared to other instruments, as the separation of the $\sigma^{\pm}$ components is usually not complete, which means that some atomic absorption will always be measured together with the background and "subtracted" from the total absorption, resulting in lower integrated absorbance signals. For higher analyte concentrations, this may result in the so-called *rollover effect*, which can also be noticed on transient signals that start to split and exhibit two maxima at high concentrations (Figure 13.16). More recently, instruments using a "three-field" mode have been introduced, where in addition to the "zero" field (magnet off) and the high field strength, an adjustable intermediate field can be used in order to deliberately reduce sensitivity and

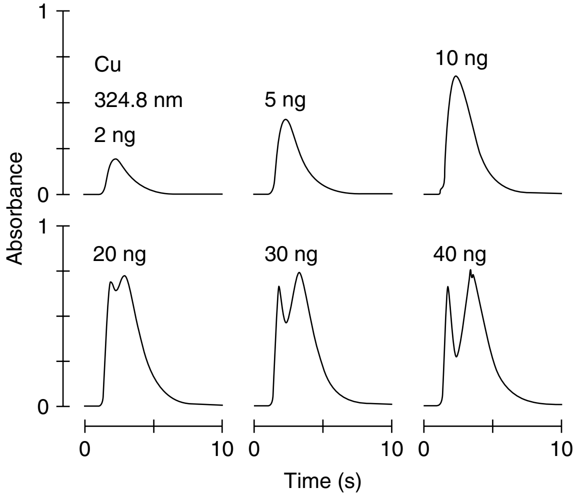

Fig. 13.16 Effect of rollover of the calibration curve on the signal shape for GF AAS; determination of increasing masses of copper in an alternating magnetic at the atomizer. (From Welz and Sperling (1999), p. 131; reproduced with permission from Wiley-VCH.)

increase linearity, making possible the determination of higher concentrations of the analyte without the need for dilution (Gleisner, Eichardt and Welz, 2003).

13.3.3.3 Spectrometers for High-Resolution Continuum Source AAS

Although LS AAS is an established, reliable, and robust analytical technique for a large number of applications, it has been questioned already in the late 1980s that if AAS could survive in the face of strong competition mainly from ICP OES and ICP-MS without a renovation of the basic concept (Hieftje, 1989). The approach that has been proposed was the use of a continuum radiation source, high-resolution spectral sorting devices and completely new detection systems. Although continuum radiation sources have been investigated as an alternative to line sources since the early 1960s (Welz *et al.*, 2005), it was only some 30 years later, when finally components became available, that made it possible to design equipment for high-resolution continuum source atomic absorption spectroscopy (HR-CS AAS) with a performance that was superior to that of LS AAS (Heitmann *et al.*, 1996, Harnly, 1999). The new approach includes a xenon short-arc lamp, a high-resolution double monochromator and a linear CCD array detector, as is shown schematically in Figure 13.17.

Radiation Source for HR-CS AAS The radiation source, a specially-designed high-pressure Xe short-arc lamp with a nominal power of 300 W is operating in a hot-spot mode, as shown in Figure 13.18(a). The hot spot with a diameter of about 0.2 mm reaches a temperature of about 10 000 K, which is the precondition for providing sufficient radiation intensity over the entire spectral range from 190 to 900 nm. Figure 13.18(b) shows that the emission

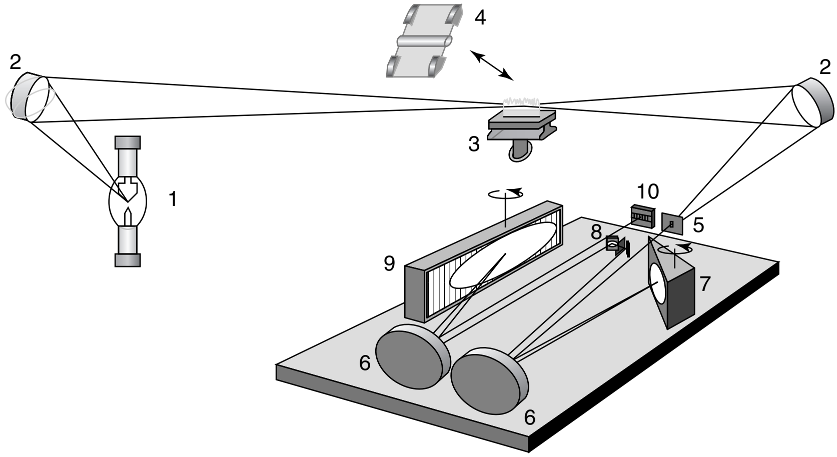

Fig. 13.17 Schematic design of an instrument for HR-CS AAS; 1 – xenon short-arc lamp; 2 – elliptical mirrors; 3 – flame atomizer; 4 – graphite tube atomizer; 5 – entrance slit; 6 – parabolic mirrors; 7 – prism; 8 – intermediate slit; 9 – echelle grating; 10 – CCD detector. (From Welz *et al.* (2003), p. 223; reproduced with permission from the Brazilian Chemical Society.)

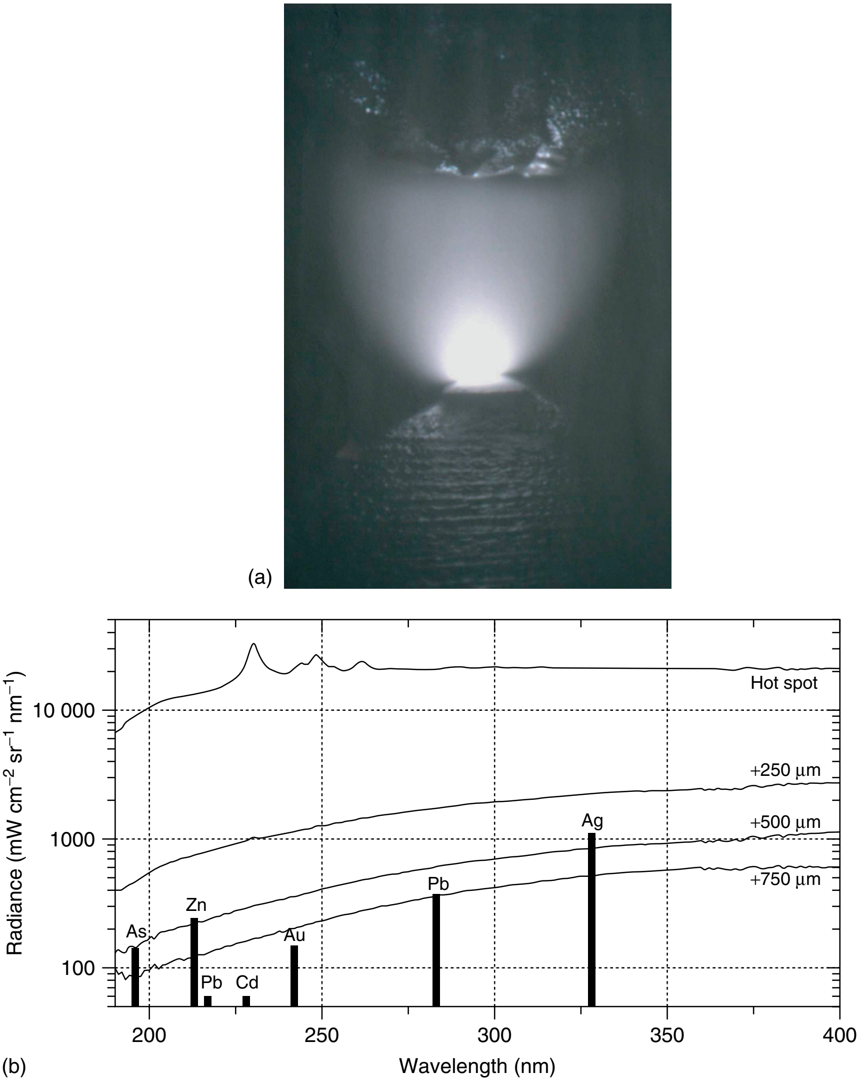

Fig. 13.18 High-pressure Xe short-arc lamp as radiation source for HR-CS AAS; (a) hot spot with a diameter of about 0.2 mm and a temperature of ~10 000 K; (b) wavelength-dependent spectral radiance in the hot spot in comparison to some selected emission lines from HCL. (From Welz *et al.* (2005), pp. 32–33; reproduced with permission from Wiley-VCH.)

intensity of this lamp in the UV range is typically 2 orders of magnitude higher than that of selected HCL and conventional continuum radiation sources. This high radiation intensity has a direct influence on the S/N ratio, and hence on the LOD, as in AAS the noise is inversely proportional to the square root of the radiation intensity. As the position of the hot spot is not stable over time, the radiation emitted by the Xe short-arc lamp is directed toward the atomizer by a set of mirrors, and it is actively stabilized by computer software to assure that the radiation beam is in a stable (central) position in the absorption volume.

Monochromator for HR-CS AAS The high-resolution double monochromator consists of a predispersing prism monochromator and a high-resolving echelle grating monochromator, both in Littrow mounting. The radiation enters the monochromator, is reflected by a parabolic mirror onto the Littrow prism, which has a mirror on its other side, so that the radiation passes the prism twice. The prism is rotated in a way that only that part of the spectrum that contains the analytical line will be reflected to pass the intermediate slit and enter the second monochromator. A second parabolic mirror directs the radiation toward the echelle grating, which provides the high resolution of the small spectrum interval selected by the intermediate slit, which is then reflected onto the detector without passing an exit slit. This double monochromator provides a resolution of $\lambda/\Delta\lambda \approx 140\,000$, corresponding to a pixel resolution better than 2 pm at 200 nm. This resolution is some 2 orders of magnitude higher than that of a conventional LS AAS monochromator, and also better than that of typical ICP OES mono- and polychromators.

Detector and Measurement Principle in HR-CS AAS After the radiation has been highly resolved by the echelle grating, it is directed to the detector, which is typically a UV-sensitive linear CCD array with 512 or 588 pixels, 200 of which are used for analytical purposes. All pixels are illuminated for typically 1–10 milliseconds and read out simultaneously, and as each pixel is equipped with an individual amplifier, the system actually operates with 200 individual detectors. Each pixel detects a small portion of the highly resolved spectrum around the analytical line, as shown in Figure 13.19 for the primary absorption line of cadmium. The center pixel measures the absorbance at the line core and the neighbor pixels measure the absorbance at the line wings. This means that in HR-CS AAS the measured absorbance becomes a function of the pixel width, whereas in LS AAS it is a function of the width (profile) of the line emitted by the radiation source. In contrast to LS AAS, however, there is the possibility in HR-CS AAS to add the absorbancies measured at several pixels and arrive at the *wavelength selected absorbance* (WSA), $A_{\Sigma n}$, for steady-state signals, and the *peak volume selected absorbance* (PVSA), $A_{\Sigma n,\mathrm{int}}$, for transient signals, where n is in both cases the number of pixels used for measurement (Heitmann *et al.* 2007). The number of pixels that are finally used for measurement has to be optimized, as each pixel also has a contribution to the noise. For narrow absorption lines, the optimum S/N ratio is usually obtained with three pixels, whereas for wider lines the sum of up to seven pixels might be used.

The availability of 200 independent and simultaneously operating detectors adds a third dimension, the spectral resolution, to the traditional absorbance-over-time measurement obtained by LS AAS, which means that three signal evaluation modes are available: first, the traditional absorbance over time can be visualized for each individual pixel of the detector; secondly, the absorbance as a function of the wavelength can also

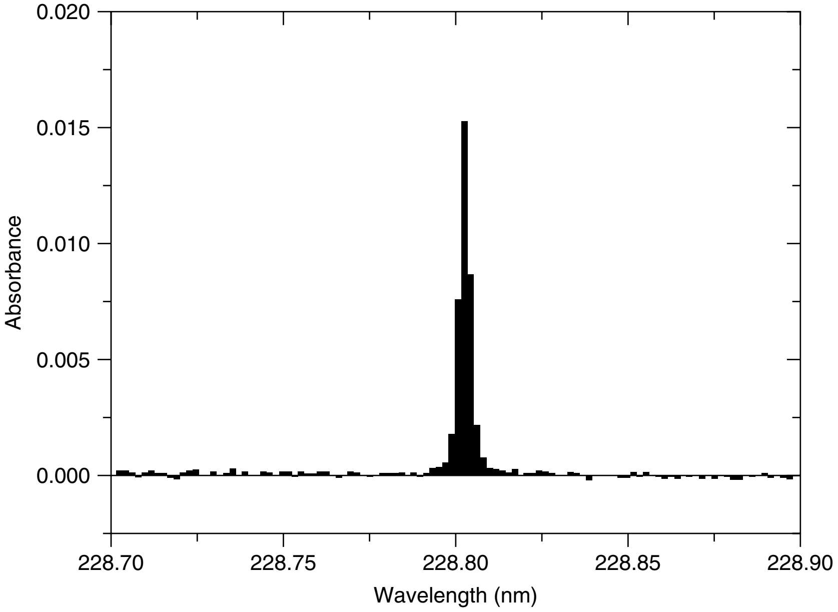

Fig. 13.19 Absorption spectrum in the vicinity of the Cd resonance line at 228.802 nm recorded simultaneously with 200 pixels of a CCD array detector. (From Welz *et al.* (2003), p. 223; reproduced with permission from the Brazilian Chemical Society.)

be visualized, showing all the spectral events in the vicinity of the analytical line; and thirdly, a time-resolved three-dimensional spectrum can be obtained, showing the entire highly resolved spectrum around the analytical line, as shown in Figure 13.20. With such information, any spectral event occurring in addition to analyte absorption, such as absorption by concomitant elements or structured molecular absorption can be detected, and appropriate measures can be taken in order to avoid or correct for spectral interferences (Welz *et al.*, 2005).

Background and Baseline Correction In HR-CS AAS, no additional instrumental devices, such as secondary radiation sources or magnetic fields, are necessary for background correction; any kind of background correction, and also the correction for baseline noise due to lamp flicker noise, and so on, is carried out with detector pixels that are not used to measure analyte absorption. This means that background measurement, background correction, and baseline correction are strictly simultaneous with the measurement of atomic absorption, which is in contrast to LS AAS, where these measurements and corrections are sequential.

Initially, we have to distinguish between continuous (within the spectral section that reaches the detector) and discontinuous absorption (refer to Section 13.3.3.2, Spectral Interferences and Background Correction in LS AAS). Any spectrally continuous increase or decrease of the radiant flux over time is measured identically at all pixels of the detector, and can be eliminated

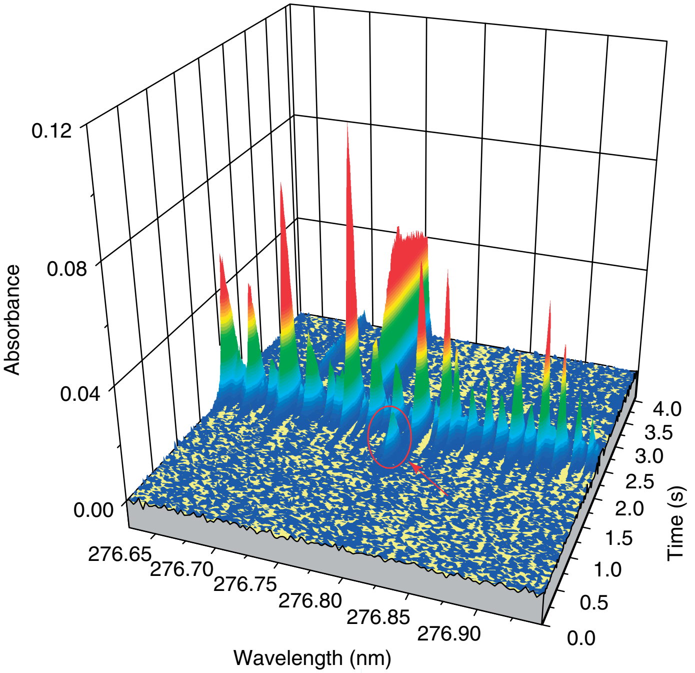

Fig. 13.20 Time- and wavelength-resolved absorption spectrum for a marine sediment recorded in the vicinity of the Tl absorption line at 276.787 nm using HR-CS GF AAS; the Tl absorption, which is marked by a circle, is temporally and spectrally resolved from the fine-structured molecular absorption and from an iron absorption line that appears only late in the atomization cycle.

using correction pixels. This includes any fluctuation in the lamp intensity (arcs are notoriously instable), but it also includes any continuous background, such as radiation scattering and molecular absorption without fine structure, as the entire radiation is passing through the atomizer. Any events affecting all pixels at the same time will be readily identified and corrected automatically, resulting in a smooth baseline and an absorption signal with an extremely low noise level, as shown in Figure 13.21 for the determination of Pb using high-resolution continuum source graphite furnace atomic absorption spectrometry (HR-CS GF AAS).

After correction for any continuous change in the radiant flux remains the discontinuous absorption of radiation. Analyte absorption is obviously discontinuous, as it occurs within a few picometers, and 3–5 pixels are typically sufficient for its measurement. If more than one absorption line of the same or of different elements is within the wavelength interval that reaches the detector, this absorption is measured as well and appears in the wavelength-resolved image. No measure is necessary if there is no spectral overlap between the analyte line and a concomitant line, as at high resolution only the signals in the center of the analytical line are

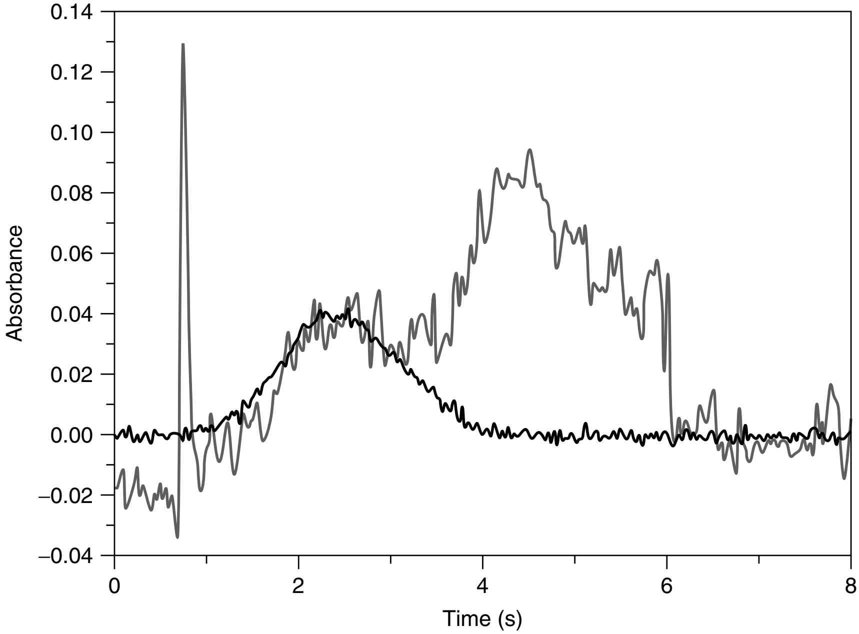

Fig. 13.21 Absorbance-over-time signal recorded for Bovine Muscle certified reference material at the Pb resonance line at 217.001 nm using one pixel only; *gray line*: without background correction; *black line*: after automatic correction for all spectrally continuous fluctuations of the intensity. (From Borges *et al.* (2006).)

considered. In the case of GF AAS there is an additional possibility, even in the case of direct line coincidence, to separate the absorbance in time, in case the analytes have significantly different volatility. Other sources of discontinuous absorption are electron excitation spectra of diatomic molecules, such as NO, PO, CS, and SiO, which exhibit pronounced rotation fine structure. These spectra can be easily recognized due to visualization of the spectral region in the vicinity of the analytical line. In this case, the same rules apply as in the case of a concomitant absorption line, i.e., no measure is necessary if there is no spectral or temporal overlap between the analyte line and the molecular absorption "lines."

In the case that analyte and concomitant atomic or molecular absorption overlap spectrally and cannot be separated in time, the software allows the user to correct for the interference using a least-squares algorithm. Figure 13.22 shows the well-known coincidence of the primary resonance line for Zn at 213.857 nm with a secondary Fe line at 213.859 nm, which cannot be separated spectrally, as the line width is greater than their distance. This interference cannot be corrected at all in classical LS AAS. Fortunately, Fe has a second absorption line at 213.970 nm within the spectral interval that reaches the detector, which can be used for correction. As the absorbance ratio between the two lines is constant and known, it is sufficient to measure the absorbance at the 213.970-nm line, calculate the absorbance at the 213.859-nm Fe line, and subtract this

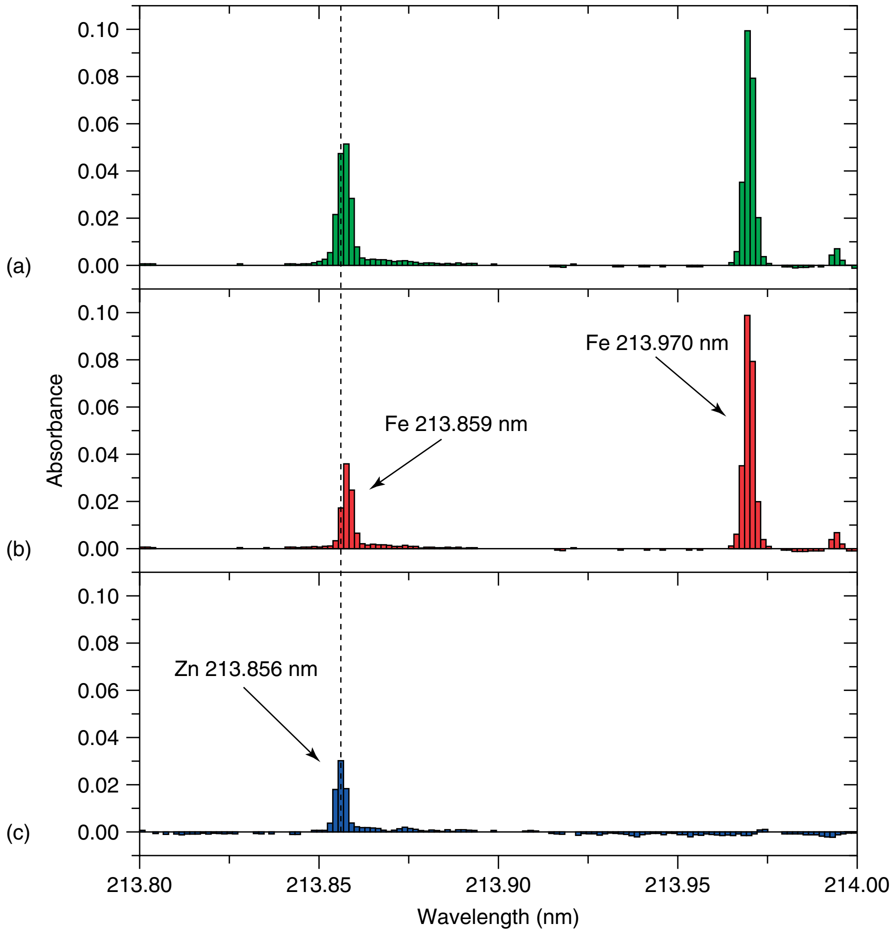

Fig. 13.22 Least-squares correction of the spectral interference due to direct-line overlap between the Zn resonance line at 213.856 nm and the secondary Fe absorption line at 213.859 nm: determination of 0.3 mg L^{-1} Zn in the presence of 1000 mg L^{-1} Fe; (a) integrated absorbance spectrum for Zn in iron matrix without correction; (b) spectrum for pure iron used for correction; (c) resulting spectrum after correction. (From Heitmann, U., ISAS – Institute for Analytical Sciences, Department of Interface Spectroscopy, Berlin, Germany, reproduced with permission.)

value from the total absorbance to get the net absorbance due to Zn.

The same algorithm can be used to correct for molecular spectra with rotational fine structure. In this case, a synthetic solution is prepared with a compound that generates the desired reference spectrum in the "atomization" cycle (such as $NH_4H_2PO_4$ to generate PO). This reference spectrum is stored in the software and "subtracted" from the sample spectrum (Welz *et al.*, 2005). This process can be repeated in case there is more than one diatomic molecule or concomitant atom causing spectral interference.

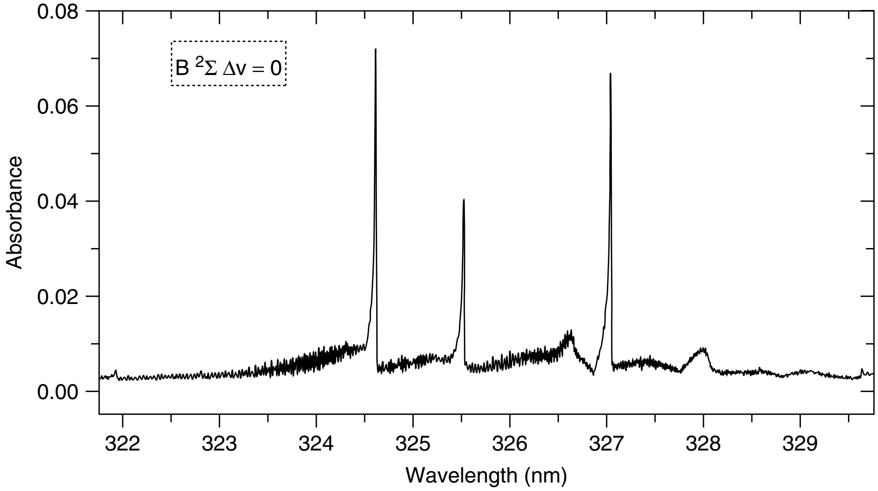

Fig. 13.23 Detail of the molecular spectrum of the phosphorus monoxide PO in the range between 322 and 329 nm, corresponding to the electronic transition X 2Π → B 2Σ. (From Welz *et al.* (2005), p. 195; reproduced with permission from Wiley-VCH.)

Advantages and Applications of HR-CS AAS There are several advantages of HR-CS AAS over conventional LS AAS, which obviously include the use of a single radiation source for all elements instead of a separate source for each analyte. The high emission intensity of the Xe short-arc lamp has no influence on the measured absorbance, which, according to Eq. (13.4) is proportional to the ratio of the incident and the transmitted radiant power; however, the emission intensity has an influence on the S/N ratio, and hence on the LOD, as the noise is inversely proportional to the square root of the radiant power. The visibility of the spectral environment around the analytical line at high resolution is providing a new dimension of information that has previously been unknown, and which can readily be used for method development and to avoid interferences. The truly simultaneous correction for all wavelength-independent fluctuations of the radiant power, including continuous background absorption, have been discussed in Section 13.3.3.3, Background and Baseline Correction, together with the correction capabilities for discontinuous background. Obviously, HR-CS AAS can be used for any application traditionally assigned to LS AAS, but it has also been shown to improve and facilitate the analysis of complex samples, especially using direct solid sampling (Welz *et al.*, 2007b). As the use of a continuous radiation source makes any wavelength between 190 and 900 nm available for analytical purposes, HR-CS AAS is not limited to atomic absorption, but can also be used for the determination of nonmetals, such as phosphorus, sulfur, and the halogens using the absorption spectra of diatomic molecules, such as PO, which is shown in part in Figure 13.23, CS, AlF, and so on (Huang *et al.*, 2006(a, b, c); Huang *et al.*, 2008; Heitmann *et al.*, 2006). The analytical applications of HR-CS AAS have been recently reviewed by Welz *et al.* (2007a).

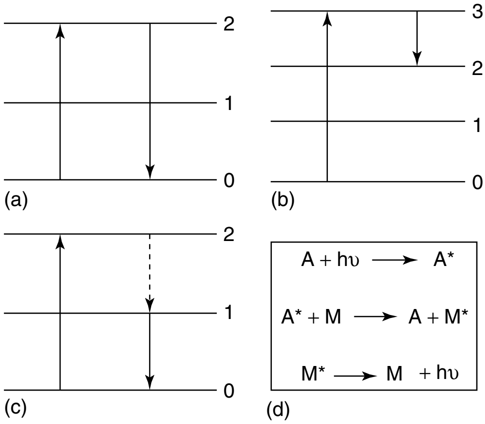

Fig. 13.24 Schematic presentation of important processes for AFS; (a) resonance fluorescence; (b) direct-line fluorescence; (c) stepwise-line fluorescence; (d) sensitized fluorescence. (Adapted from Greenfield (1994), p. 566, reproduced with permission of The Royal Society of Chemistry.)

13.3.4
Atomic Fluorescence Spectrometry

Atomic fluorescence was studied as early as 1902 by Wood (1902), and Nichols and Howes (1924) considered fluorescence in flames, but neither of these publications dealt with analytical applications. Winefordner and Vickers (1964) were the first to investigate the possibilities of using AFS as a practical analytical technique. Veillon *et al.* (1966) demonstrated the usefulness of continuum radiation sources for AFS, whereas West (1967) investigated EDL. Further information about the research activities during that period might be obtained from a review article by Winefordner and Mansfield (1967). The major advantage of AFS was the significantly better *S*/*N* ratio, and hence better LOD compared to FAAS. Nevertheless, AFS has never found general application as an analytical technique. Among the reasons for that might be that the best *S*/*N* ratios were obtained in low-temperature flames that were more subject to matrix effects. The main reason, however, was that the research in AFS was coinciding in time with the development of GF AAS and ICP OES, and none of the instrument manufacturing companies was prepared to invest in yet another technique. Nowadays, AFS has found a niche in combination with chemical vapor generation for the determination of mercury and some hydride-forming elements, such as arsenic and selenium.

13.3.4.1 General Principles

Atomic fluorescence is a radiational deactivation process, which occurs after the excitation of free atoms by the absorption of radiation of characteristic wavelength from an excitation source. Atomic fluorescence can occur by a number of different processes, but only four of them are considered to be of importance and are schematically represented in Figure 13.24 (Browner, 1974; Robinson, 1990; Greenfield, 1995).

Resonance fluorescence (Figure 13.24a) occurs when atoms absorb and reemit radiation of the same wavelength. Lines corresponding to transitions between excited electronic states and the ground state of an atom constitute most analytically useful examples of resonance fluorescence, since the transition probabilities for resonance transitions are

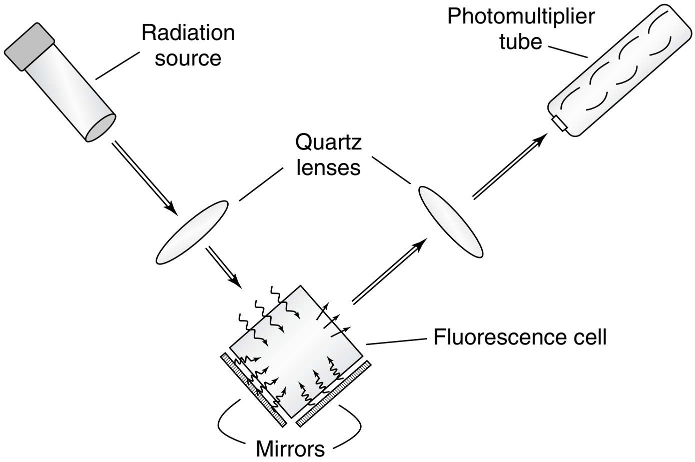

Fig. 13.25 Schematic design of an atomic fluorescence spectrometer.

usually much greater than those for other transitions.

Nonresonance fluorescence occurs when the exciting line and the observed fluorescent line are of different wavelengths. *Stokes direct-line fluorescence* results when the exciting and the fluorescent lines originate from optical transitions with a common upper level (Figure 13.24b). An atom is excited (usually from the ground state) to a higher excited state, and then undergoes a direct transition to a metastable level above the ground state, emitting a fluorescent line at longer wavelength, compared to that of the exciting radiation. When the upper level of the exciting and the emitted lines are different, *Stokes stepwise-line fluorescence* is said to occur (Figure 13.24c). Atoms excited by radiation lose part of their energy, usually by collisional deactivation, before emitting fluorescence radiation of longer wavelength. *Anti-Stokes fluorescence* (not shown here) occurs when the wavelength of the fluorescent line is shorter than that of the exciting line. The deficit in photon energy is usually supplied thermally, and the term *thermally-assisted* fluorescence can be used.

In addition to the above-discussed types of atomic fluorescence, another, although less usual type exists, called *sensitized fluorescence*. In this process, an atom or molecule excited by absorption of electromagnetic radiation (donor) transfers its excitation energy to the sample atom (acceptor) by collision. The acceptor then undergoes radiative deactivation, resulting in atomic fluorescence. The process is schematically represented in Figure 13.24(d).

13.3.4.2 **Instrumentation**

The basic setup of an AFS instrument consists in a radiation source, an atomizer, a spectral sorting device, a detector, and devices for signal processing and readout, as shown in Figure 13.25. The detection of the fluorescence radiation should always be misplaced in relation to the incident radiation, that is, for instance, be positioned at a 90° angle, in order to prevent that photons emitted by the radiation source reach the detector.

Atomizers for AFS The physical and chemical environments within an atomizer have a profound effect upon the magnitude of the fluorescent flux emitted from the atomizer in addition to its influence on atomization efficiency. In practice, the excited atom is almost inevitably subject to radiationless deactivation due to collisions with other species present in the atomizer. These so-called *quenching collisions* are characterized by a quantum yield, Y, which is the number of quanta emitted as fluorescence to the number of quanta absorbed and capable of producing fluorescence. Quantum yields were calculated for several analytes, gas mixtures, and temperatures (Sychra, Svoboda and Rubeška, 1975); for air–acetylene and air–hydrogen flames Y was found to be typically below 0.1; values close to $Y = 1$ could only be obtained in hot argon environment, which would make ET atomizers an ideal source for AFS.

A variety of atomizers have been used for AFS, including flames (Sychra, Svoboda and Rubeška, 1975), graphite furnaces (Massmann, 1968), and ICP (Greenfield, 1994); however, there are no instruments commercially available with such configurations. The only instrumentation that is available nowadays for AFS are specialized apparatus for the determination of mercury (Cai, 2000) using the cold-vapor technique, which does not require any atomizer, and for the hydride-forming elements (refer to Section 13.3.3.1, Atomizers for Chemical Vapor Generation). In the latter case special atomizers are used, such as small hydrogen diffusion flames, where the atomization occurs by a chemical process rather than a thermal one. The interferences that might be observed during generation and separation of the gaseous analyte species from the liquid phase are identical to those observed for AAS (refer to Section 13.3.3.1, Atomizers for Chemical Vapor Generation).

Radiation Sources The intensity of the fluorescence signal is directly proportional to the intensity of the incident radiation, that is, the excitation source has a major influence on the sensitivity that can be obtained by AFS. This dependence can be mathematically expressed by means of the simplified Eq. (13.8), where Φ_0 and Φ_F represent the incident and the fluorescence (emitted) radiant power, κ_0 corresponds to the atomic absorption coefficient, ℓ is the length of the absorption cell, and φ is the quantum efficiency of the fluorescence process (Robinson, 1990).

$$\Phi_F = \Phi_0(1 - e^{-\kappa_0 \ell})\varphi \qquad (13.7)$$

Significant research in AFS was therefore done for the development of high-intensity radiation sources, particularly electrodeless discharge lamps (Sychra, Svoboda and Rubeška, 1975). Modern instruments usually employ a line radiation source, such as a hollow cathode lamp or an electrodeless discharge lamp; these lamps are similar to those used for AAS (refer to Section 13.3.3.2, Radiation Sources for LS AAS). Other sources, such as specially designed mercury vapor lamps, might be used as well.

When lasers are used as an excitation source in AFS, the technique is called *laser-excited atomic fluorescence spectrometry* (*LEAFS*). Among the advantages that are associated with the use of lasers are the higher radiant power compared to conventional line sources, resulting in high sensitivity, and the extended linear dynamic range, which may cover up to 7 orders of magnitude, and the possibility to perform sequential multielement analysis, using oscillator-based lasers (Stchur *et al.*, 2001; Hou *et al.*, 1998). Disadvantages include the high cost and complexity of laser systems.

Spectral Sorting Devices and Detectors One of the advantages of AFS is the selective character of the fluorescence radiation to be monitored, that is, usually only the analyte element can absorb the radiation emitted by the primary source if a line source is used. This means that the monochromator might even be a simple nondispersive system, that is, a filter. The monochromator used in AFS has the sole function of isolating the analytical fluorescence wavelength from other wavelengths that might be emitted by concomitants or by the analyte. Lasers require more sophisticated optical devices, such as beam expanders and diffraction gratings (Hou *et al.*, 1998).

The detectors used in AFS are similar to those used in AAS and OES. The PMT is by far the most frequently used detection device, although solid-state detectors, such as the CCD, have also been employed (for details refer to Section 13.3.2.3).

Interferences Nonspectral interferences are obviously independent of the detection technique and specific for the sample introduction and atomization technique. Reference can therefore be made to similar atomizers used in AAS. Spectral interferences due to direct-line or near-line overlap is extremely unlikely with line radiation sources, as usually only the analyte can absorb the radiation and emit fluorescence. The most serious problem, which cannot be eliminated by improving spectral resolution or by modulating the radiation source, is radiation scattering at nonvolatilized aerosol particles, particularly in flame atomizers. This problem is most serious for resonance fluorescence and might be avoided using a nonresonance fluorescence line; this, however, is usually associated with a significant loss of sensitivity and therefore not generally applicable. Another, although less frequently encountered problem is broadband fluorescence emitted by molecules in the same spectral interval where atomic fluorescence is monitored. This interference also cannot be eliminated by modulating the radiation source, as the fluorescence is caused by the radiation source. Both interferences are much more serious if a continuum radiation source is used instead of a line source. The problem of thermal emission from the atomizer can be solved by modulating the primary radiation source and using a selective amplifier.

13.4
X-Ray Spectroscopy

X-ray spectroscopy (XRS), like optical spectroscopy, is based on the measurements of emission, absorption, fluorescence, scattering, and diffraction of electromagnetic radiation. X-rays are defined as radiation of short wavelength, typically between 10 pm and 10 nm (0.1–100 Å), which is generated by *deceleration* of high-energy electrons or by electron transitions in the *inner orbitals* of atoms (Jenkins and de Vries, 1970; Jenkins, 1988). Upon ejection of an inner electron from an atom, the remaining electrons in the outer orbitals will decay to lower-energy states to compensate for the electron loss and to fill in the vacancy in the inner orbital. These transitions are characterized by the emission of the excess energy in the form of X-ray photons with characteristic energies corresponding to the energy of the electron transition; therefore, each element has its own characteristic X-ray spectrum (Carr-Brion and Payne, 1970). These transitions are named after the orbital from where the original electron has been ejected. For instance, ejection of an electron from the innermost orbital generates "K" X-rays; ejection from the next orbital generates "L" X-rays, and so on, which is in accordance to the atom model of Bohr. Each emission is also associated to a determined transition probability, which is indicated by Greek letters (α, β, γ). For instance, a K-series spectrum, corresponding to ionization from a K-shell, consists of a strong K_α and a weaker K_β line due to a less-frequent electron transition (Müller, 1972).

13.4.1
Theoretical Principles

13.4.1.1 Emission of X-Rays

For analytical purposes, X-rays may be produced in different ways: (i) by bombardment of a metal target with a high-energy electron beam; (ii) by exposing a substance to a primary X-ray, generating a secondary X-ray fluorescence beam; (iii) by using a radioactive source that emits X-rays upon its decay; and (iv) by using synchrotron radiation. X-ray sources, like sources for optical radiation, often generate both, continuous and discontinuous (line) spectra. The continuous radiation is known as *white radiation* or *bremsstrahlung*, as it is the result of the deceleration of high-energy electrons.

The most usual X-ray sources are *X-ray tubes*, which are operated at controlled (high) voltages up to 100 kV applied between a cathode and an anode. In an X-ray tube, a hot filament, acting as a cathode, emits electrons that are accelerated in a high-voltage field to impact against a metal anode (target). The impact of the electrons with the anode generates heat and electromagnetic radiation in the form of X-rays, as a result of the deceleration of the electrons and the conversion of kinetic energy. Under certain conditions, only a continuous spectrum is obtained, as shown in Figure 13.26(a), which under other conditions may be superimposed by a line spectrum, as shown in Figure 13.26(b). The continuous X-ray spectra are characterized by an exactly defined short-wavelength limit, λ_0, which only depends on the acceleration voltage, but is independent of the target material. The maximum photon energy corresponds to an abrupt deceleration of the electron to the kinetic energy 0 in a single impact; the continuum at longer wavelengths corresponds to a stepwise deceleration in multiple collisions. The superimposed line spectra are due to electron transitions within the atom, and are characteristic for the element, as is discussed in the context of X-ray fluorescence (refer to Section 13.4.1.3). The line spectra are simple and consist of a few lines only.

Radioisotopes are also common excitation sources; however, they are some 4 orders of magnitude weaker compared to X-ray tubes. In this case, a γ-ray-emitting radioisotope, such as ^{241}Am, ^{109}Cd, ^{153}Gd, ^{155}Eu, or ^{145}Sm is used, and γ-rays induce the emission of

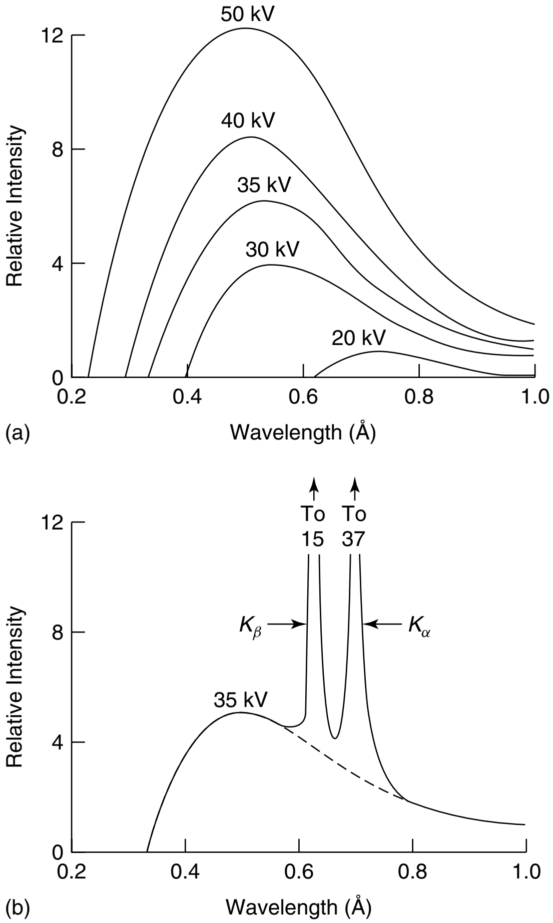

Fig. 13.26 Typical spectra emitted by X-ray tubes under different conditions; (a) continuous spectra emitted by an X-ray tube with a tungsten target using different acceleration voltages; (b) continuous spectrum with superimposed line spectrum emitted by an X-ray tube with a molybdenum target. (From Skoog *et al.* (1998), Brooks & Cole, P. 273; reproduced with permission from Cenage learning Inc.)

X-rays either by direct impact on the sample surface or by impact on a secondary target, which will then emit X-rays that are used to excite sample components (known as the *γ-X source*). Several advantages are ascribed to radioisotope excitation sources, such as high stability and low cost (Jenkins, 1988).

The acceleration of high-energy electrons in a high vacuum tube under the influence of a strong magnetic field results in the emission of the so-called *synchrotron radiation*, which can also be used as an excitation source in XRS. Synchrotron radiation can be considered as magnetic *bremsstrahlung*, and it can be used as a source either directly or after modifications, which include selection by an absorber and the use of diffraction crystals and mirrors. Owing to the high intensity of synchrotron radiation, the analytical sensitivity of X-ray fluorescence (XRF) is significantly increased, as well as the S/N ratio (Saisho, 1989).

13.4.1.2 Absorption of X-Rays

When an X-ray penetrates a thin layer of a solid substrate, its intensity is reduced due to absorption and scattering. Except for the lightest elements the latter effect can be neglected, at least in the wavelength range of strong absorption. Similar to the emission spectrum, the absorption spectrum of an element is simple and consists of a few lines only. The absorption spectrum of lead and silver, which are shown in Figure 13.27, consist of a few peaks only with the first one at 0.14 Å. A peculiarity of X-ray absorption spectra is their discontinuous increase with so-called absorption edges. One of the inner electrons of the atomic shell is expelled upon the absorption of an X-ray photon, resulting in an excited ion. In this process, the entire energy $h\nu$ of the radiation is distributed to the kinetic energy of the electron and the potential energy of the excited ion. The probability of absorption is highest when the photon energy corresponds exactly to the energy that is necessary to expel the electron from the atom, that is, if the kinetic energy of the expelled electron is close to zero. For higher photon energy the probability decreases gradually, and for lower photon energy abruptly, as the photon does not have enough energy to expel an ion from the K-shell any more, and the next peaks are reached only when the photon energy reaches a level that corresponds to the energy of the L electrons.

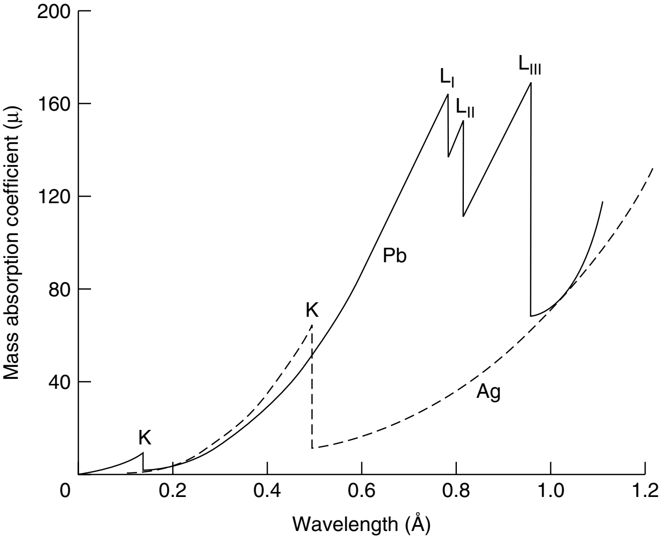

Fig. 13.27 X-ray absorption spectrum of silver and lead. (From Skoog *et al.* (1998), Brooks & Cole, P. 277; reproduced with permission from Cenage learning Inc.)

13.4.1.3 X-Ray Fluorescence (XRF)

The absorption of X-rays produces electronically excited ions that return into their ground state by electron transitions from higher energy levels. These transitions are associated by the emission (fluorescence) of characteristic wavelengths, which are identical to those that are generated by electron bombardment. However, the wavelengths observed in XRF are always longer than those of the corresponding absorption edge, as the complete liberation of the electron, that is, ionization of the atom, is necessary for absorption, whereas fluorescence only requires transition of an electron from a higher to a lower energy level. The intensity of the emitted X-ray photon will depend on the effectiveness of the de-excitation process within a given atom, and the *fluorescence yield* can be defined as the fraction of all electron transitions that are associated with the emission of an X-ray photon (Müller, 1972). The fluorescence yield increases dramatically with increasing atomic number, and is close to unity for elements with atomic numbers above 70.

13.4.2
Instrumentation

13.4.2.1 X-Ray Fluorescence

The most commonly used technique is XRF, which has a wide range of application in the analysis of solid materials and is characterized as a nondestructive technique. Commercially available XRF instruments can be classified into wavelength-dispersive and energy-dispersive instruments. *Wavelength-dispersive* (WD) instruments, which are schematically represented in Figure 13.28(a), generally use an X-ray tube as the source in order to compensate the energy losses that are encountered when an X-ray is first collimated onto a crystal and then dispersed into its wavelength components. Analyzing crystals made of a wide variety of materials have been used, including LiF, Si, pentaerythritol (PE), topaz, CaF_2, and many

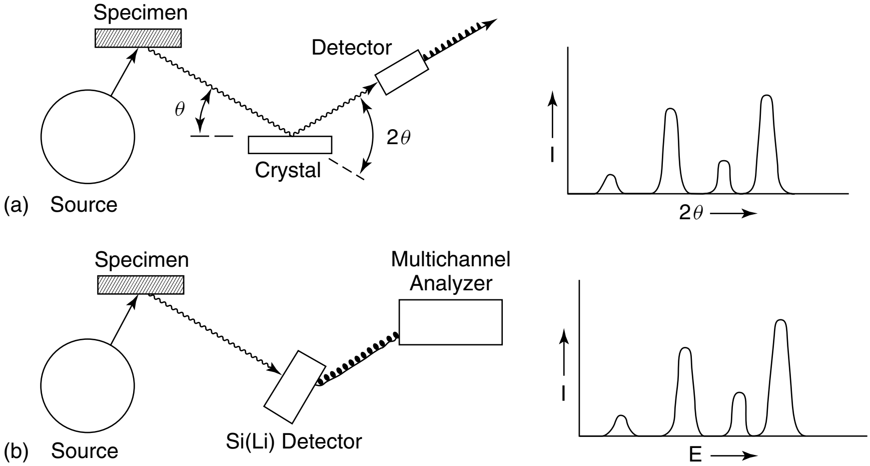

Fig. 13.28 Schematic design of typical XRF instruments; (a) wavelength-dispersive X-ray fluorescence equipment; (b) energy-dispersive X-ray fluorescence equipment. (From Jenkins (1988), p. 54; reproduced with permission from Wiley-Interscience.)

others, depending mainly on the atomic number of the element to be determined and on the specific application. We distinguish between sequential single channel and simultaneous multichannel instruments.

Single-channel instruments can be operated manually or automatically. The former ones can be used for the *quantitative determination* of a few elements. In this case, crystal and detector are adjusted at an appropriate angle (θ and 2θ) and the photons counted for a long enough time to produce a sufficiently high signal. Automatic instruments are better suited for *qualitative analysis*, where the entire spectrum has to be registered. For this purpose, analyzing crystal and detector are rotated synchronously maintaining their relative angular position (Lachance and Claisse, 1994).

Wavelength-dispersive *multichannel instruments* are big and expensive instruments that allow the simultaneous detection and determination of up to 24 elements. The individual channels, each of which consists of a crystal and a detector, are grouped radially around an X-ray source and a sample holder at an appropriate angle for a given analyte line. Each detector has its own amplifier, analyzer, and counter or integrator. The simultaneous determination of all elements may take between a few seconds and a few minutes. Instruments of this type are made for a specific application and offer little flexibility for other purposes.

In *energy dispersive* (*ED*) instruments, illustrated in Figure 13.28(b), the fluorescence radiation beam coming from the sample is immediately directed toward a semiconductor detector, which is coupled to several electronic devices that are capable of selecting the signal according to small differences in the energy, depending on their wavelength. In this case, a spectrum of voltage pulses is obtained, which is directly proportional to the spectrum of X-ray photon energies entering the detector, as shown in Figure 13.29 (Jenkins 1988; Lachance and Claisse, 1994).

The obvious advantages of ED systems are their simpler design and the absence of movable parts, which also simplifies their operation. The absence of collimators and diffracting crystals, and the short distance between sample and detector increase the signal intensity by about 2 orders of magnitude, which allows the use of much weaker (and less expensive) radiation sources (refer to Section 13.4.2.1). Although this then results in lower sensitivity compared to wavelength-dispersive instruments, their much lower price and their ability to measure all the elements within the range at the same time makes them an attractive alternative.

There are three main types of X-ray detectors to convert X-ray photon energy into voltage pulses. A gas flow *proportional counter* is a tube filled with a mixture of an inert gas (typically Ar) and a quenching gas (such as CH_4) with a wire along its radial axis. The tube wall is grounded and a high potential (usually around 1.8 kV) is applied to the wire. As the X-ray photons enter the tube, the inert gas is ionized and the electrons generated in the ionization process are accelerated toward the wire (anode), colliding with other neutral gas species and generating more ionized gas species in a cascade effect. A voltage pulse is therefore produced, which is proportional to the energy of the incident X-ray photon. The proportional counter is ideally suited for measurement of longer wavelengths (above 1.5 Å).

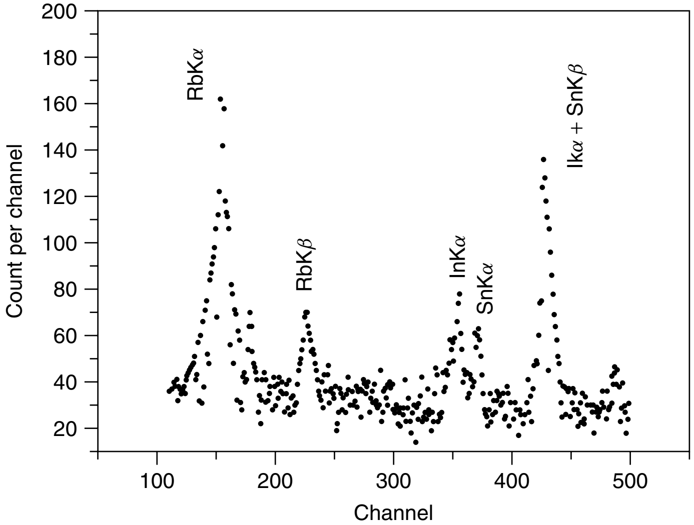

Fig. 13.29 Spectrum of an iron sample recorded with an ED XRF equipment. (From Ekinci and Íngeç (2008), p. 1120, reproduced with permission from Elsevier.)

A *scintillation counter* can be used for shorter wavelengths. In this detector, the incident X-ray photons impact against a phosphor substance, such as a NaI crystal doped with Tl, resulting in the emission of lower energy photons, which are then accelerated to a PMT, generating electrons in a cascade effect, similar to the PMT used in optical spectroscopy. The generated current is proportional to the energy of the incident X-ray photon. A variation of this detector is the *gas scintillation counter*, where a gas is used instead of a solid phosphor.

Semiconductors are also frequently employed in detectors, particularly in energy-dispersive instruments. The most usual is the *Si(Li) detector*, where a small Si cylinder, compensated by Li in order to increase the electrical resistivity, is used. In this case, a p–i–n-type diode is assembled and, upon impact, X-ray photons generate a number of electron-hole pairs and, consequently, a determined electric charge. Application of a high voltage to the Si disk results in transfer of the accumulated charge to a charge-sensitive preamplifier, producing a charge pulse, the voltage amplitude of which is proportional to the energy of the incident X-ray photon. Electronic noise is reduced by cooling the detector, usually with liquid nitrogen.

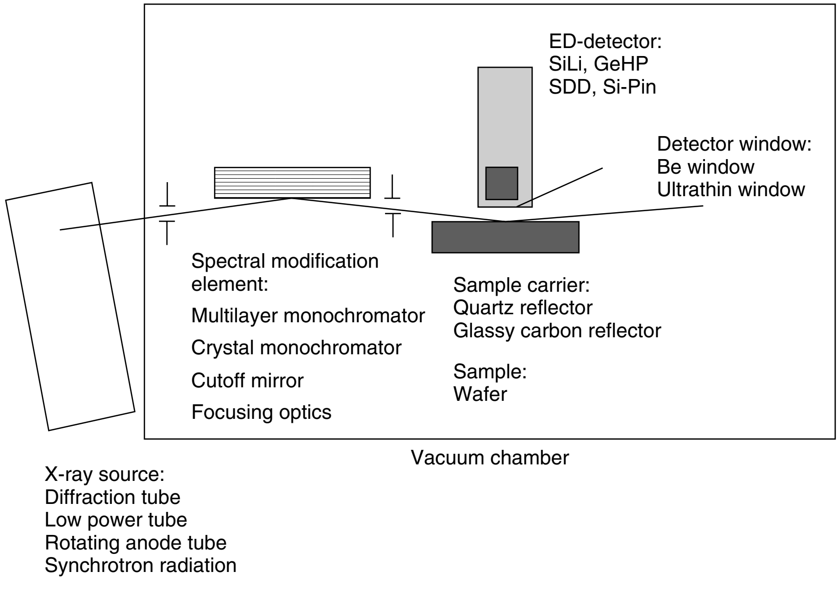
The major limitation of all XRF techniques is the need of solid reference materials – usually certified reference materials – with an analyte content and a matrix composition as close as possible to the composition of the sample for calibration in order to compensate for matrix effects.

13.4.2.2 Total-Reflection (TR) XRF

Total reflection XRF is a variation of energy dispersive X-ray fluorescence (ED XRF), which is based on the fact that at an incident angle below the critical angle, the primary radiation beam is completely reflected. The reflection angle is exactly the same as the incidence angle, and the intensity is also roughly the same, except for a small fraction of the radiation that may be refracted by the sample (Wobrauschek, 2007; Yoneda and Horiuchi, 1971). As at a low incidence angle the X-ray photons practically do not penetrate the sample substrate or support, the scattering of radiation, which is a major source of background in XRF, is remarkably reduced, which ultimately results in an improvement in the S/N ratio and, consequently, in the LOD. In addition, the sample itself is irradiated twice by the X-ray photons, as both the primary incident and the reflected beam strike the sample surface. The result is a highly sensitive XRF technique with LOD in the picogram per gram range for selected applications (Knoth and Schwenke, 1978; Wobrauschek, 2007).

The instrumental setup for total-reflection X-ray fluorescence (TR XRF) is not much different from that for ED XRF, except for the fact that the primary radiation beam has to be adjusted to enter the sample at a glancing angle of a few arc seconds. This can be achieved by placing reflection units and controlled apertures in the beam path between the source and the sample chamber. In addition, in TR XRF, the detector is positioned directly above the sample, as represented schematically in Figure 13.30. As in most ED XRF instruments, X-ray tubes, and Si(Li) detectors are commonly used.

Prior to TR XRF analysis, samples must be placed on a reflective, flat polished surface. Measurements can be performed in air, in a He atmosphere or in a vacuum chamber, which has the advantage of avoiding the scattering of primary X-ray photons from atmospheric gas molecules and is mandatory



ED-detector:
SiLi, GeHP
SDD, Si-Pin
Detector window:
Be window
Ultrathin window
Spectral modification element:
Multilayer monochromator
Crystal monochromator
Cutoff mirror

for the detection of low-atomic-number elements. Samples are more suitably analyzed as aqueous solutions, and solid samples should typically be digested prior to analysis (Klockenkämper and von Bohlen, 1999). The application of TR XRF for trace element determination covers a wide range of sample types; a complete review has been published by Wobrauschek (2007).

13.4.2.3 Particle-Induced X-Ray Emission (PIXE)

Particle (or proton) induced X-ray emission (PIXE) is a technique based on the emission of X-ray photons by sample constituents excited by collision with charged particles, usually protons. The sequence of events is identical to the one described for XRF, that is, emission of X-ray photons following the filling of electron vacancies by outer-shell electrons (Johansson and Campbell, 1988). Instrumentation for PIXE is rather similar to that for ED XRF, except for the excitation source. In PIXE, a proton beam with energies varying typically between 1 and 10 MeV and beam currents of a few microamperes is generated by means of a small particle accelerator. The proton beam is collimated, usually by a magnetic field, and the proton energy is stabilized and uniformed by passing through a slit, before entering the sample chamber, which is under vacuum. An Si(Li) detector is typically employed (Johansson and Campbell, 1988; Khan and Crumpton, 1981).

Several advantages are associated with the use of PIXE, such as the ability to perform fast multielement analysis, the high sensitivity for elements with atomic numbers above 11, the suitability for small samples (micro- or μ-PIXE) and the lower *bremsstrahlung*, due to the smaller deceleration experienced by protons upon collision with electrons (Khan and Crumpton, 1981). The application of PIXE ranges from the analysis of pigments in historic paintings (Neelmeijer *et al.*, 2000) to biological samples (Bertrand, Weber and Schoefs, 2003).

13.4.2.4 Portable Instrumentation

Portable (field) XRF instruments are commercially available and have been gaining importance for a range of on-site applications. The development of portable XRF instruments has become possible mostly due to the development of small X-ray tubes and to the use of radioisotopes as X-ray sources. Portable instruments have been mostly developed for "conventional" XRF, but instruments for PIXE (Pappalardo *et al.*, 2007) and TR XRF (Mages *et al.*, 2003), among others, have been described as well. Applications range from archaeometrical studies (Zarkadas and Karydas, 2004) to coating thickness evaluation (Carapelle *et al.*, 2007).

13.5
Outlook

Most of the instrumental techniques of atomic spectrometry can nowadays be considered established techniques, so that no dramatic innovations should be expected. Miniaturization is an interesting trend that not only reduces the size of the equipment but also often reduces sample consumption and measurement time, and improves LOD and LOQ. Microplasmas with dimensions of 1 mm or less, usually microwave-induced, generated by high-frequency or dc discharges, are a promising field of research in OES, and have been experiencing increasing popularity in the past few years (Foest, Schmidt and Becker, 2006; Broekaert and Siemens, 2004). Yu, Du and Wang (2007) proposed a miniature AFS system in a lab-on-valve for mercury determination, and Wormhoudt *et al.* (2005) described a determination of carbon in steel by LIBS using a microchip laser and miniature spectrometer. It is not easy to predict, however, if such systems will find entrance into routine laboratories, or if they will remain restricted to research labs.

The most recent development in atomic spectrometry, HR-CS AAS, has been received extremely well in the market, and will have a significant impact not only on classical LS AAS but also on alternate techniques, such as ICP OES and ICP-MS. The most obvious next step will be the development of simultaneous HR-CS AAS, which will make it even more competitive. Although this development depends on further progress in detector technology, it will, for sure, take less than a decade until this step becomes technically feasible.

INTRODUCTION

The atom can be considered to be the basic building block of nature at all levels of matter above the nuclear. The intrinsic properties of the isolated atom in large measure determine the more complex properties of bulk matter, in whatever form this matter may take. It is therefore often the case that detailed understanding of atomic structure and other atomic properties is necessary in order to understand such matter in any state, i.e., ionized, neutral gas, or condensed matter. A basic goal of atomic physics is to obtain that understanding.

One could in principle completely categorize isolated atoms by their electronic and electromagnetic properties, that is, by a complete description of the dynamics of the orbiting atomic electrons and by the ways in which atoms interact with external particles and fields. The study of such properties belongs properly to what could be characterized as "fundamental" atomic physics. There is not a very large distance between this characterization and the many applied areas that depend upon it.

For the purposes of this article one can move a step away from the fundamental aspects to refer instead to the atomic properties that derive from atomic dynamics, that is, to those characteristics of atoms that are specific to a particular atomic species and state (these terms are discussed more fully below), and that reveal some important aspect of their structure. Such properties are generally studied by means of some selective technique, of which there are now many. Recent years have witnessed dramatic improvements in traditional laboratory instrumentation and in the addition of important new experimental techniques to the atomic physicist's bag of tricks. The principal such devices will be discussed in the following sections.

Even further removed from fundamental atomic concepts are the observables that are actually studied by atomic scientists—atomic *signatures*. Atomic signatures are closely related to, but not necessarily identical to, atomic properties. These latter are those characteristics of atoms that are determined from the application of the known laws of electricity and magnetism, applied to atoms through the rules of quantum mechanics (these are

briefly referred to in Sec. 4). For example, while atomic spectra can be considered to be signatures, atomic energy levels are atomic properties which are inferred from atomic spectra, but are not generally directly observable. In the discussion that follows, we start with a compendium of atomic properties, then proceed to atomic signatures, and then specialize our discussion to several particularly important applied atomic physics techniques.

The most useful weapon in the experimentalist's arsenal, utilized by physicists and chemists for well over a century, is optical spectroscopy. Even here recent advances in spectroscopic techniques, mainly attributable to lasers, have totally revolutionized the study of atomic physics, and of atomic properties in particular. This article will touch on such developments, although the reader is referred to the article on ATOMIC SPECTROSCOPY for a more complete discussion.

1. CHARGE AND MASS

The most important atomic (and chemical) property of an atom is the charge of its atomic nucleus, which determines the number of electrons that orbit it in the neutral atom and which plays the principal role in determining the dynamics of these electrons in their orbital motion around the nucleus. While the structure and abundances of nuclei are the domain of nuclear rather than atomic physics, once the nuclear charge is determined atomic properties follow. The nuclear charge is itself determined by the number of protons in the nucleus (the atomic number Z), while the total number of protons and neutrons, i.e., the number of nucleons (the atomic weight), is responsible for virtually all the atomic mass, except for the very small contribution of the orbiting electrons.

Atoms of a given element may possess different numbers of neutrons, such variants being referred to as *isotopes*. Thus, the familiar 92 atomic elements from hydrogen ($Z=1$) to uranium ($Z=92$) are constructed from the 92 naturally occurring members of the periodic table, with a number of transuranic elements thrown in for good measure. Apart from significant though small differences in their spectra, and of course their masses, isotopes of a given element possess very similar physical and chemical properties. (An important exception to this statement can occur because of the different statistics obeyed by even and odd isotopes, but these do not generally play a role in atomic, as opposed to condensed matter, physics.)

Because of the similarity in the chemical and physical properties of the isotopes of a given element, isotope separation is generally a nontrivial pursuit. As a consequence, isotope separation schemes tend to exploit nuclear rather than atomic isotopic properties. Despite this, while isotopic spectra of a given element are similar, their differences are significant enough so that lasers, with their intrinsically high spectroscopic resolution, can be fruitfully exploited in some instances to achieve isotope separation in useful quantities.

One of the greatest intellectual achievements of the twentieth century has been the rapid development of quantum mechanics in the 1920s. Quantum mechanics (*q.v.*) replaced Newtonian mechanics in describing the dynamical behavior of microscopic particles such as atoms. Among its earliest, dramatic successes was its ability to predict the chemical and physical properties of the atomic elements, starting with very few basic principles. From these the systemization of the *periodic table* followed. It is important to emphasize that were ordinary Newtonian mechanics to govern the dynamics laws of orbiting electrons in analogy to planetary motion, none of the ordered and generally predictable properties of the elements would exist.

(We do not attempt to discuss the subject of quantum mechanics in any detail here, as this would take us too far afield from our intent of discussing atoms and their properties, even though these are in fact determined in the first instance by the laws of quantum mechanics. The list of references contains the names of several excellent source books for thorough discussions of this subject.)

2. THE PERIODIC TABLE

The periodic table is a two-dimensional array of atoms arranged according to the number of electrons in the neutral atom. At first this systemization, by Mendeleev and others, was strictly empirical, based on the similar chemical and physical properties possessed by atoms when suitably arranged by columns and rows. Only after the advent of quantum mechanics and the subsequent understanding of the quantum many-body problem that resulted was the empirical basis of the periodic table replaced by a thorough understanding of this order, stemming from many-body electron orbit theory. It is sufficient for our purposes to note that electron orbits, unlike planetary motion, arrange themselves in shells as atomic number increases, with each shell being filled (or in some cases partially filled) before newly added electrons start to fill new shells. The number of electrons in the outermost unfilled shell or subshell determines the atomic *valence*, a quantity which can be positive or negative, depending on whether the last unfilled shell contains an excess or a deficiency of electrons. For example, the halogens (fluorine, chlorine, bromine, etc.) possess a valence of -1, since their last unfilled shell or subshell contains a deficiency of one electron to make it complete.

The simplest examples of shell structure are the column one and column eight elements. Column one, i.e., atoms possessing a single valence electron, consists of atomic hydrogen and the alkali metals, lithium, sodium, potassium, rubidium, cesium, and francium. Hydrogen, while having some characteristics in common with the alkali metals, is really unique in the periodic table. It is by far the most abundant element in the Universe, its chemical reactivity makes it a partner in a huge variety of chemical reactions, and it is a constituent of many simple molecules, including those of biological interest. And in addition to its ubiquity it is also of fundamental importance as the principal testing ground for theory, since it is the simplest of all atomic systems and therefore is the most amenable to calculation. Because of their single valence electron, column one atoms are chemically very active. Equally active are the halogens, fluorine, chlorine, bromine, iodine, and astatine. As noted above these lack one electron to make up a complete subshell. As a consequence, while the alkalis readily give up their valence electron, i.e., are easily ionized, the halogens have strong electron affinities, which chemists would refer to as being electronegative (see Sec. 7).

The rare-gas elements are obtained with the completion of the lowest nonzero angular momentum subshell for each principal quantum number, excepting helium, which fills the first shell. (This shell can only contain angular momentum states equal to zero.) These elements, helium, neon, argon, krypton, xenon, and radon, are normally chemically inert, and all occur in the gaseous state under normal conditions of temperature and pressure. In fact, in recent years it has been shown that these gases can be chemically reactive, under certain restrictive conditions. One consequence of this reactivity has been the development of a new class of lasers, the so-called "excimer" lasers, some of which rely on this reactivity to produce lasers with the useful characteristic of being broadband, i.e., capable of lasing over a relatively wide range of wavelengths.

The empirical ordering exhibited by the periodic table, including the shell structure hierarchy, follows from the approximate picture of ground-state electron configurations determined by solutions to the Schrödinger equation. According to these solutions each shell has associated with it a *principal* quantum number n. Convention designates the various shells as K, L, M, etc., in accordance with whether $n=1,2,3$, etc. The principal quantum number is the main determinant of the overall electron energy; it also corresponds to the number of nodes, i.e., the zeros in the radial part, of the electronic wave function. Within each shell energy states are classified into subshells determined by orbital and spin angular momenta and their projections along an atomic axis of symmetry. The lighter elements are constructed in a regular fashion by filling shells and subshells sequentially. For the heavier elements it can happen that outer shells or subshells are completed before all energy states with lower principal quantum number are filled, an example being the series of rare earth elements from lanthanum ($Z=57$) to hafnium ($Z=72$). Since the outer electron configurations for these elements are the same they possess similar chemical properties. The reader is referred to any standard book on modern physics for a complete description of the periodic table.

3. ATOMIC STATES AND ENERGY LEVELS

Without specifically stating so, the discussion in the above section assumed that the atomic properties which are systematized in the periodic table refer to the lowest energy state of the atom, called the "ground state." Left alone, unperturbed by external influence, this state corresponds to the electronic configurations for which the total electron energy of the system is at a minimum. Here is another dramatic difference between so-called "classical" mechanics, which would describe the electronic motion using Newton's laws under the action of electromagnetic forces, or the relativistic generalization of these, and quantum mechanics. Because accelerating charges radiate, Newtonian mechanics would mandate that all electronic orbital motion collapses the atom, that is, the atomic electrons would fall into the nucleus. That this does not happen is attributable to the fact that under specific conditions the rules of quantum mechanics permit so-called "stationary states," states in which, and only in which, orbiting electrons do not radiate (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES).

The only truly stable stationary state is the ground state. However, above the ground state all atomic systems possess an infinite number of stationary excited states, which can be reached in a variety of ways, for example, by collisions with other atoms or molecules, by interactions with radiation fields, or simply by being placed in a high-temperature environment (which is another way of generating interactions with particles and fields). Apart from the ground state, which possesses an infinite lifetime, lifetimes of all other states are finite (see Sec. 9).

Generally these excited states are still bound states, that is, the atom remains electrically neutral. In addition, one or more of the atomic electrons may receive from an external source sufficient energy to remove it completely from the atom, which becomes ionized. Ionization phenomena are discussed in Sec. 5.

There is a distinction between atomic state and atomic energy level. It can happen that more than one state can possess the same energy, in the absence of some perturbing interaction. Such states are described as being *degenerate*, the degeneracy being removed by the interaction. While this distinction can be extremely important in a variety of phenomena, for the purposes of this article we can neglect this distinction between state and level. Just as is the periodic table, energy levels for a given atomic species are systematized. The arrangements of these levels in any atom are again governed by the laws of quantum mechanics, which mandates that these levels be characterized by a set of quantum numbers. No two atomic states can possess all the same such numbers—this is the famous "exclusion principle," without which all electrons in an atom would fall into the lowest orbit, and thus would have doomed our universe to an existence in which no interesting chemistry or biology could flourish. There are in general four quantum numbers for each involved electron which labels an atomic state. The most important one, from an energy point of view, is the *principal* quantum number, an integer usually designated by n, which plays the dominant role in determining the mean distance of the involved electron from the nucleus. All electrons in a given shell possess the same principal quantum number. A second quantum number, l, is related to the orbital angular momentum. l is also an integer; the orbital angular momentum is given by $\sqrt{l(l+1)}$, in units of $h/2\pi$, where h is Planck's constant, the unit of angular momentum in quantum mechanics. A third quantum number, m, corresponds to the projection of the angular momentum along an axis of symmetry of the atom, which is equal to $mh/2\pi$. The fourth quantum number is the (half integral) electronic spin projection along the same axis, equal to $\pm h/2\pi$. (Generally speaking each quantum number corresponds to a "degree of freedom" of a particle. For the electron there are three spatial degrees of freedom, plus one degree of freedom due to the intrinsic electron spin.) Because there is a magnetic interaction between the orbital and spin angular momenta for each electron's orbital motion and between electrons as well, various coupling schemes are possible; these determine both the methods of classification and the actual values of the electronic energy levels and spectra of the elements.

The role played by these quantum numbers in establishing the periodic table has already been discussed in Sec. 3. The excited atom's energy levels are determined by the ordering of these quantum numbers as they acquire higher values. As with the periodic table, the energy levels of an atom can be arranged in columns, each corresponding to different values of orbital angular momentum and electron spin projection, with each row corresponding to a different principal quantum number. A simple example is atomic lithium ($Z=3$)—an alkali atom which for most practical purposes is a one-electron atom, since the first two electrons form a closed shell, and therefore do not play an active role in most lithium interactions. The complete set of appropriate quantum numbers for each atomic electron is referred to as an "orbital," in analogy to the classical counterpart of electron motion.

4. IONIZED ATOMS

Ionized atoms play dominant roles in a wide variety of phenomena, many of which are discussed in detail in other articles of this Encyclopedia. The entire field of plasma physics deals with ionized gases, and ionized species dominate such disparate fields as gas lasers (see LASERS, GAS), gaseous discharges (see ELECTRIC DISCHARGES) including fluorescent light sources, upper atmospheric and solar atmospheric physics (see ATMOSPHERIC PHYSICS), flames, and combustion (*q.v.*). Many high-energy particle accelerators use ion beams as input; ion beams are also used in a wide variety of practical applications including ion implantation (*q.v.*) in solids and ion beam irradiation for biological and medical uses. Plasma etching (*q.v.*), one of the newest technologies for the manufacture of computer chips, also relies on gaseous discharges to generate ionic currents for deposition onto substrates. Mass spectroscopy (see SPECTROMETERS, MASS) almost universally requires ionic beams to measure the generally unique atomic signature of charge-to-mass ratio, the most powerful tool in the experimentalist's arsenal for assaying specific concentrations of particular atomic (and molecular) species (as opposed to optical spectroscopy, which, as discussed in Sec. 1, is the most powerful experimental tool for studying atomic structure—see ATOMIC SPECTROSCOPY).

The stage of ionization can be anything from single ionization (one electron removed) up to fully ionized (all electrons removed). Removal of the first electron is the easiest to accomplish with respect to the energy required. The "stablest" element is helium—as much like a tiny billiard ball as atoms get—and helium requires only about 24 eV (electronvolt) for single ionization, where 1 eV is the amount of kinetic energy acquired by an electron in accelerating through a potential difference of one volt. The removal of each successive electron is more difficult, i.e., requires more energy. Removing the second electron in helium, for example, requires about 54 eV. Removing the 92nd electron from atomic uranium requires more than a GeV!

5. ATOMIC WAVE FUNCTIONS

The most fundamental of all atomic properties is the atomic wave function. This quantity represents the solution of the Schrödinger equation, or its relativistic counterpart (the Dirac equation). In principle all properties of the isolated atom could be obtained were its wave functions precisely known, since it describes—as best as can be done quantum mechanically—the complete set of coordinates of the atomic electrons in both magnitude and phase, from which these properties can be derived. (Such a complete set is not solely confined to spatial coordinates; for example, the wave function also includes a description of electronic spin.) It is a fundamental property of quantum mechanics that the wave function cannot itself be observed directly. Mathematically the wave function can be expressed as a function ψ (psi) of position and spin coordinates of each of the N electrons in the atom, as a function of time. For an isolated atom in the absence of external forces, the wave function describes stationary states, for which the time dependence is periodic with a frequency that is proportional to the energy of the state. Although ψ, which is generally complex (representing magnitude and phase), is not observable, its absolute value squared represents the electron density in probabilistic terms. Thus the electron charge cloud (what one might imagine an atom to look like were one to observe it from a distance) is given by $\psi\psi^*$, the product of the wave function by its complex conjugate. "Pictures" of atoms showing these charge clouds have served as metaphors for atomic structure since the early days of quantum mechanics, although these are actually computed charge clouds rather than observed ones.

The only exactly solvable atomic wave equation is that of atomic hydrogen, since this is a two-body problem (electron + proton). Even helium is not exactly solvable since the Schrödinger equation is not separable in the coordinates of its two orbiting electrons. The beautiful diagrams that represent $\psi\psi^*$ for hydrogen derive from the fact that the angular portion of ψ consists of pure associated Legendre polynomials, while the principal quantum number n is represented simply by the number of nodes in the radial part of ψ.

Although helium and heavier atomic wave functions are not exactly solvable, modern computational techniques can generate these with considerable precision and reliability, although the going gets rougher as one progresses through the periodic table. One of the most important practical goals of computational physics is the generation of reliable wave functions for ground and excited states, and indeed there are available codes that can be employed by users for this purpose. How good are these? In the last analysis they must meet the test of agreement with experiment, that is, by their ability to predict measurable atomic properties—the atomic signatures of Sec. 11. Such comparisons show that computational techniques are very powerful, and are of course rapidly getting better.

Finally, one general remark: not only are atomic properties derivable from wave functions, they also serve as input data for more complex phenomena, including collisions between atomic systems and other particles, both nonreactive and reactive. In virtually all such processes computational methods require as input reliable wave functions. From this point of view, study of isolated atoms serves as an invaluable test of the reliability of atomic wave functions for use in such applications.

The reader can be referred to a variety of sources for the generation of appropriate wave-function algorithms, using various approximation techniques. The most useful of these employs variations on so-called Hartree–Fock models. Such models are based on the assumption that each electron moves in the field of the remaining electrons (and nucleus), with the entire ensemble being made self-consistent. For heavier atoms Hartree–Fock is augmented by inclusion of relativistic effects, whence the model is designated as Hartree–Fock–Dirac.

6. NEGATIVE IONS

Besides suffering a loss of one or more orbiting electrons, many atoms of the periodic table can exist in stable configurations with an extra electron. These are negative ions, which play such an important role in many gaseous phenomena, including the upper atmosphere. Most negative ions exist in the molecular rather than the atomic state. However, some of the most important elements in the periodic table possess negative ions. Perhaps the most important of these are atomic oxygen and hydrogen, which help govern the dynamics and the radiation properties of the upper atmosphere and the solar corona, respectively.

The properties of negative ions are quite different from those of positive ions. Positive ions are stable since the remaining electrons are even more tightly bound to the nucleus than in the neutral atom. Negative ions, on the other hand, tend to be loosely bound, since the electrons' attraction to the atom must rely on detailed atomic structure properties rather than on the simple Coulomb attraction of positive ions. Also, negative ions usually possess only a single energy level, rather than the infinity of levels possessed by positive ions. All these properties result in the negative ion being much less stable, with respect to ionization, than its positive counterpart. The degree of stability is governed by the negative ion's *binding energy*, or electron affinity, the energy required to remove the excess electron. This is the negative-ion analog to the ionization energy of the positive ion. Binding energies range from only a few millielectron volts for some atomic systems to, at most, a few electron volts. The largest atomic binding energies, as might be expected, are those of the halogens. (Some *molecular* systems possess even larger electron affinities, and are therefore very useful as sinks for free electrons, e.g., are excellent high-voltage insulators.) There are no known doubly charged negative ions, and as already noted, very few cases of systems possessing more than one bound negative-ion state.

7. LIFETIMES, TRANSITION PROBABILITIES, AND MATRIX ELEMENTS

All atomic states except the ground state possess finite lifetimes, even when totally unperturbed by external influence. The range of such lifetimes is immensely broad, ranging from fractions of nanoseconds to many years, depending upon the characteristics of the particular states involved. A more specific descriptor of energy level stability is the *transition probability*, describing the relative rate of an atom spontaneously decaying to another, lower state. Transition probabilities can be calculated by taking the quantum-mechanical matrix elements of the transitions, i.e., the moments of atomic wave functions over electron coordinates of states connected by the transition in question. They describe the rates at which transitions occur between energy levels that are connected by what would classically correspond to radiating multipole moments. The most common of such matrix elements is that of the electric dipole, the moment obtained by calculating the space average of the position vector of the radiating electron, taken over pairs of states that differ by a single unit of orbital angular momentum. This is the quantum analog of a classically oscillating electric dipole charge, which sets up a field similar to that of a radiating dipole antenna. (Magnetic dipole radiation can also occur, although with orders of magnitude lower probability.)

Higher-order electric and magnetic multipole moments also radiate, in analogy to higher-order classically oscillating multipole charges, though with transition probabilities that decrease with increasing multipole order. Accordingly atomic transition probabilities for electric quadrupole transition probabilities will also be orders of magnitude smaller than electric dipole probabilities.

Typical lifetimes of states which radiate through electric dipole transitions in the visible spectrum are in the range of 10^{-7}–10^{-8} s; inner-shell transitions generally lie in the uv or x-ray region, with correspondingly shorter lifetimes. It is for this reason that the design of uv and x-ray lasers is difficult, since population inversion—the normal requirement for laser operation—becomes increasingly more difficult as the lifetime of the upper state of the laser transition becomes shorter.

8. METASTABLE STATES

There exist significant numbers of excited states which possess extremely long lifetimes, that is, which are not connected to lower states by transition matrix elements of any significant strength. These states are *metastable*—they are not truly stable, since they lie above the ground state and can undergo transitions to lower states either by weakly connected spontaneous decay or through some external perturbation. Perhaps the most famous of all metastable states are the 2*s* states of atomic hydrogen ($n=2$, orbital angular momentum$=0$), which lie some 10.2 eV above the ground state, and which cannot decay since they possess the same orbital angular momentum, namely, zero, as the ground states (we refer to these states in the plural since while the *electronic* configurations of 1*s*, 2*s* are unique these are actually doublets because of the interaction of the electronic and nuclear magnetic moments). The unperturbed lifetimes of the 2*s* states are approximately $\frac{1}{7}$ sec.

Metastable states can occur for a variety of reasons, always involving a violation of appropriate, either strict or approximate, *selection rules*. Such rules categorize those changes of appropriate quantum numbers in a transition that are permitted by the rules of quantum theory. Important high-lying metastable states exist in the rare gases and in mercury—the latter state playing an important role in the efficiency of fluorescent mercury lamps. Many elements possess low-lying metastable states, wherein principal and orbital quantum numbers are the same as those of the ground state, but with electron spin orientations which forbid electric dipole transitions. Such metastable states, for example, in oxygen and nitrogen play a significant role in upper atmosphere dynamics.

9. ATOMIC PROPERTIES

In addition to atomic energy levels there are a variety of atomic properties that are derivable, in principle, from atomic wave functions and that play major roles in many practical situations. We briefly note the most important of these here and refer the reader to individual sections for more detailed discussions.

9.1 Magnetic Moments

The individual electron orbitals of atomic states which do not form complete shells or subshells generally possess net angular momenta. Likewise, the electron spins of unpaired electrons will also result in a net angular momentum. These several individual angular momenta, orbital and spin, will combine to form a net, overall angular momentum for the entire electron configuration of the particular atomic state. Precisely how this comes about depends in detail on the nature of the magnetic spin-orbit interaction—in light atoms, usually the unpaired electron spins first couple to form a net atomic spin S, and the orbital angular momenta couple to form a net orbital momentum of integral value (in units of Planck's constant) L, and the separate S and L momenta then couple to form the final atomic angular momentum J—the so-called L-S coupling scheme. In very heavy atoms, the coupling first occurs between l and s for each electron to form individual j's which then couple to form the final J. This is the j-j coupling scheme. Intermediate cases also occur.

In any case, both the intrinsic spin and the orbital momenta have magnetic fields associated with them, as is the case for any rotating charges. Further, these are *dipole* fields, that is, fields whose spatial dependence (external to the sources) are the same as those that would be produced by magnetic dipoles. The ratio of magnetic moment to the angular momentum that produces it is called the *gyromagnetic ratio*. The natural unit of magnetic moment for atomic systems is the *Bohr magneton*, which in terms of fundamental atomic constants is $eh/4\pi mc$, equal in SI units to 9.2723×10^{-24} J T^{-1}. In units of the Bohr magneton the magnetic moment of a p orbital ($l=1$) is 1. In the same units the spin angular momentum of the free electron is $\frac{1}{2}$, while the corresponding magnetic moment of the electron is approximately 1. Accordingly, while the gyromagnetic ratio for electron orbitals is 1, that of the electron spin is approximately 2—actually, 2.0023; quantum electrodynamic effects are responsible for the so-called "anomaly" in the g value.

Magnetic effects significantly alter atomic energy levels, generally on a scale of millielectron volts, and are referred to as *fine structure*. Such fine structure is also observable spectroscopically through the dependence of atomic spectral wavelength on external magnetic fields—the *Zeeman effect* (see ZEEMAN AND STARK EFFECTS). Such fields could be intentionally generated laboratory fields, or could be local fields resulting from environmental effects, which can therefore serve as a probe for the study of magnetic fields of astrophysical or geophysical interest—i.e., sunspots, aurorae, galactic fields.

9.2 Magnetic Resonance

These magnetic moments in the unperturbed atom are responsible for many important magnetic effects, perhaps the most important of these being ferromagnetism (*q.v.*) and paramagnetism (*q.v.*) in condensed matter. Electron paramagnetic resonance (*q.v.*) is a technique which relies on the absorption of radio frequency or microwave radiation to cause transitions among the Zeeman levels of a paramagnetic medium. This is a cousin to nuclear magnetic resonance (see MAGNETIC RESONANCE, NUCLEAR), which relies on the same principle to probe the local fields seen by precessing protons and other nuclei in condensed matter environments, notably those of biological and medical interest. Such resonance techniques can be used either as a fundamental tool to measure magnetic moments of atoms and nuclei in known magnetic fields, or, turned around, to employ the known magnetic moments of atoms and nuclei as magnetometers, either in instrumentation, or, as noted in the last paragraph, as a probe of natural environments (see MAGNETIC RESONANCE IMAGING).

The existence of atomic magnetic moments led to the development of magnetic resonance techniques, both in bulk matter and, notably, in atomic beam spectroscopy. This technique, which was pioneered by I. I. Rabi and his students at Columbia University in the 1930s and 1940s, relied in the first instance on the mechanical force which acts on a magnetic moment in the presence of a nonuniform magnetic field (a uniform field generates a *torque* on a magnetic dipole, but not a net force). This force was exploited even earlier by Stern and Gerlach to demonstrate the spatial quantization of atomic angular momentum. Rabi used this "Stern–Gerlach" force, generated by use of specially shaped magnetic polefaces, to deflect atomic beams. These generally consisted of alkali-metal atoms, which are easily produced in beams and which possess large magnetic moments in their ground states. When radio-frequency fields are applied that are in resonance with the precessing moments, the resulting torques cause the atoms to "flop," that is, change their spatial orientation. This in turn alters the mechanical force which acts on them past the radio-frequency region, causing a change in detector signal (see MAGNETIC RESONANCE SPECTROMETERS).

9.3 Hyperfine Structure

Atomic magnetic fields interact with, i.e., couple to, the far weaker magnetic moment of the atomic nuclei. This interaction energy results in significant modification of atomic energy levels, called *hyperfine structure.* Hyperfine structure is on a scale of microelectronvolts, as a general rule, rather than millielectronvolts (fine structure) and electronvolts (electronic energy levels). Equivalent interactions between the atomic electric quadrupole moment and the nuclear quadrupole moment result in additional energy level modifications (even higher-order multipole moment interactions occur, and can be observed in precision measurements).

The Rabi method of studying hyperfine structure via atomic beam magnetic resonance revolutionized our knowledge of the static properties of the atomic nucleus. Such a technique, which directly observes hyperfine transitions, is far more sensitive to hyperfine energy levels than is normal optical spectroscopy, which has to rely on very precise measurements of small differences in optical wavelengths to observe the same interaction. Only with the advent of high resolution laser sources has hyperfine spectroscopy using optical techniques become competitive with magnetic resonance spectroscopy (see MAGNETIC RESONANCES, DETERMINATION OF STRUCTURES BY). Again, as happens constantly throughout experimental physics, the method can be, and has been, turned around to be used as a primary frequency standard—the atomic clock. Commercial atomic clocks using cesium atomic beams are available; such standards are of immense value in a variety of aerospace applications.

Perhaps of even greater importance in the development of current technology, atomic beam magnetic resonance was the first application of the use of commercial (or homebuilt) tunable oscillators to the control of atomic oscillations. Subsequently, along with parallel developments in electron paramagnetic resonance techniques and electric resonance techniques for molecules in beams, the first maser was built, by Townes and Schawlow, in 1953. The maser (acronym for microwave amplification by the stimulation of electromagnetic radiation) concept led naturally to the development of the laser, named in analogy to the maser, in 1959 (see LASER PHYSICS).

9.4 Atomic Parameters

We summarize here a number of other important atomic properties related to atomic structure and derivable from atomic wave functions, either of single states or, through appropriate matrix elements, by moments that connect several such states. These play major roles in determining physical and optical properties of neutral gas-phase systems as well as of weakly ionized plasmas. (The behavior of strongly ionized plasmas is usually dominated by collective effects, although atomic properties even here turn out to be extremely important because of the radiation properties of nonhydrogenic impurities in high-temperature plasmas.)

9.4.1 Polarizability. The atomic polarizability describes the distortion of the atomic charge cloud caused by the application of an external electric field. The lowest-order distortion is the electric dipole polarizability, which represents the charge separation that occurs in the atom when it is placed in an external uniform electric field.

The dipole polarizability plays an important role in atomic collision processes, where the electric field is generated by the collision partners. For neutral gases the polarizability is responsible for an attractive force between neighboring atomic partners, called the *van der Waals interaction.* This results from the instantaneous electric dipole of an orbiting electron in one of the partners inducing a dipole in the other. The product of polarizabilities appears in the so-called "van der Waals constant" which determines the strength of this interaction. Polarizability also governs the dielectric constants of gases, which is attributable to the inducing of static or dynamic electric fields in bulk matter by an external field. It can control ion mobilities in gases. Generally the above manifestations of polarizability refer to static, or dc, applied electric fields. Dynamic polarizabilities refer to frequency-dependent induced moments. Dynamic polarizabilities determine the index of refraction for the transmission of radiation through gases.

Polarizabilities form two hierarchies in order of powers of the applied field, one related to departure from linearity of the induced moments with increasing electric field strength and the other related to the order of the multipole moment with the spatial dependence of the applied field. Thus, each induced multipole contains a series of atomic constants, each proportional to a power of the applied field, and likewise each power of the spatial dependence of the electric field has associated with it a polarizability multipole. Applied fields of what would be considered normal intensity before the advent of high-powered lasers are generally of strength insufficient to generate more than the first term in these expansions, namely, the electric dipole polarizability, the parameter that is generally tabulated in data compendia. However, high-intensity lasers can easily generate nonlinear effects in bulk media, and the higher-order moments which govern these are responsible for the various nonlinear optical gas-laser interactions, including harmonic generation, four-wave mixing, and phase conjugation (see OPTICS, NONLINEAR).

Polarizabilities can be calculated using appropriate atomic matrix elements, or directly from known wave functions using variational formulas. Conversely, experimental determinations of polarizabilities can be used as a sensitive test of accuracy of computed wave functions. Atomic states whose wave functions are spherically symmetric possess scalar polarizabilities, that is, the induced moments in an external field will always lie along the direction of the field. However, most atomic systems are not spherically symmetric, even in their ground states, and these will in general possess tensor polarizabilities, that is, the induced moments in an external field will not lie in the direction of the field. Such polarizabilities then are describable by two parameters for each member of the polarizability hierarchy, for example, the polarizabilities that describe the induced moments along the two symmetry axes of the asymmetric atomic charge cloud (atoms possess time-averaged cylindrical symmetry), or equivalently, an average polarizability and a polarizability anisotropy. Again just as with scalar polarizabilities these are in principle derivable from exact knowledge of the atomic wave functions or, equivalently, matrix elements, although the set of such matrix elements may require inclusion of contributions from the continuum—that is, unbound states above the ionization limit—and these are particularly difficult to compute.

9.4.2 Diamagnetic and Paramagnetic Susceptibilities. All atoms are *diamagnetic,* in the sense that externally applied magnetic fields will induce magnetic moments in the atom as a consequence of the orbital motion of the atomic electrons (see DIAMAGNETISM). The magnetic moment induced by diamagnetism generates, as a microscopic application of Lenz's law, its own magnetic field which is oriented opposite to the applied field, external to the atom. Atoms which possess intrinsic magnetic moments are, in addition, *paramagnetic,* that is, their moments will be spatially aligned in external magnetic fields according to the usual prescriptions for spatial quantization (see PARAMAGNETISM). For such atoms the paramagnetic effect will dominate over the generally much smaller diamagnetic effect. A bulk system consisting of paramagnetic atoms in the gaseous state will then possess a net magnetism determined by Maxwell–Boltzmann statistics. Such systems are also optically active. If a magnetic field is applied parallel to the direction of propagation of an incident polarized light beam, the plane of polarization is rotated, with the degree of rotation directly proportional to the strength of the magnetic field. This is the *Faraday effect* (see MAGNETOOPTICAL DEVICES). The proportionality constant is called the *Verdet constant.* The Faraday effect has a variety of applications in optical and waveguide devices (usually, however, using paramagnetic materials in the condensed phase). The Faraday effect can account for the rotation of polarization in large galactic clouds in the presence of galactic magnetic fields.

10. ATOMIC SIGNATURES

We discuss here the several diagnostic techniques that are used to identify, or detect, specific atomic systems and states. The prime diagnostic tool of all is, of course, atomic spectroscopy (*q.v.*). Since atomic energy levels are specific to individual elements and to isotopes of elements, spectroscopy can be used to identify these unambiguously and without great difficulty. Resonance fluorescence—stimulating the emission of atomic radiation by selective excitation using lasers—is of singular value in such identifications. However, there are other diagnostic methods that do not involve radiation, which add invaluable tools to the investigator interested in atomic identification.

The neutral, isolated atom is not an easy object to observe. Apart from its radiation signature its electric neutrality renders it almost impervious to observation. The relatively crude diagnostic of mass deposition—allowing atoms to deposit on a substrate and be weighed—can be, and has been, used. However, there are far more sensitive detection schemes available.

Apart from resonance fluorescence, sensitive atomic detection schemes rely upon the ionization of the atom first, followed by measurement of an electric current—a two-step process. Ionization is most easily accomplished by use of *surface ionization,* wherein an atom gives up its valence electron to a metal surface and evaporates as an ion. For this to be accomplished the atom must possess an ionization potential that is comparable to, and preferably less than, the work function of the metal. This condition is most readily satisfied by the alkali metals interacting with almost any refractory metal surface such as tungsten or platinum. Alkali metals can be detected with virtually 100% efficiency by this means. This work function can be increased by oxidation of the surface thereby significantly enhancing the number of elements that can be detected by surface ionization.

Equally efficient is ionization of high-lying metastable states, such as metastable hydrogen and the metastable states of the rare gases. Here the excess energy of the metastable state is converted into kinetic energy of the valence electron, which can be sufficient to ionize (the *Auger effect*—see AUGER SPECTROSCOPY). Both of these methods are restricted to relatively small classes of atoms, those with low ionization potentials or with high metastable energies. The most general method, albeit a brute force one, is the use of electron impact ionization. This method is generally used in mass spectrometry applications, and such devices are readily available commercially. It has the disadvantage of being relatively inefficient, in general ionizing only a fraction of 1% of the neutral atoms. Another brute force method, the use of *field emission* (see FIELD EMISSION AND FIELD IONIZATION), is very effective in ionizing atoms near conducting whiskers to which strong electric fields are applied. However, this method possesses limited applicability and is effective only over small areas. A more general and selective method is the use of *resonant ionization spectroscopy (RIS)* to ionize. Many schemes can be used for this purpose. An atom can be raised to a highly excited state by laser excitation, either in a one or two step process, with an external electric field then used to ionize. RIS efficiencies can approach and even exceed 100% (the same atom can be detected more than once!), and it is nondestructive, leaving the atom in the same state after as before detection.

11. SUMMARY

In this short article we have attempted to outline some of the principal characteristics of atomic systems and to link these to some important applications. The brief discussions herein presented cannot attempt to cover these in detail; the reader is referred to the many articles of this Encyclopedia that do treat them more comprehensively. Some general sources for seeking further information on the many topics lightly touched on here are listed in the references given below. Certain extremely important topics that belong properly within the study of atoms have barely been noted here, since they address so-called "fundamental," as opposed to "applied," topics. However, as has been mentioned more than once in this article, there is not a large separation between these two supposedly disparate areas. Yesterday's fundamental studies were the basis of today's practical applications, and this statement applies equally well for today's fundamental studies and tomorrow's applications.

The best source material that covers both of these aspects of atomic structure and properties is contained in the series of volumes generically entitled "Atomic Physics," which presents all the invited papers and selected contributed papers of the biannual conference series "International Conference on Atomic Physics" (ICAP). Included in recent volumes are papers on structure of very high-Z atoms, tests of nonconservation of parity in weak interactions by spectroscopic techniques, the development of very high precision time and frequency standards, energy levels and electron correlation effects in very highly excited (Rydberg) states, properties of such states in strong electric and magnetic fields, precision measurements of hyperfine and fine structure in atomic hydrogen, analogous studies in "exotic" atoms (see the article EXOTIC ATOMS AND MOLECULES), precision measurements of fundamental atomic constants (see CONSTANTS, FUNDAMENTAL), and precision tests of fundamental concepts in quantum mechanics using atomic physics techniques (i.e., Bell's inequality and the Einstein–Podolsky–Rosen "paradox"), to mention some of the important "hot topics" of current interest.

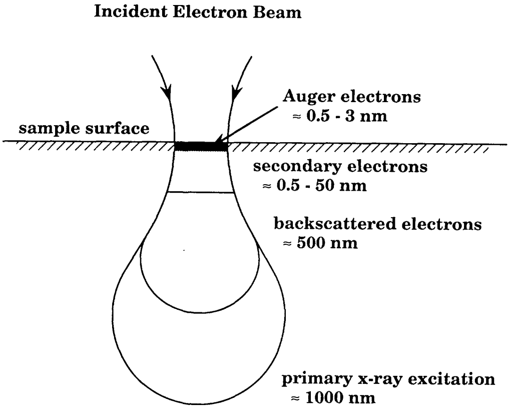
INTRODUCTION

When a solid sample is bombarded with energetic electrons (1–10 keV), core electrons will be ejected from an energy level E_x for a depth of approximately 1–2 μm. The core hole E_x is then filled by an internal process in which electrons from energy level E_y fall into the core holes E_x. Energy balance is achieved either by x-ray photon emission (fluorescence) with energy approximately $E_y - E_x$ or by ejection from the solid sample of a third electron from energy level E_z. The third electron, called an Auger electron after Pierre Auger, who first observed such events in a cloud chamber (Auger, 1925), is thus ejected from the atom with an energy E_{Auger} given approximately by

$$E_{\text{Auger}} = E_z + E_y - E_x. \tag{1}$$

Because the energy levels E_z, E_y, and E_x are unique for each element, the Auger electron E_{Auger} will have a unique energy. Thus, if the Auger energy spectrum from 0 to $\approx$ 2 keV is measured, then all the elements present on the solid sample, except hydrogen and helium, may be identified (Seah and Briggs, 1983).

Auger electron spectroscopy (AES) is a surface-sensitive technique because of the intense inelastic scattering that occurs for electrons in the energy range 0 to $\approx$ 2 keV, illustrated schematically in Fig. 1. Only Auger electrons from the outermost $\approx$ 0.5–3 nm of a solid survive to be ejected and measured in the spectrum.



Incident Electron Beam
Auger electrons ≈ 0.5 - 3 nm
sample surface
secondary electrons ≈ 0.5 - 50 nm
backscattered electrons ≈ 500 nm
primary x-ray excitation ≈ 1000 nm

FIG. 1. Schematic diagram comparing Auger electron escape depths with emission depths for backscattered electrons and x rays (after Joshi, 1986).

Harris (1968a, 1968b, 1974) at General Electric was the first to realize that the small Auger peaks, which occur on a much larger background of secondary electrons ejected from the sample surface, could be separated from the background through the use of ac modulation and detection techniques. He used potential modulation of the analyzer to obtain the differentiated Auger electron spectrum, $d[EN(E)]/dE$ vs E, which has been used ever since (potential modulation is described in Sec. 3.1.1).

The addition of electron-beam steering optics and a secondary electron detector enables the now modified Auger electron spectrometer to obtain both Auger and secondary electron images of the sample under study. The modified apparatus is known as a scanning Auger microprobe (SAM).* A SAM apparatus provides an ultrahigh-vacuum environment in which to obtain Auger spectra of localized areas (typically $\approx$ 25 nm–1 μm), a high-brightness tightly focused electron gun, a high-transmission electron energy analyzer, and a computer system to acquire and manipulate the resultant data. A SAM can also function as a medium-resolution scanning electron microscope (SEM). While questions of chemical composition are easily answered using the AES-SAM, structural- and chemical-state information is much more difficult to extract.

The present article will review both the physical principles involved in the Auger electron process and phenomenological approaches to the analysis of Auger electron spectra. A detailed discussion of the experimental apparatus, which then leads into a description of experimental techniques such as *in situ* sample fracture and depth profiling, will be presented. Finally, several applications of AES to problems in microelectronics, metallurgy, mineralogy, etc., will be briefly discussed. The example applications discussed here are selected for their breadth across several different fields.

The present article is not an exhaustive review of the application of AES to specific systems; the recent bibliographic reviews [Fulghum *et al.* (1989) and Turner (1990, 1988, 1986)] provide more complete coverage. The reader is encouraged to pursue specific information from the many excellent review articles [Powell and Seah (1990); Nebesny, Maschhoff, and Armstrong (1989); Joshi (1986); Seah (1984); Werner and Garten (1984); Morgan (1983); Shimizu (1983); Zinner (1983); Stein and Joshi (1981); Wild (1981); and Hondros and Stoddart (1980)] and from the additional references given here.

---

*In the present article, SAM will refer to scanning Auger microprobe, not to be confused with Scanning Acoustic Microscope.

To start, Table 1 presents a summary of both the capabilities and applicability of Auger electron spectroscopy to the study of solid surface composition (Joshi, 1986).

1. THE AUGER ELECTRON PROCESS

A schematic diagram of the Auger emission process in a solid is presented in Fig. 2. The Auger process is a three-electron process. The incident electron beam strikes the sample with energy E_p, which must obviously be greater than the binding energy for the K (or L, M, etc.) core level E_K (or E_L, E_M, etc.) and ionizes the K (L, M) core level, Fig. 2(b). Due to the variation of the ionization cross section with energy, the incident electron-beam energy E_p must be greater than approximately $5E_K$ for efficient core-level ionization to occur (Briggs and Rivière, 1983). An electronic transition from an outer (lower-energy) level, for example, the L_1 level, to the core ionization hole relaxes the ionized atom. As a result, the energy $E_K - E_{L_1}$ becomes available and produces either characteristic x-ray photon or electron emission, Fig. 2(b). The first process is that of x-ray fluorescence while the second is Auger electron emission. The energy $E_K - E_{L_1}$ can be given to another electron in the same (L_1 in the present example), or less energetic (M), energy level, and that electron is ejected. Thus, the energy of the ejected Auger electron is

$$E_{KL_1L_{2,3}} = E_K - E_{L_1} - E^*_{L_{2,3}}, \tag{2}$$

where E_i are now the binding energies of the ith atomic energy levels [cf Eq. (1)] and $E^*_{L_{2,3}}$ is starred because it represents the binding energy of the $L_{2,3}$ level in the presence of a hole in level L_1, and therefore has an energy different from $L_{2,3}$ in its ground state. A doubly ionized final state results, Fig. 2(c). Note that the zero of energy is assumed to be at the Fermi level, since it is normal in AES to measure binding energies with respect to the Fermi level.

The Auger energy expressed by Eq. (2) is a function only of atomic energy levels. For each element in the periodic table, there is a unique set of Auger energies since no two elements have the same atomic binding energies (Davis *et al.*, 1976; McGuire, 1979). Thus, analysis of Auger energies leads immediately to elemental identification.

For heavy elements, the number of energetically possible Auger transitions for a given primary electron energy can become increasingly large as the number of atomic energy levels increases. However, the Auger transition probabilities favor only a few of the many possible transitions, so that the problem of elemental identification is feasible.

1.1 Auger Electron Current

The derivation of the Auger electron current is presented following the analysis of Seah (1983a). A total ionization $\sigma_{AX}(E_p)$ is caused by incidence of the primary electron beam, with energy E_p and current I_0, upon the sample. Additional ionization of atomic energy levels is caused by backscattered energetic electrons. If the number of backscattered electrons with sufficient energy to ionize atomic energy level X is given by

$$\int_{E_{AX}}^{E_p} \sigma_{AX}(E) n(E) dE, \tag{3}$$

where $n(E)$ is the true backscattered electron spectrum per unit incident electron, then the total ionization due to both the primary electron beam and the backscattered energetic electron may be written as

$$\sigma_{AX}(E) = \sigma_{AX}(E_p)[1 + r_M(E_{AX}, E_p, \alpha)], \tag{4}$$

where the backscattering term r_M is dependent upon the matrix M in which the A atoms are embedded and the angle α between the surface normal and the incident electron beam. The backscattering term r_M typically varies between 0.1 and 1.5 for 5-keV electrons incident at 30° from the surface normal (Shimizu and Ichimura, 1981; Ichimura and Shimizu, 1981).

The Auger electron created by the ionization process has a probability e^{-1} of traveling

Table 1. Auger electron spectroscopy—summary of capabilities (after Joshi, 1986).

Use	Estimated Analysis Time
(1) 0–3-nm surface elemental analysis for all elements except H and He. (2) Depth vs composition profiling and thin-film analysis. (3) ⩾20-nm lateral resolution surface chemical analysis. (4) Grain-boundary and other interface analyses facilitated by sample fracture. (5) Identification of phases in cross sections.	(1) Survey spectra: ≈5 min for a complete scan from 0–2000 eV. (2) Selected peak analyses: ≈15–30 min depending upon the number of peaks. (3) Depth profiling: ≈30–300 min or longer. (4) Auger elemental imaging: ≈30–300 min or longer.
Limitations	Examples of Applications
(1) Quantitative detection sensitivity is from 0.1 to 1.0 at.% (2) Accuracy of quantitative analysis limited (±30%) when calculated using sensitivity factors. Better quantification (±10%) when standards that closely resemble the samples are available. (3) Insensitive to H and He. (4) Electron-beam charging may limit the analysis of insulating materials. (5) Electron-beam damage may limit analysis of organic and biological materials.	(1) In-depth compositional variation of thin films used for microelectronic applications; thin films and coatings used for metallurgical surface modifications. (2) Analysis of grain-boundary chemistry to determine the role of precipitation and solute segregation on mechanical properties, corrosion, and stress corrosion cracking. (3) Analysis of surface contamination of materials as a result of thin-film processing, corrosion, wear, and catalysis.
Samples	Capabilities of Related Techniques
(1) Form: Solids with low vapor pressure [$\leqslant 1.33 \times 10^{-6}$ Pa (10^{-8} Torr) at 25 °C]. (2) Size: Limited by specific instrument; $2 \times 1 \times 1$ cm is typical; powder particle $\geqslant 1$ μm diameter may be analyzed. (3) Topography: Flat surfaces are preferable; rough surfaces may be analyzed either in small areas (≈1 μm^2) or averaged over large areas (≈200 μm^2). (4) Preparation: Frequently none; samples must be free of fingerprints, oils, and other high-vapor-pressure materials.	(1) X-ray photoelectron spectroscopy: provides compositional and chemical binding-state information; less destructive of organic and biological samples. (2) Ion scattering spectroscopy: provides unambiguous surface composition (3) Secondary-ion mass spectrometry: part-per-billion elemental detection sensitivity; surface composition information; depth profiling capability; sensitivity for all elements, including H and He. (4) Electron probe: analysis to 1 μm depth and lateral resolution; quantitative and nondestructive. (5) Analytical electron microscopy: chemical analysis in conjunction with high-resolution transmission electron microscopy.

FIG. 2. Schematic diagram of the Auger emission process in a solid (after Rivière, 1983).

a distance $\lambda_M(E_A)$ in the matrix material before being inelastically scattered and no longer appearing in the Auger peak at energy E_A. The distance $\lambda_M(E_A)$ is known as the inelastic mean free path. The flux of Auger electrons decays as $\exp[z/\lambda_M]$ as a function of distance z from the point of origin. The characteristic depth from which Auger electrons can be emitted is $\lambda_M(E_A)\cos\theta$ (commonly called the escape depth), where θ is the angle of emission relative to the surface normal. Values of λ are typically 2–10 atomic layers for Auger electrons with $E_A > 10$ eV, Fig. 3 (Seah and Dench, 1979), which accounts for the surface-sensitive nature of Auger electron spectroscopy [and x-ray photoemission spectroscopy (XPS) as well]. The curve shown in Fig. 3 is a compilation of experimental data derived from Auger transitions for many elements.

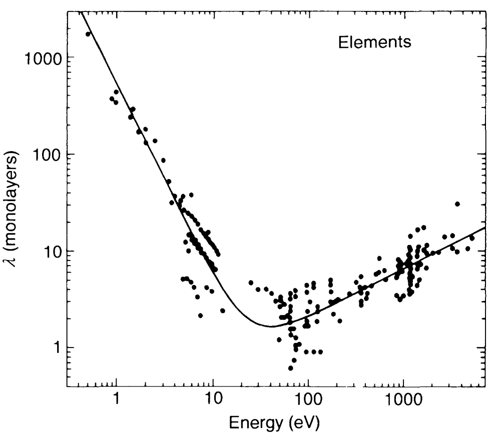

FIG. 3. The dependence of λ, the inelastic mean free path, on electron energy. The curve is a compilation of experimental data derived from Auger transitions for many elements (after Seah and Dench, 1979).

The emitted Auger electrons are detected by an electron kinetic-energy spectrometer with a transmission efficiency $T(E_A)$, and an electron detector of efficiency $D(E_A)$. Thus, the Auger electron current I_A may be written as

$$I_A = I_0\sigma_A(E_p)[1 + r_M(E_A,\alpha)]T(E_A)D(E_A) \times \int_0^\alpha N_A(z)\exp[-z/\lambda_M(E_A)\cos\theta]dz, \tag{5}$$

where $N_A(z)$ is the A-atom distribution with depth z into the sample surface. The current should be integrated over the appropriate angular entrance aperture of the electron spectrometer.

1.2 Phenomenological Analysis of AES Data

At the present time Eq. (5) is not used directly for the quantification of Auger data. Instead, Eq. (5) is used as a starting point and various simplifications are made (Hall and Morabito, 1979) to determine the mole fractions of the specimen constituents. The end result is a simplified expression which is generally applicable to the analysis of multicomponent solids.

Starting with the simplest multiconstituent solid, a homogeneous binary system, *AB*, the number of unknowns in Eq. (5) can be reduced by considering the ratio of intensities I_A/I_B for *AB* and the ratio of intensities for the pure element standards I^∞_A/I^∞_B, recorded on the same AES instrument,

$$\frac{X_A}{X_B}=F^A_{AB}\frac{I_A/I^\infty_A}{I_B/I^\infty_B}, \tag{6}$$

where X_A and X_B are the mole fractions of *A* and *B*, respectively, in the solid *AB*, and the Auger electron matrix factors F^A_{AB} are given by

$$F^A_{AB}(X_A\rightarrow 0)=\left(\frac{1+r_A(E_A)}{1+r_B(E_A)}\right)\left(\frac{a_B}{a_A}\right)^{1.5}, \tag{7}$$

$$F^A_{AB}(X_A\rightarrow 1)=\left(\frac{1+r_A(E_B)}{1+r_B(E_B)}\right)\left(\frac{a_B}{a_A}\right)^{1.5}, \tag{8}$$

where r_A and r_B are the backscattering factors for *A* and *B* in *AB* [see Eq. (4) above] and a_M is the atom size of *A* derived from $1000\rho_M N a^3_M = A_M$ where ρ_M is the density, *N* is Avogadro's number, and A_M is the mean atomic weight of the matrix. The ratio r_A/r_B is relatively energy independent (Shimizu and Ichimura, 1981), and so F^A_{AB} varies little across the composition range from *A* to *B* and may usefully be considered a constant for the *AB* system.

The above approach was originated by Hall and Morabito (1979), who calculated the matrix terms for the two extremes of Eqs. (7) and (8) for 4860 binary systems. In this way, they showed that in 86% of the binary systems

$$F^A_{AB}(X_A\rightarrow 0)=F^A_{AB}(X_A\rightarrow 1) \tag{9}$$

is valid to within 5%. If the matrix factors are ignored, then Eq. (6) reduces to

$$X_A=\frac{I_A/I^\infty_A}{\sum\limits_{i=1}^{n} I_n/I^\infty_n}. \tag{10}$$

1.3 Sensitivity Factors and Auger Intensities

In the absence of a large number of pure elemental standards, from which values for I^∞_A, I^∞_B, etc. may be obtained, the Auger signal from the sample may be normalized relative to both

1. the signals of all of the sample Auger peaks present in the spectrum, and
2. the signal of the pure sample element compared to the signal from a pure elemental target, typically silver.

The latter, shown in Fig. 4, are readily available in handbooks (e.g., Davis *et al.*, 1976). Thus,

$$X_A=\frac{I_A/S_A}{\sum\limits_{i=1}^{n} I_n/S_n}, \tag{11}$$

where I_A is the intensity of the Auger peak associated with element *A*, and S_A is the Auger

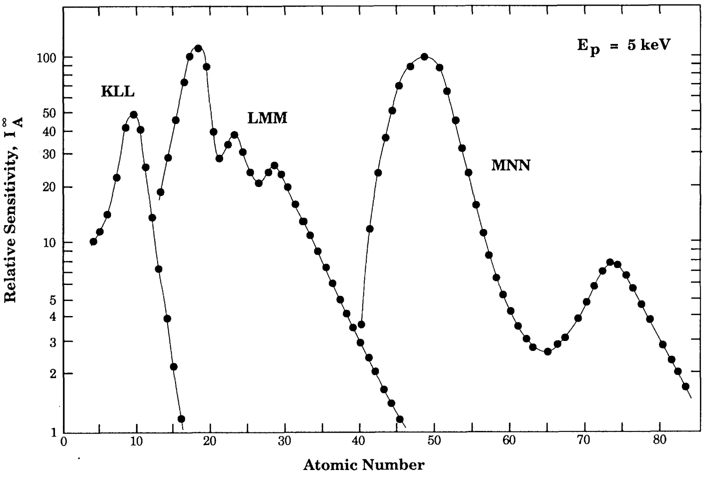

FIG. 4. Relative sensitivity factors for the elements from derivative AES spectra obtained at E_p=5 keV compiled by Davis *et al.* (1976).

sensitivity factor for element A at the particular E_p employed. The Auger sensitivity factors are used for I_A^∞, I_B^∞, etc., subject to the assumptions that

1. the peak shapes are the same in both the analysis and reference spectra,
2. the analyzers used for both spectra have the same resolution, and
3. the same modulation is used in both cases.

The choice of Auger intensities I_A and I_B is a matter of some debate (Nebesny *et al.*, 1989; Seah, 1983a). The use of peak-to-background (P/B) ratios in AES was first introduced as a means of correcting for small microtopographical variations on the surfaces of solid samples and has been assessed (El Gomati, 1988). More recently, Powell and Seah (1990) have critically reviewed the major steps in typical AES (and XPS) quantitative analyses and have commented on the major sources of error which lead to estimates of uncertainty in AES measurements.

2. EXPERIMENTAL APPARATUS

A photograph and a schematic diagram of a typical scanning Auger microprobe (SAM) are presented in Fig. 5. The stainless-steel ultrahigh vacuum chamber, which contains the electron gun and electron kinetic-energy analyzer, is visible on the left-hand side in Fig. 5(a), while the data-acquisition and analysis computer with associated displays and printer is seen on the right. The instrument control electronics are below. Each of the major subsystems of the instrument is discussed in greater detail below.

2.1 Vacuum System

2.1.1 General. Auger spectra are acquired in an ultrahigh-vacuum (UHV) environment. There are two main reasons for this. First, the Auger electrons, of energy $\approx$10–4000 eV, must not be scattered by the ambient gas to a degree sufficient to cause signal attenuation. The condition that the electron mean free path be much greater than the physical dimensions of the Auger spectrometer is met by a vacuum in the 1.33×10^{-3} to 1.33×10^{-4} Pa (10^{-5} to 10^{-6} Torr) range. The second reason for an UHV environment is far more stringent; the rate of sample surface contamination, from whatever source, must be slow compared to the Auger analysis time. Since Auger spectroscopy samples a depth of only a few atomic layers, typically the first one or two layers, and sensitivities of $\approx$ 0.5 at. % are routine, Auger spectra are extremely susceptible to surface contamination effects, which therefore mandates UHV conditions. Base spectrometer pressures of 6.7×10^{-9} to 2.7×10^{-8} Pa (5×10^{-11} to 2×10^{-10} Torr) are typical.

The three types of vacuum pumps commonly found on Auger spectrometers are sputter ion, turbomolecular, and titanium sublimation pumps. Each type of pump has both advantages and disadvantages peculiar to its operation (Rivière, 1983) with an Auger electron spectrometer. In general, sputter ion pumps of capacity 100–200 L s^{-1} are employed as the main or holding UHV pump. Their operation is somewhat feeble with respect to their capacity to pump both noble gases (especially helium) and hydrogen. Turbomolecular pumps are generally used to pump spectrometers from atmospheric pressure to 1.33×10^{-3} to 1.33×10^{-4} Pa (10^{-5} to 10^{-6} Torr), where sputter ion pumps become effective, and to differentially pump sputter ion guns (see Sec. 2.5). For long-term use, however, questions of bearing lifetime and especially mechanical vibration, a serious impediment to operation at high magnifications (e.g., $> 10\,000\times$), plague turbomolecular pumps. Titanium sublimation pumps are typically used at pressures $\leqslant 1.33 \times 10^{-4}$ Pa (10^{-6} Torr) to getter hydrogen, hydrocarbons, and other reactive gases (i.e., oxygen and nitrogen-containing gases). Sublimation pumps reduce the gas ingestion load that the sputter ion pump is exposed to as UHV conditions are attained. Detailed information about the production and measurement of ultrahigh vacuum conditions is presented in the article VACUUM TECHNIQUES AND INSTRUMENTATION.

2.1.2 Sample-Load-Lock and Ion-Gun Differential Pump. Most Auger spectrometers typically utilize a small (20–50 L s^{-1}) turbomolecular pump for two purposes. First, the pump serves to evacuate a small, auxiliary chamber adjacent to the main vacuum chamber and employed as a sample load lock, shown schematically in Fig. 5(b). A sample on

FIG. 5. (a) A typical scanning Auger microprobe (SAM). The stainless-steel ultrahigh-vacuum chamber, which contains the electron gun and electron kinetic-energy analyzer, is visible on the left-hand side. The data-acquisition and analysis computer with associated displays and printer is seen on the right-hand side. The instrument control electronics are below. (b) Schematic diagram of a SAM. In the diagram, Fil is a LaB_6 filament, Cond Lens is a condenser lens, Det is an electron detector, CMA is a cylindrical mirror analyzer, Obj is an objective lens, SED is a secondary-electron detector, and Stage is a sample manipulation stage.

a carrier may be placed in the load lock, the load lock pumped to a relatively high vacuum 1.33×10^{-5} to 1.33×10^{-6} Pa (10^{-7} to 10^{-8} Torr), and the sample introduced into the spectrometer using a mechanical or magnetic linear motion feedthrough shaft. The load lock greatly increases the productivity of the Auger apparatus since it obviates the need to bake out and pump the system into the UHV range every time a sample must be changed. Thus, samples may be inserted into and removed from the AES spectrometer in minutes rather than days. The small turbomolecular pump also serves to pump differentially a sputter ion gun attached to the Auger apparatus for sputter depth profiling (see Sec. 2.5 below). The turbomolecular pump evacuates the sputter gas (typically argon) from the filament region of the sputter ion gun, thus relieving the gas load on the sputter ion pump.

2.2 Electron Gun

The electronic and mechanical stability of the electron gun is of utmost importance. The lack of stability, or drift, of the electron gun can severely limit the ability to perform Auger analysis of small samples ($\approx$ 0.1 μm) over long periods of time ($\approx$ 1 h) because the electron beam will drift away from the sample point of interest.

2.2.1 Thermionic. Thermionic emitters are typically employed in AES. Due to advances in design and reliability, filaments of lanthanum hexaboride (LaB_6), with its greater brightness ($\approx 10^6$ A cm^{-2} sr^{-1}) and lifetimes in excess of 500 h, are displacing those of tungsten (W) (brightness $\approx 10^4$ A cm^{-2} sr^{-1}) (Christou, 1976). Electron-beam diameters have decreased over 1000× during the ≈20 yr commercial development of Auger spectroscopy, as shown in Table 2. In purely electrostatic electron guns, spot size has decreased progressively from $\approx$ 400 to 0.5 μm, while a beam diameter of $\approx$ 0.1 μm is obtainable with electromagnetic guns prevalent today.

Table 2. Progress in AES beam diameter.

Date	Beam diameter (μm)	Beam current (nA)	Beam voltage (keV)
Early 1970s	400	2×10^4	2.5
Mid 1970s	40	5×10^3	5
Mid 1980s	0.5	10	10
Late 1980s	0.1	1	25

2.2.2 Field Emission. Field emission guns, which have even greater brightness ($\approx 10^7$ A cm^{-2} sr^{-1}) than LaB_6 thermionic emitters, have been employed only rarely in AES to date. However, field emission sources employed with electrostatic electron-gun optics exhibit beam diameters typical of thermionic guns with electromagnetic optics (Prutton *et al.*, 1982). Hence, as smaller and smaller beam diameters are required, the use of field emission guns is expected to increase.

2.3 Electron Kinetic-Energy Analyzer

The electron kinetic-energy analyzer is the heart of the Auger spectrometer. Because of the low electron kinetic energies involved ($\approx$ 10–4000 eV), and because magnetic fields are difficult to produce and control in UHV, all Auger spectrometers to date use electrostatic electron kinetic-energy analyzers exclusively. The two principal types are the cylindrical mirror analyzer (CMA) and the hemispherical sector analyzer (HSA).

Two different definitions of energy resolution are in current use. The absolute resolution ΔE is defined as the full width at half-maximum (FWHM) height of a particular Auger peak. The relative resolution is defined as $R=\Delta E/E_0$, where E_0 is the kinetic energy at the peak position. The Auger linewidth is independent of the linewidth of the incident electron beam. Therefore, the resolution requirements are determined by the linewidths of the Auger peaks themselves, which are typically several eV wide. In practice, it is desirable to have high sensitivity at high Auger energies ($>$ 1000 eV), where the production of Auger electrons is diminished due to branching into x-ray fluorescence relaxation channels, and high absolute resolution at low Auger energies ($<$ 150 eV). This is achieved by operation at constant relative resolution. For further information about electron kinetic-energy analyzers, see SPECTROMETERS, ELECTRON AND ION.

2.3.1 Cylindrical Mirror Analyzer. The cylindrical mirror analyzer is shown schematically in Fig. 6. Auger electrons enter at an angle α to the axis of cylindrical symmetry and pass between two coaxial cylinders of ra-

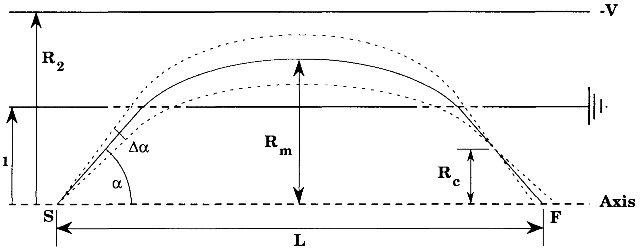

FIG. 6. Diagrammatic arrangement of a cylindrical mirror analyzer (CMA). R_c is the position of the minimum trace width [after Bishop, Coad, and Rivière (1972) and Rivière (1983)].

dii R_1 (inner) and R_2 (outer). The potential of the inner cylinder is at ground, while the potential of the outer cylinder is at $-V$. Electrons emitted from a source S on the axis with a particular energy E_0 are deflected by the outer cylinder potential through another aperture to focus on the axis at F. The relationship between V and E_0 is given by

$$\frac{E_0}{eV}=\frac{K}{\ln(R_2/R_1)}, \tag{12}$$

where K is a geometrical constant. For the special case of $\alpha = 42° 18'$, the CMA becomes a second-order focusing electron kinetic energy analyzer with $K = 1.31$ (Zashkvara *et al.*, 1966). It is desirable to achieve maximum sensitivity compatible with adequate resolution by operating the CMA with apertures that accept a range of angles about α, typically $\Delta\alpha=6°–10°$. For the angle $\alpha = 42° 18'$, the distance on the symmetry axis between the source and focus is $6.1R_1$; and the maximum distance off axis reached by the electrons, R_m, is given by

$$R_m=R_1\exp(1.3 \sin^2\alpha) \tag{13}$$

or, for $\alpha = 42° 18'$, $R_m= 1.8R_1$.

Scanning the potential $-V$ applied to the outer cylinder of the CMA gives the energy distribution of the electrons traversing through it. Because the transmission of the CMA varies as E_0, the energy distribution obtained is not $N(E)$, but rather $EN(E)$.

The half-width energy resolution for a CMA operated in the double-focusing mode, i.e., the entrance angle $\alpha = 42° 18'$, is given by

$$\frac{\Delta E}{E_0}=\frac{0.18w}{R_1}+1.39(\Delta\alpha)^3 \tag{14}$$

(Rivière, 1983) where w is the slit width (assumed to be equal at the entrance and exit), R_1 is the inner cylinder radius, and $\Delta\alpha$ is the angular aperture. For the CMA, the relatively wide angular apertures used (typically $\approx$ 6°) tend to limit the resolution obtainable. For example, a CMA built with an inner radius R_l of 3 cm and an angular aperture $\Delta\alpha$ of 6° will have a theoretical half-width resolution $\Delta E/E_0$ of 0.16% (1.6 eV for a 1000-eV Auger electron) for source sizes of 1–5 μm. Adjustable slits at the exit of the CMA are commonly employed to vary the energy resolution of commercial AES spectrometers over a broad range, e.g., from 0.3% to 2.0%.

The single-pass CMA is most effective in AES because of its very high transmission. This is the single most important property for an AES analyzer because the source area in AES using a highly focused electron beam is invariably much smaller than the acceptance area of the analyzer. With the small signal levels inherent in submicron Auger studies, high electron energy analyzer sensitivity is an absolute requirement. In this instance, the CMA is much preferred over the HSA because of the full 2π electron entrance cone and the high transmission ($\approx$ 10%) of the CMA compared to the HSA ($\approx$ 1%– 2%).

2.3.2 Hemispherical Sector Analyzer.

The hemispherical sector analyzer, also known as the concentric hemispherical analyzer, is more widely used in x-ray photoemission (or photoelectron) spectroscopy (see PHOTOEMISSION AND PHOTOELECTRON SPECTRA) than in Auger electron spectroscopy. The HSA is shown schematically in Fig. 7. Two hemispherical surfaces of inner radius R_1 and outer radius R_2 are positioned concentrically. Potentials V_1 and V_2 are applied to the inner and outer surfaces, respectively, and $V_2 > V_1$, so that a potential difference $\Delta V= V_2- V_1$ is established between the surfaces. While a continuous infinity of equipotential surfaces exists between the two surfaces, only the median equipotential surface is established with radius R_0. All other equipotential surfaces re-

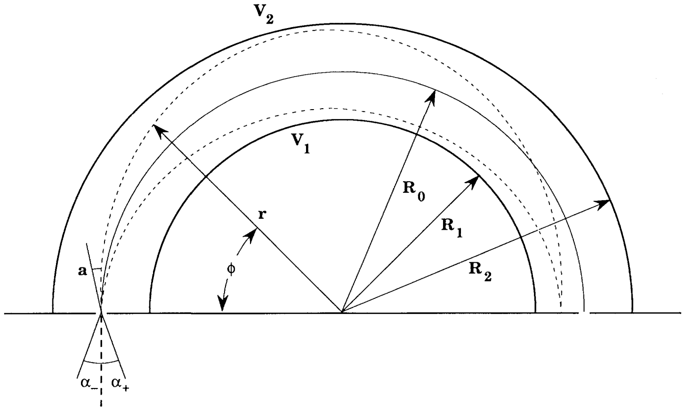

FIG. 7. Schematic diagram of a concentric hemispherical sector analyzer (HSA). If E is the kinetic energy of an electron traveling in an orbit of radius R_0, then the relationship between E and V is given by Eq. (16). ϕ and r are the angular and radial coordinates, respectively, of an electron of energy $E_0(=e\Delta V_0)$ entering the analyzer at an angle α to the slit normal (after Roy and Carette, 1971).

sult in radii greater or less than R_0. Entrance and exit slits are centered at radius R_0. In the ideal situation,

$$R_0=(R_1+R_2)/2. \tag{15}$$

The relationship between the deflecting potential ΔV and the ideal energy E for an electron trajectory that follows the equipotential R_0 is given by

$$e\Delta V=E(R_2/R_1-R_1/R_2). \tag{16}$$

The HSA, like the CMA, is double focusing. Early HSA Auger analyzers were operated by maintaining the potential along radius R_0 at ground potential and varying the specimen potential. Today, however, the situation is reversed—the specimen is grounded and the potentials of the analyzer hemispheres, now isolated from ground, are scanned.

The half-width energy resolution for an HSA operated in the double-focusing mode is given by

$$\Delta E/E_0=w/2R_0+\alpha^2/4, \tag{17}$$

(Rivière, 1983), where w is the slit width (assumed to be equal at the entrance and exit), R_0 is the interhemisphere equipotential cylinder radius, and α is the entrance angle into the HSA (equivalent to $\Delta\alpha$ of the CMA). For the HSA, it is desirable to use a large entrance angle for increased sensitivity, and it is common to use α so that $\alpha^2 \approx w/2R_0$. Thus, Eq. (17) reduces to

$$\Delta E/E_0=0.63w/R_0, \tag{18}$$

so that for a given R_0, there is an inverse relationship between the pass energy E and the slit width w for a certain absolute resolution. To illustrate, an HSA built with an interhemisphere equipotential cylinder radius R_0 of 10 cm and a pass energy E of 1000 eV will have a theoretical half-width resolution $\Delta E/E_0$ of 6.3×10^{-4} % (0.0063 eV for a 1000–eV Auger electron) for an entrance slit width of 1 μm. In practice, such high resolution is not obtained.

2.3.3 Electron-Gun–Electron-Kinetic-Energy Analyzer Orientation. There are two electron-gun–electron-kinetic-energy analyzer orientations in common use. In the first, the electron gun is coaxial with the electron kinetic-energy analyzer. This geometry has been used only with cylindrical mirror analyzers. Typically, the electron gun is located either inside the inner CMA cylinder or at a greater axial distance from the sample than the CMA.

Many of the samples to be analyzed by Auger spectroscopy are fractured *in situ* [i.e., within the scanning Auger microprobe (SAM) instrument]. This technique not only is the basis for many metallurgical investigations (corrosion, fatigue, etc.), but also provides an uncontaminated surface in an UHV environment for analysis. Because these fracture surfaces are quite rough (on a microscopic scale), an electron energy analyzer with a coaxial electron gun is useful because Auger electrons enter the CMA from the same sample area that is illuminated by the electron gun. More simply stated, the CMA sees no "shadowing" of Auger electrons emitted from a rough surface.

In the second geometry, the electron gun axis is located orthogonally (i.e. at 90°) to the electron kinetic-energy analyzer axis. In this case, severe shadowing can result, in which regions of the sample are shielded from the detector. Shadowing may limit the performance of the SAM during the analysis of fracture samples. The coaxial geometry offers the advantage of being able to analyze and map rough surfaces with much more signal collection than the orthogonal geometry.

2.4 Detectors

2.4.1 Electron Detectors. Multistage or continuous dynode electron multipliers (CDEM; also known as Channeltrons) are typically employed to detect Auger electrons. The CDEM may be biased to operate in either a pulse counting mode, for low counting rates (small-diameter electron beams), or an analog (continuous) mode, where the signal is large.

A relatively new development is the use of position sensitive detectors in electron spectrometry. The position-sensitive detector is constructed by combining a microchannel plate (MCP) assembly with a resistive anode. The MCP assembly may consist of a pair or triplet of plates, to obtain a peak gain of $\approx 5\times10^6$. The simultaneous detection of a range of energies reduces the measuring time required or, alternatively, increases the signal-to-noise ratio (van Oostrom, 1984).

2.4.2 Additional Detectors. Oftentimes, additional electron and x-ray detectors are added to the Auger electron spectrometer. These detectors permit several different types of analysis to be performed on the sample while it is in the spectrometer. Most frequently, a secondary electron detector (SED) is added to the Auger electron spectrometer. Addition of a secondary electron detector to the Auger spectrometer permits the Auger spectrometer to be operated as a medium-resolution secondary electron microscope (SEM), with great utility in locating specific features of the sample for further Auger analysis.

Less frequently, a semiconductor x-ray detector is added to the Auger electron spectrometer. This detector permits energy dispersive x-ray analysis (EDX) to be performed. Because x rays emanate from a balloon-sized region 1–2 μm in diameter, the number and identity of elements in the sample bulk may be rapidly identified. However, EDX analysis is not surface sensitive and may not reveal any information about the elements located at the sample surface.

2.5 Ion Guns

Practically all modern Auger electron spectrometers are equipped with a sputter ion gun, which allows for bombardment of the specimen surface by an energetic beam of rare-gas ions. Sputter ion guns are used both to clean and to erode the surface by energetic ion impact. Ion-bombardment cleaning is necessary to remove atmospheric gases chemisorbed and physisorbed on the specimen surface; sample fracture (Sec. 2.6.4) and surface scribing (Sec. 2.6.5) may also be employed. The sputter ion gun may also be used to obtain a compositional depth profile (i.e., the in-depth distribution analysis of chemical composition) of a specimen (Sec. 3.2). In this application, an impact or sputter crater forms on the specimen surface as energetic ion bombardment progresses. Both thermionic ionization and discharge sputter ion guns are in common use and are described in greater detail.

To obtain good depth resolution, the AES signal must originate from the flat portion of the sputter crater bottom (Zinner, 1983). Means to insure uniform erosion include defocusing the ion beam or rastering it over the sample surface. To exclude edge effects, only the central portion of the crater bottom is probed in AES analysis.

2.5.1 Thermionic. The simplest type of ion gun is similar in construction to an ionization gauge tube used to measure vacuum pressures. A hot-wire filament emits electrons into a positively biased wire-mesh grid cylinder, within which the electrons make several oscillations before being collected. A gas, typically argon, for sputtering the sample surface, is admitted to the gun at pressures between 1.33×10^{-2} and 1.33×10^{-3} Pa (10^{-4} and 10^{-5} Torr), and argon ions produced in the grid are accelerated by an extraction plate to a potential of $\approx$ 0.5–5 kV. This type of ion source can produce a maximum ion current density of $\approx 1\ \mu\text{A cm}^{-2}$ in a $\approx$ 200-μm spot at 5 cm from the gun exit aperture.

The advantages of this type of ion source are low cost, reliability, and ion-beam purity, since few energetic neutral atoms are produced in the ionizing region. A disadvantage of this type of ion gun is that either the AES spectrometer must be valved off during sputtering, since the ion pump must not be allowed to pump argon continuously, or differential pumping of the ion gun must be provided (Rivière, 1983).

2.5.2 Discharge. A second popular type of ion gun employs a gas discharge to produce ionization of the gas in the gun. Typically, the combined action of both electric and magnetic fields on argon at high pressure in the confined space of the ion-gun source produces a cold-cathode discharge from which the positive ions are extracted. Because the apertures in the ion gun are sufficiently small, differential pumping of the source is possible, allowing the pressure in the AES spectrometer to be maintained at a low level, e.g., 1.33×10^{-6} to 1.33×10^{-7} Pa (10^{-8} to 10^{-9} Torr), permitting Auger analysis to proceed during sputtering. More sophisticated ion guns of this type can produce an ion spot size of $\approx$ 0.1 mm diameter at 2–10 kV. This type of ion source can produce a maximum ion current density of $\approx 200\ \mu\text{A cm}^{-2}$.

In spite of the much greater current density of the discharge ion gun compared to the simple ionization ion gun, there are two disadvantages to this type of ion source. Ions inside the gun can strike and sputter other internal surfaces as well as being extracted into the ion beam. Therefore, arcing will occur when the accumulation of conductive material on insulating surfaces becomes sufficient to cause breakdown. Additionally, the ion beam is not pure and contains an appreciable proportion of energetic neutral atoms in addition to positive ions (Rivière, 1983).

2.6 Sample Handling

2.6.1 Sample Stage. The ability to manipulate the position of a sample in a precisely controlled manner after the sample has been inserted into the Auger spectrometer is essential. There are, in general, three reasons for this.

1. Because the shapes and sizes of specimens can vary widely, the optimum position for spectrometer energy resolution and sensitivity for one sample will not be the same as for the next sample.
2. It is often desirable either to move laterally or to rotate the sample during analysis in order to view and analyze a different region of the sample.
3. If other analysis techniques are available on the spectrometer, such as energy-dispersive x-ray analysis (EDX), it may be necessary to position the sample for analysis different from AES.

The considerations listed above suggest that at a minimum, 5 degrees of freedom in movement should be available. Typically, these involve the x, y, and z translation and both axial (z axis) and azimuthal (z tilt) rotation.

The temporal mechanical stability, or drift, of the sample stage or manipulator is of utmost importance. The drift of the sample manipulator (or the electron beam, see Sec. 2.2), can severely limit the ability to perform Auger analysis of small samples ($\approx 0.1\ \mu$m) over long periods of time ($\approx$ 1 h) because the sample stage will drift away from the electron beam.

2.6.2 Sample Carousel. A carousel-type sample holder, allowing multiple samples to be loaded into the vacuum chamber and stored under UHV conditions, is highly desirable in order to maximize the experimental throughput of the SAM. After loading several samples, the vacuum system can recover to its base pressure without further sample introductions [e.g., load samples in morning (or better, the previous evening) and analyze samples throughout the day].

2.6.3 Sample Heating and Cooling. Sample heating and cooling stages may also be useful. For heating stages which heat the entire sample and sample mount, temperatures are limited to typically 600 °C, with a long-term stability (several hours) of ± 2 °C. If the sample is thin, e.g., a foil or wire, then direct or indirect (i.e., filament) resistive heating of the sample may be used. However, the heating current should be kept as low as possible in order to reduce the effect of the magnetic fields produced on the low-energy Auger electrons. The heating stage should dissipate as little heat as possible to the Auger spectrometer, since radiational heating of other vacuum elements may result in increased outgassing, i.e., higher pressures in the Auger apparatus and possibly additional noise in the AES spectra.

Sample cooling stages are somewhat simpler in construction than heating stages and typically involve a thermally conductive pathway (copper block, heavy copper braided wire, etc.) between the sample stage and a liquid-nitrogen Dewar.

2.6.4 Sample Fracture. In the context of Auger spectroscopy, a clean surface is defined as the state of a surface in which AES does not detect any features other than those which constitute the bulk composition of the sample. Upon introduction of a sample into an AES spectrometer, initial observation will almost always reveal carbon, oxygen, and sometimes sulfur. Although ion bombardment is universally used for surface cleaning, either by itself or in combination with heating, ion bombardment may introduce artifacts, either chemical or topographical (or both), into the AES analysis of which the user should be aware. Preferential sputtering in alloys and compounds can lead to a change in the measured surface composition.

One method of producing a clean surface in an Auger spectrometer is by *in situ* fracture within the UHV environment. While many materials (metals, alloys) are too ductile at room temperature to cleave, fracture may occur at temperatures lower than the brittle-ductile transition temperature. The fracture path may then be transgranular (through individual grains) or intergranular (on grain boundaries); in either case, a surface free from contamination is produced. Note that the intergranular surface may contain impurities which have segregated from the bulk, which may then be further studied.

All practical fracture stages provide for liquid-nitrogen cooling of the sample to attempt to obtain a brittle fracture. Typically, the sample may be cooled to between 77 and ≈ 200 K. While many practical fracture stages use an impact hammer or chisel to fracture the sample, which places the sample in both tension and compression, tensile stages are available for doing quantitative fracture studies in the AES spectrometer UHV environment (e.g., from UHV Instruments, Inc., Buffalo, NY).

2.6.5 Sample Scribing. Another method of preparing a clean surface is by mechanical removal of the original surface and its associated contamination. A mechanism to scratch or scribe the surface, while not frequently found on commercial Auger electron spectrometers, can be a quite useful, simple, and inexpensive addition to the AES system. To study changes in the surface composition of alloys and compounds as a result of either ion bombardment or surface segregation, it is desirable to examine a clean surface that has a composition equal to the bulk composition. Two different methods have usually been employed to create such a surface: transgranular fracture (described above) and scribing (Betz, 1980; Betz, Marton, and Braun, 1980; Betz, Dudonis, and Braun, 1981).

The utility of sample scribing applies to three areas of Auger analysis: routine AES of samples without sputtering, AES of insulating thin films on conducting substrates, and direct measurement of preferential sputtering. By using a scriber to provide an atomically clean bulk surface rather than sputtering, the effects of preferential sputtering, in which different elements are removed from the surface at different rates, are avoided. Of secondary importance is potential contamination of the surface by low-level contaminants in the argon sputtering gas. This problem may be especially severe for highly reactive surfaces such as aluminum and titanium alloys. Auger analysis of insulating thin films on conducting substrates is often facilitated by scribing the surface, which provides a conducting pathway for the incident electrons to be dissipated from the sample.

Scribing may be used to provide a direct measurement of preferential sputtering. From the AES signal ratio for a scribed (or fractured) alloy AB surface, where R_{AB}^{bulk} is the ratio between the bulk concentrations of A and B, and $R_{AB}^{\text{sput sur}}$ is the ratio from the sputtered alloy AB surface of A and B, the component sputter yield ratio Y_A^c/Y_B^c can be obtained from

$$\frac{Y_A^c}{Y_B^c}=\frac{R_{AB}^{\text{bulk}}}{R_{AB}^{\text{sput sur}}}=\frac{c_A^{\text{bulk}}/c_B^{\text{bulk}}}{c_A^{\text{sput sur}}/c_B^{\text{sput sur}}}\,. \tag{19}$$

For the Ag–Pd system, nine alloys with $c_{\text{Ag}}=5\%$–95% were sputtered with 2-keV Ar ions under oblique incidence (75°) and also scribed and fractured (Betz, Marton, and Braun, 1980; Betz and Wehner, 1983). Surface enrichment of Pd with ion bombardment was observed using AES [Ag (351/355 eV) and Pd (326/330 eV) transitions]. The component sputtering yield ratio varied from 1.6 for Pd-rich alloys to 3.4 for Ag-rich alloys,

$$Y^c_{\mathrm{Ag}}/Y^c_{\mathrm{Pd}}=1.6 \text{ to } 3.4 \text{ as } c_{\mathrm{Ag}}=5\% \text{ to } 95\%. \tag{20}$$

2.7 Data Acquisition System

2.7.1 AES Spectrometer Digital Control. The AES electron optics may be operated under digital control to facilitate system automation, to simplify system operation, and to maximize the experimental throughput of the Auger spectrometer system. Digital control contributes ultimately to faster analyses and improved data accuracy and reproducibility. All electron-gun functions including beam parameters (beam voltage, emission current, condenser and objective lens voltages and currents), static beam positioning, scanning mode (i.e., multipoint/multiarea analyses, line scans, elemental maps, etc.), and scanning parameters may be controlled. The electron kinetic-energy analyzer and electron detector electronics and power supplies may also be digitally controlled. Predetermined data-acquisition parameters should be available in order to minimize setup time.

Auger spectra, $N(E)$ vs E, are typically converted to digital form as acquired. Once the digital Auger data have been collected, the data may be analyzed by various methods at a later time. Analog data, on the other hand, are subject to problems of uncertainty in peak position and peak area due to dependence upon instrumental time constants, modulation levels, and scanning speeds. If smoothing of the data is to be performed, it is much better to smooth digital data in a controlled manner rather than to rely upon the correct selection of scanning speed and time constant by the operator. One of the most severe disadvantages of analog data-collection methods is that it precludes data accumulation (i.e., signal averaging) to improve the signal-to-noise ratio (SNR) of a given Auger spectrum.

2.7.2 SAM Data-Analysis Computer. In addition to digital control of the AES spectrometer, additional computer software is required to analyze the data as it is acquired. The analysis computer also both serves to maximize the experimental throughput of the Auger spectrometer system and contributes ultimately to faster analyses and improved data accuracy and reproducibility. Some of the functions of the analysis computer are as follows:

1. spectral display and expansion;
2. smoothing;
3. derivative spectra;
4. peak integration and area measurement;
5. analysis of overlapping spectral features;
6. addition and subtraction of spectra;
7. peak maximum identification and location; and
8. noise spike removal.

Functions 1–3 are used in the vast majority of Auger spectra that are acquired. Function 4 is used quite frequently, while functions 5–8, though only occasionally required, are nonetheless desirable features of any data analysis package.

Associated with the AES data-analysis computer may be a full range of ancillary computer equipment such as color graphics display, color pen plotters, cameras, or archival storage media for the display, presentation, or storage of the digital AES data. For a review of computerized data acquisition and analysis, see DATA ACQUISITION SYSTEMS.

2.7.3 Ancillary SAM Capabilities. Typically the AES instrument provides a variety of ancillary signal processing features, which may be used occasionally either to calibrate and adjust the electron (and ion) optics or to obtain additional information regarding the experiment at hand. These measurements fall into three broad categories:

1. current measurement (absorbed by the sample, secondary electron, selected energy secondary electron, primary electron beam, and sputter ion beam);
2. secondary electron image manipulation (image polarity, contrast, brightness, offset, and gamma); and
3. specimen bias (positive/negative with respect to the instrument ground).

3. EXPERIMENTAL TECHNIQUES AND DATA ANALYSIS

3.1 AES Experimental Techniques

3.1.1 Auger Data Acquisition. As commonly practiced, the electron energy distribution, $N(E)$ vs E, is accumulated directly by pulse counting (for small primary electron currents, $I_p \leqslant 10^{-7}$ A) or current-to-digital conversion and measurement (for $I_p > 10^{-7}$ A). Plots of $dN(E)/dE$ vs E are produced by digital differentiation and reduce the effect of the high secondary electron background.

Older Auger spectrometers use an analog electronic method to generate $d[EN(E)]/dE$ vs E displays of Auger data. The electronic method involves imposition of a small alternating voltage on the outer cylinder of the CMA and synchronous detection of the in-phase component of the analyzer output using a phase-sensitive detector (i.e., lock-in amplifier). Because the transmission of a CMA varies as E_0, the electron kinetic energy, the distribution obtained as the outer cylinder potential V is swept is $EN(E)$, not $N(E)$. Modulation of V by a small sinusoidal signal with synchronous detection will extract $d[EN(E)]/dE$ vs E. The high secondary electron background will not be modulated and is thus eliminated from the resultant spectrum. Harris (1968a, 1968b, 1974) first used potential modulation of the analyzer to obtain differentiated Auger spectra.

Digital electronic control of the electron beam used in AES offers various choices in examining a given surface. The electron beam may be fixed on one particular point, or it may be rastered over many different points, lines, or small rectangular regions. A rastered electron beam can be used to obtain secondary electron images of the surface topography to complement AES information (Joshi, 1986).

3.1.2 Auger Point Spectra. Digital control of the electron gun permits Auger data from several different geometries and/or energy regions to be collected. Perhaps the most common are single or multiple Auger point spectra, in which the electron beam remains at one point, $I(x_0,y_0)$, on the sample for the duration of the Auger data acquisition. Similarly, Auger spectra at multiple data points, $I^n_{i=1}(x_i,y_i)$, where I_i is the Auger signal at one point and n is the number of points, may be acquired.

At each analysis location, the electron kinetic-energy analyzer may be scanned through the entire Auger kinetic energy range (typically $\approx$ 30–1000 or 2000 eV). Alternatively, several $\approx$ 20–30-eV energy windows may be recorded which include Auger transitions for only those elements of interest. For example, for GaAs, only energy windows at 1055–1085 eV and 1215–1245 eV, which bound the Ga and As *LMM* Auger transitions, respectively, need be recorded. A variation on single/multiple Auger point scanning is to acquire Auger data from single/multiple areas, typically rectangularly shaped with arbitrary width and length.

3.1.3 Auger Line Scans. Quite often Auger line scans are useful, especially when the sample is prepared such that a cross-sectional view of an interface is observable. Single (or multiple) vertical (or horizontal) lines, $I^n_{i=1}(x_0,y_i)$, of either single (or multiple) elements may be acquired. In this manner, a one-dimensional view of the change in elemental concentration across an interface may be constructed.

3.1.4 Auger Mapping. By rastering the electron beam across a sample, and at each raster location measuring the amount of an element present, $I^n_{i;\,j=1}(x_i,y_j)$, an image may be constructed in which the intensity of each raster point (pixel) represents the amount of the element present. Typically the Auger signal is collected for only one, two, or three energies at each (x_i,y_j) point. These energies include the peak of the Auger transition for those elements of interest and either one or two base-line energies from which to establish the background signal. In this manner, a two-dimensional view, or Auger map, of the change in elemental concentration across a surface may be constructed and is particularly useful during the early stages of analysis to distinguish significant from insignificant features of the surface.

3.2 AES Depth Profile Analysis

3.2.1 Sequential Versus Continuous Acquisition. The combination of an Auger electron spectrometer and an ion gun may be used to obtain a compositional depth profile (i.e., the in-depth distribution analysis of chemical composition) of a surface (Zinner, 1983). The depth profile may be obtained either sequentially or continuously. In the sequential technique, by alternately and repeatedly sputtering the surface, gating off the ion gun, and subsequently measuring the surface composition by Auger analysis, the chemical composition of the surface at each depth may be obtained. Alternatively, in the continuous technique, by continuous sputtering with simultaneous Auger analysis, the chemical composition of the surface may be obtained. Since the sputtering proceeds continuously, each depth, for each element, is slightly different than for each other element. Specimen rotation during sputtering has been shown to give improved interfacial resolution for multilayered samples (Zalar, 1985).

The data obtained during the depth profile experiment consist of Auger signal intensities of the detected elements, I_x, as functions of sputtering time, t. The data must then be converted to concentration c_x versus depth z data by an appropriate calibration of both the concentration and depth scales. The calibration of the concentration scale has been discussed above.

3.2.2 Calibration of the Depth Scale. The velocity of surface erosion is described by an instantaneous sputtering rate $\dot{z}=dz/dt$ which determines the mean eroded depth z as a function of sputtering time according to

$$z(t)=\int_0^t \dot{z}\,dt \qquad (21)$$

(Hofmann, 1983). The sputter rate $\dot{z}$ (m/s) is determined by

$$\dot{z}=(M/\rho N_A e)S j_P, \qquad (22)$$

where M is the atomic mass number; ρ is the density (kg m^{-3}); $N_A=6.02\times10^{23}$ (Avogadro's number); $e=1.6\times10^{-19}$ (electron charge); S is the sputtering yield (atoms/ion); and j_P is the primary-ion current density (A m^{-2}). For a constant sputtering rate, Eq. (21) shows a direct proportionality between sputtered depth and time, $z = \dot{z}\,t$. In this case the z axis (depth) is linear with the sputtering time and only one point is necessary to determine the calibration factor $\dot{z}$. From Eq. (22), $\dot{z}$ can be calculated by taking the sputtering rate S from literature data (Behrisch, 1981; Seah, 1981; and Oechsner, 1975) and measuring j_P with a Faraday cup.

A better method to obtain the sputtering rate $\dot{z}$ is to measure the time required to sputter through a layer of known thickness, e.g., an evaporated metallic layer or an oxide layer, for given ion-gun operation parameters. Anodized tantalum foils have proved useful for this purpose, since the thickness is easily controlled by the formation voltage. In addition, due to the sharp metal-oxide interface, oxidized tantalum foils provide a quick test method for the instrumental depth resolution. Thus, $\dot{z}$ is determined with knowledge of the Ta_2O_5 sputtering rate as compared to the material under study.

A third possibility is to measure the actual sputtered crater depth after depth profiling by conventional interferometry or stylus methods.

3.3 Depth Deconvolution Techniques

3.3.1 Factor Analysis. An old analytical technique, factor analysis (Malinowski and Howery, 1980), newly applied to Auger lineshape analysis of spectra selected from a compositional depth profile, can determine the presence and number of new chemical states formed at an interface (Gaarenstroom,1982). The procedure is superior to other methods of interpreting Auger line shape and depth profile data, such as visual inspection, spectral stripping, or peak area measurements. The range of information gained by employing factor analysis is broad: determination of the number of components, quantitative analysis from overlapping spectra, extraction of spectra for unidentified components, and speed of analysis ($\approx$ 20 times faster than spectral stripping and integration).

As an example, Fig. 8(a) shows a conventional Auger depth profile of Pt-zirconia, while Fig. 8(b) shows a chemical state depth profile of Pt-zirconia computed from Auger line-shape information. Spectra of the three individual components Pt, PtZr, and ZrO_2 are calculated by the factor analysis technique, and may be compared to spectra of reference materials in order to verify the chemical identity of the unknown (i.e., interfacial) component (PtZr in this example).

3.3.2 Depth Profiling of Multilayers—Logistic Functions. The composition versus depth distribution of a solid/solid interface as determined by Auger sputter depth profiling can be described by a logistic function of the form

$$Y=\frac{A+a(T-T_0)}{1+e^x}+\frac{B+b(T-T_0)}{1+e^{-x}}, \tag{23}$$

where Y is a measure of the surface elemental concentration of one of the components that defines the interface (Kirchhoff, Chambers, and Fine, 1986). T is a measure of the sputtering depth and is usually expressed as sputtering time assuming a constant sputtering rate. A is a measure of the preinterface surface concentration for one of the elements of the interface, and B is a measure of the postinterface surface concentration, where "pre" and "post" are taken in the sense of time. The empirical parameters a and b are introduced to account for additional time dependence of instrumental effects. T_0 is the apparent midpoint of the interface region, and x is a dimensionless, reduced time defined as $(T-T_0)/D$. The scaling factor D is the characteristic time for sputtering through the interface region. All measures of the interface width will be proportional to D. Asymmetry in the depth profile can be accommodated by allowing D to vary with time. A least-squares fitting program has been written which fits the above equation to the measured Auger spectral intensities to within the measurement error (approximately 1%). The statistics associated with the least-squares fit allow confidence limits to be placed on the measured widths of interface regions and on the asymmetry associated with each such region.

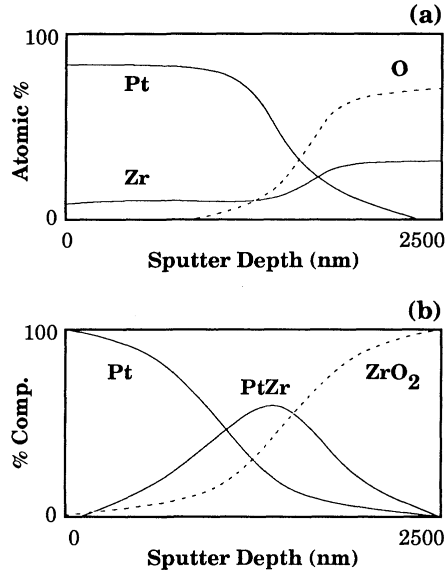

FIG. 8. (a) Conventional Auger depth profile of Pt-zirconia. (b) Chemical state depth profile of Pt-zirconia computed from Auger line-shape information (from Gaarenstroom, 1982).

4. APPLICATION OF AES TO SELECT SYSTEMS

A list of the applications of Auger electron spectroscopy to a variety of problems of current research interest is given in Table 3. Brief descriptions of each of these problems is presented in the following section.

4.1 Microelectronics

4.1.1 General. The role of analytical instrumentation is becoming increasingly critical as all aspects of microelectronic technology trend towards increasing circuit density. For a review of microelectronic devices and technology, see MICROELECTRONICS. Submicrometer feature sizes necessitate analytical techniques with comparable, or better, lateral and depth resolutions. A scanning Auger microprobe, because of its high lateral ($\approx$ 50–100 nm) and depth ($\approx$ 0.5 –3 nm) resolutions and inherent capability to function as a scanning electron microscope, is ideally suited to identify and correlate submicrometer features (SEM) with elemental analysis (AES) of these features.

By combining an Auger electron spectrometer with *in situ* ion-beam sputter etching, depth profiling on a very small scale [2-nm resolution in $\leqslant$ 100-nm depth (Helms, 1982)] may be performed. Several of the applications of scanning Auger microscopy (SAM) to microelectronics technology are as follows.

1. Wafer evaluation: AES may be used to determine that the wafer surface is free of contamination (polishing residues, etching residues, inclusions, particulates, films, surface haze, etc.).
2. Oxidation processing steps: oxide thick-

ness, segregation of impurities to the oxide surface, and localized oxide defects in metal-oxide-semiconductor (MOS) gate oxides may all be examined.

3. Wet chemical or plasma etching: etch resistant residues may be identified; redeposition of materials on side walls of steps can be detected.
4. Diffusion or ion implantation doping: the minimum detectable concentration of dopants detectable by SAM is $\approx 0.1\%$ or $\approx 10^{19}$ cm^{-2}. While this is adequate to characterize the first step (i.e., low-temperature step in which dopant is deposited onto the surface) of a normal two-step diffusion process, AES is not sensitive enough, in general, to detect dopants in finished devices. Similarly, the thickness, uniformity, and concentration of the dopant in high-dose shallow ion implants can be measured.
5. AES is applicable to many problems which involve metallization systems.
   (a) The composition distribution through the thin film depth may be obtained, and reveals segregation and annealing effects. Impurity concentrations and the interface chemistry of both Ohmic contacts and Schottky barrier diodes may be determined.
   (b) Refractory metal silicide features and contact metallization may be monitored to determine if the refractory

metal has fully reacted with the silicon.
   (c) The stoichiometry of codeposited silicides may be determined.
   (d) Aluminum spiking through shallow emitter junctions may be observed.
   (e) Interlayer diffusion and the effectiveness of diffusion barriers can be determined.
6. Packaging and bonding: the surface chemistry of pad and mating lead materials determines their bondability, strength, and electrical integrity.

Rather than to enumerate the literally thousands of journal articles in which AES and SAM are used to characterize microelectronic devices [by 1983 the number of papers published per annum for AES exceeded 1000 (van Oostrom, 1984)], the reader is referred to the review articles on applications of AES in microelectronics by Thomas and Joshi (1983), Helms (1982), Holloway (1980a, 1980b), Lowry and Hogrefe (1980), Olson *et al.* (1983), and van Oostrom (1984), which include extensive references.

4.1.2 Microelectronic Device Diffusion Barriers. As features of very-large-scale integrated microelectronic devices evolve into submicron dimensions, highly reliable diffusion barriers are necessary for metal contacts to shallow junctions. Several complementary analytical techniques—Auger electron spectroscopy (AES), Rutherford backscattering spectroscopy, secondary neutral mass spectroscopy, and secondary-ion mass spectroscopy—have all been used to investigate a reliable contact structure composed of sputtered W as the diffusion barrier and a thermally formed $TiN_y/TiSi_z$ contacting layer (Grove *et al.*, 1989). Similarly, refractory metal diffusion barriers for III-V semiconductor Ohmic contacts have been studied using Auger techniques (e.g., Huelsman and Fonstad, 1985).

4.1.3 Semiconductor Surface Potential Distribution. A contactless measurement technique known as Auger voltage contrast (AVC) for the observation of *p-n* junctions and regions using a scanning Auger microprobe has been described (Pantel *et al.*, 1982). By detecting the energy shift in Auger peaks related to Fermi-level changes in a semiconductor, internal potential variations as low as 20 meV can be measured with high lateral resolution. The source of potential contrast is clearly separated from other secondary emission contrast sources, such as topography, crystallinity, surface contamination, etc. Thus, AVC imaging of a doped semiconductor surface reveals *p-n* doped regions with high resolution and clarity, while these regions are not revealed by secondary electron microscopy.

The AVC technique may also be used for electrical depth profiling of shallow *p-n* junctions (Pantel, 1983). Depth profiling is obtained either directly, using an angle-lapped semiconductor surface, or indirectly, using sputtering. Note that while the sensitivity of Auger spectroscopy for the detection of chemical species is 10^{19}–10^{20} cm^{-3}, the AVC measurements correspond to a concentration of electrically active dopants of $\approx 1\times10^{15}$ cm^{-3}. For shallow junctions ($\approx$ 40 nm), sputter ion milling may be used to determine *p-n* junction depth. The main advantage of the AVC technique over traditional Rutherford backscattering, neutron activation, staining, pulsed capacitance, spreading resistance, or secondary-ion mass spectroscopy techniques is excellent depth resolution and information on the electrical activity of dopants.

4.2 Superconductors

Auger spectroscopy has long been used to study fracture surfaces and grain-boundary segregation processes (Seah, 1980, 1983b, 1983c). Alloyed superconducting Nb_3Sn-bronze wire filaments were fractured under ultrahigh-vacuum conditions $\approx 4\times10^{-7}$ Pa ($\approx 3\times10^{-10}$ Torr) and the structure and elemental composition of the individual wire filaments were examined (Suenaga and Jansen, 1983).

Comparison of Auger electron spectra obtained from intergranular and transgranular areas exposed on fracture surfaces of sintered $YBa_2Cu_3O_{7-\delta}$ specimens indicates that most grain boundary surfaces are deficient in oxygen and rich in copper compared to the bulk (Kroeger, *et al.*, 1988). No evidence of segregation of impurities to grain boundaries was observed. The results suggest that the grain-boundary layer is nonsuperconducting and a likely contributor to the problem of low critical current densities in $YBa_2Cu_3O_{7-\delta}$ materials. For a review of superconductivity, see SUPERCONDUCTIVITY, LOW TEMPERATURE and HIGH TEMPERATURE SUPERCONDUCTIVITY.

4.3 Metallurgy

4.3.1 Grain-Boundary Segregation. The classic example of catastrophic intergranular failure in engineering materials involves the disintegration of a turbine rotor from the Hinkley Point Power Station (United Kingdom) steam turbine generator during a routine overspeed test in 1969 (Kalderon, 1972). Scanning electron photomicrographs of a fracture surface from the failed rotor material revealed that the fracture had closely followed the prior austenite grain-boundary path with little deformation or energy expending processes. In other words, the rotor failed through brittle fracture. The fracture behavior is not characteristic of the particular alloy steel in general, since other rotors made from this material were quite safe.

Auger examination (Fig. 9) of a fracture surface from the failed rotor material showed that the fracture surface contained $\approx$ 0.45 monolayer of phosphorus at the grain boundaries. Thus, the catastrophic turbine rotor failure resulted from the segregation of the phosphorus impurity in the steel to the grain boundaries. This demonstrates the degree of care that must be taken, from casting to casting, to control the level of impurities in engineering materials.

4.3.2 Thin-Film Interdiffusion Studies. Bulk diffusion information can be extracted from Auger depth profile data of thin double-layer films (Pamler, 1987). In the case of a diffusivity which is independent of concentration, the one-dimensional diffusion equation can be written as

$$\frac{\partial c}{\partial t}=D\frac{\partial^2 c}{\partial z^2}\,. \tag{24}$$

The film consists initially of two separate layers with concentrations c_1 and c_2 (100 at.% and 0 at.%, respectively). In theory (Shewmon, 1963), the layers should be infinitely thick, but in practice, it is sufficient only that the thin-film thickness be greater than the diffusion length. After locating the origin $z = 0$ at the interface, the post-annealed composition profile $c(z,t)$ can be described by the complementary Gaussian error function to give

$$c(z,t)=\frac{1}{2}\left(\operatorname{erfc}\frac{z}{2\sqrt{Dt}}\right)\,. \tag{25}$$

Hall and Morabito (1976) proposed a simple deconvolution procedure to extract the diffusion coefficient D for the case that both annealed and unannealed profiles are error functions:

$$D=\frac{1}{4\pi t}(G_t^2-G_0^2), \tag{26}$$

which takes into account both the slope G_t of the annealed sample and the slope G_0 of the unannealed sample. The gradient,

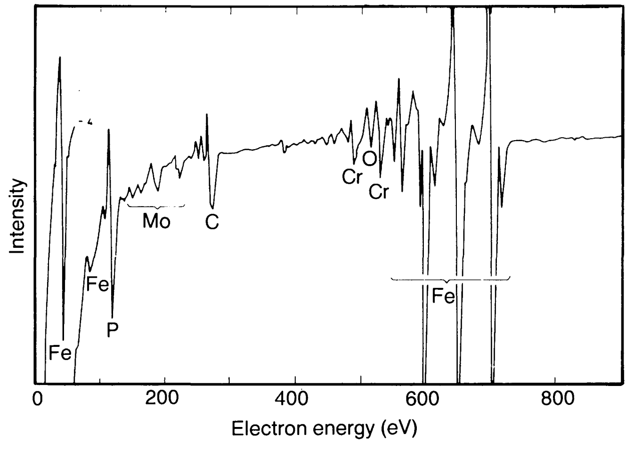

FIG. 9. Auger electron spectrum from the grain-boundary surface of the failed Hinkley Point power plant turbine rotor material exhibiting $\approx$ 0.45 monolayer of phosphorus segregated at the grain boundary (after Seah, 1975).

$G(z)=(z_{0.895}-z_{0.105})^{-1}$,

is the reciprocal of the difference in distance between the 89.5% and 10.5% points on a linear-probability scale (Hall, 1953) and is valid as long as the slope is linear at the interface ($z = 0$). More sophisticated analyses are available for situations in which the diffusivity should be considered as a function of concentration and when grain-boundary diffusion occurs in addition to bulk diffusion (Pamler, 1987).

4.3.3 Historical Metallurgy. Complementary analytical techniques were used to show that a panel of Ghiberti's "Doors of Paradise" of the Baptistry in Florence was originally gilded by fire or Hg-gilding (Mello, 1986). Auger spectroscopy provided an atomic layer-by-layer surface-composition depth profile. Metallographic microscopy showed that when amalgam was spread over the bronze substrate it accumulated in depressions on the metal surface. The Au layer was particularly porous and penetrated into the deep surface pits; this was confirmed by SEM. A depth profile of the outer surface showed that Hg was not on the external layer but in the outer portion of the Au film, so that it is unlikely to be from external contamination. An electron microprobe study of lower strata within the metal showed a little Au-Cu diffusion and the outer surfuce of the Au layer at minus 3–4 μm, in agreement with other Hg-gilded samples.

4.4 Other Applications

4.4.1 Corrosion. Corrosion processes which involve the formation or rupture of passivating thin films on metal surfaces have long been studied by AES (McIntyre, 1983, and Castle, 1986). Protective chromate, phosphate, nitrite, and molybdate films on iron formed by corrosion inhibitors added to aerated distilled water were first studied by Auger depth profile analysis in 1978 (Lumsden and Szklarska-Smialowska, 1978). More recently, an Auger depth profile study of corrosion-inhibiting films formed using synthetic cooling-water conditions has been published (Schreifels *et al.*, 1989). Similarly, AES has also been used to study the effects of fuel additives on the hot corrosion of industrial gas turbine blade alloys (Schweitzer *et al.*, 1982).

4.4.2 Insulating Samples and Mineralogy. The largest drawback to the use of Auger electron spectroscopy on insulating surfaces is sample charging (Wei, 1988). Certain beam conditions and tilt angles can prevent charging, however.

Insulators under electron-beam bombardment can remain neutral under certain beam conditions (Bruining, 1954). No charging will occur at the crossover voltages E_{p1} and E_{p2} where the primary beam current (I_p) is equal to the backscattered electron current (I_γ) plus the secondary electron current (I_δ) or $I_p=I_\gamma+I_\delta$ (Hochella *et al.*, 1986). Figure 10 shows secondary electron emission (I_δ) as a function of primary electron-beam energy (E_p) for an insulator. E_{p1} and E_{p2} typically differ by a few thousand electronvolts, and E_{p1} is usually only a few tens of volts (Dawson, 1966), too low to be useful in AES. Most Auger work on insulators is performed near E_{p2}, which is typically between 2 and 5 keV.

Tilting the sample relative to the primary beam axis permits the collection of unshifted Auger spectra at higher E_p than can be achieved with an untilted specimen. Tilting the sample results in an increase in both the backscattered and secondary emission efficiency for any particular beam energy (Kanter, 1961).

Hochella *et al.* (1986) demonstrated that the instrument and sample conditions under which a reasonable signal-to-noise ratio can be achieved for small spot AES/SAM of silicate, oxide, and sulfide mineral surfaces without charging or significant sample degradation are as follows:

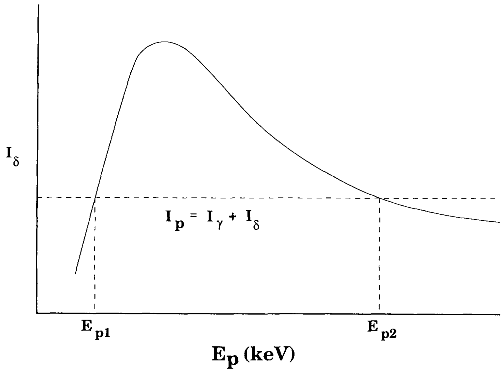

FIG. 10. Secondary-electron emission (I_δ) as a function of primary electron-beam energy (E_p) for an insulator (see text) (after Hochella *et al.*, 1986).

1. beam voltage typically 3 keV and no greater than 5 keV;
2. beam currents between approximately 1 and 20 nA for < 1-μm beam diameters;
3. tilt angle typically between 40° and 60°;
4. flat to semirough surface topology; and
5. light C, CO, CO_2 atmospheric contamination, sometimes resulting in a weak C Auger peak in the AES spectrum.

Scanning Auger microscopy is suitable for the semiquantitative probing of < 1-μm grains in rocks as well as performing surface studies with very high lateral resolution [Hochella *et al.* (1986)].

4.4.3 Surface Extended Energy-Loss Fine Structure. Auger electron spectrometers may be used, without modification, to obtain bond length information for certain types of systems. Surface extended energy-loss fine structure (SEELFS) is a new surface analytical technique [De Crescenzi (1985); Idzerda *et al.*, (1985a); Natarajan, Abel, and Hoffman (1985)] which provides structural information such as bond lengths and nearest neighbor coordination number. SEELFS is quite similar to EXAFS (extended x-ray absorption fine structure), except that electron energy-loss spectra are measured using an Auger electron spectrometer from approximately 50 to 500 eV above the core excitation edge of the material being studied.

While SEELFS may be used to study bulk metals and compounds [e.g., Cu (Idzerda *et al.*, 1985b) and GaAs (Terauchi *et al.*, 1985)], due to the surface sensitivity of the electron detection technique, SEELFS is more advantageously employed to study low atomic number submonolayer adsorbates on metals [e.g., Si-C (Natarajan, Abel, and Hoffman, 1985), Ni-O (De Crescenzi *et al.*, 1983), and Ti-O (Morar and Park, 1983)]. SEELFS is especially useful to study other absorbate/substrate systems which are inaccessible to current EXAFS techniques because of overlapping extended fine structure (Morar and Park, 1983).

4.4.4 Chemical Effects in AES. AES can be used as a valence-band spectroscopy that is surface sensitive, particularly when one or more valence electrons are involved in the Auger process (Madden, 1983). Experimentally observed changes in Auger line shapes have proved useful in identifying chemical states of elements at surfaces, particularly carbon, sulfur, nitrogen, and oxygen. Figure 11 illustrates changes in carbon *KVV* line shapes for three different carbon environments [molybdenum carbide (Mo_2C), silicon carbide (SiC), and graphite (C)] ranging from carbidic to graphitic (Haas, Grant, and Dooley, 1972). Note that both peak energy shifts and line-shape changes can affect quantitative analysis significantly. Similarly, analysis of Auger line shapes has been used to study the interaction of CH_3OH with oxygen precovered Cu (Hegde, 1984; Kamath *et al.*, 1982).

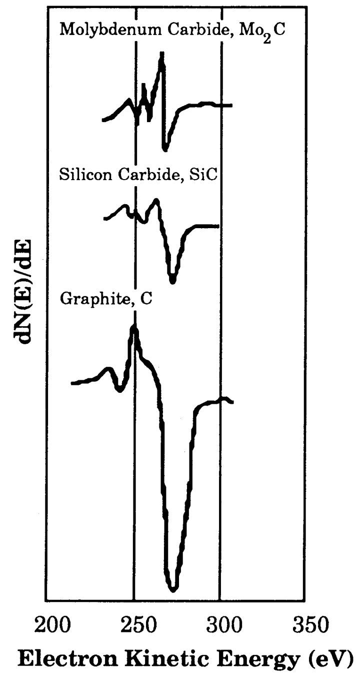

FIG. 11. Changes in carbon *KVV* line shapes for three different carbon environments ranging from carbidic to graphitic (after Haas, Grant, and Dooley, 1972).

GLOSSARY

Auger Line Scan: A one-dimensional view of the change in elemental concentration across an interface may be constructed by sweeping an electron beam in a line across the interface and measuring the elemental Auger electron peak intensity at multiple points on the line.

Auger Map: By rastering the electron beam across a sample surface, and at each raster point measuring the elemental Auger electron peak intensity, an image may be constructed in which the intensity of each raster point represents the amount of the element present. In this manner, a two-dimensional view, or Auger map, of the change in elemental concentration across a surface may be constructed.

Auger Sensitivity Factor: A set of relative normalization factors used in place of pure elemental standards to determine atomic concentrations from the Auger peak intensities of unknown samples.

Backscattering Term: A factor which accounts for sample ionization by backscattered energetic electrons produced in the sample by the primary electron beam.

Component Sputtering Yield Ratio: For a homogeneous alloy *AB*, the component sputtering yield ratio is the ratio of the bulk ratio of *A* to *B* to the ratio of *A* to *B* observed at a sputtered surface.

Cylindrical Mirror Analyzer (CMA): An electron kinetic-energy analyzer in which electrons pass between two coaxial cylinders of different radii. For the special case in which the entrance angle is $\alpha = 42^\circ\ 18'$, the CMA becomes a second-order focusing electron kinetic-energy analyzer.

Depth Profile: A compositional depth profile of a sample is the in-depth distribution analysis of chemical composition in the vicinity ($\approx 1\ \mu\text{m}$) of the sample surface.

Factor Analysis: A technique for Auger line-shape analysis of spectra selected from a compositional depth profile in which the presence and number of new chemical states formed at an interface may be determined.

Hemispherical Sector Analyzer (HSA): An electron kinetic-energy analyzer in which electrons pass between two hemispherical surfaces of different radii. The HSA is a second-order focusing electron kinetic-energy analyzer when electrons exit through the aperture of the exit slit and when the electron trajectory is within the limits imposed by the hemispherical surfaces.

Inelastic Mean Free Path: The probability-e^{-1} distance that Auger electrons created by the ionization process travel in the matrix material before being inelastically scattered and no longer being collected by the detection optics.

Logistic Function: A function involving an exponential and shaped like the letter "S."

Scanning Auger Microprobe (SAM): The addition of electron beam steering optics and a secondary electron detector enables the now modified Auger electron spectrometer to obtain both Auger and secondary electron images of the sample under study. The modified apparatus is known as a scanning Auger microprobe.

Spectral Stripping: An iterative process of subtracting known elemental Auger spectra from an unknown Auger spectrum to resolve small Auger peaks in the unknown Auger spectrum.

Surface Extended Energy-Loss Fine Structure (SEELFS): The electron analog of EXAFS (extended x-ray absorption fine structure), in which electron energy-loss spectra are measured using an Auger electron spectrometer from approximately 50 to 500 eV above the core excitation edge of the material being studied.

INTRODUCTION

The traditional automotive propulsion system consists of the engine and the drive train, which together comprise the power train.

The engine is a machine that converts chemical energy stored in a fuel into useful mechanical work. By far the most common engine in automobiles is a multicylinder reciprocating mechanism that consumes a spark-ignited mixture of gasoline and air. The compression-ignited diesel engine, burning diesel fuel, dominates the heavy-duty truck field and also enjoys limited application in passenger cars and light-duty trucks.

The drive train includes a transmission and a differential mechanism. The transmission facilitates variation of its input/output speed ratio, usually in finite steps, to match the performance characteristics of the engine to the requirements of the vehicle. It also provides for operation of the vehicle in reverse. The differential allows the driving wheels on opposite sides of the vehicle to rotate at different speeds, as necessary during a turning maneuver.

In the automobile, the engine is most often located at the front of the vehicle, with power being transmitted to either the two rear wheels or the two front wheels. Alternatively, a rear-mounted or midship-mounted engine has been used with rear-wheel drive, and four-wheel drive has also been employed.

1. THERMODYNAMIC CYCLE

Because the energy conversion accomplished in the engine involves thermodynamics, it is helpful to understand the basic thermodynamic cycle after which the engine is patterned.

1.1 Air-Standard Cycle

Operation of the spark-ignition gasoline-fueled engine commonly used in automobiles is based on the Otto cycle. The air-standard Otto cycle, i.e., an Otto cycle in which the working fluid is approximated by air having a constant specific heat, is represented on a pressure-volume plane in Fig. 1. At the beginning of the cycle (point 1), the air is at its lowest pressure and temperature, and the cylinder volume is at its maximum. If the common slider-crank mechanism is used to effect the cycle, this means that the piston is at bottom dead center (BDC). As the piston rises toward top dead center (TDC) at 2, the cylinder air is compressed reversibly and adiabatically. From 2 to 3, heat is added at constant volume, increasing cylinder pressure and temperature. From 3 to 4, the cylinder air undergoes reversible adiabatic expansion. From 4 to 1 the air is cooled to its original state.

The area under a curve on a pressure-volume diagram is proportional to mechanical work. The area under 1-2 represents compression work done on the cylinder gas; that under 3-4 represents expansion work done by the gas. The difference, i.e., the enclosed area of the diagram, represents the net work done by the cycle. Its ratio to the heat added from 2 to 3 is the indicated thermal efficiency of the cycle, which is a function of the compression ratio ($V_1/V_2=r$) and the ratio of specific heats of the working fluid ($\gamma=1.4$ for a perfect diatomic gas). The thermal efficiency of the air-standard Otto cycle can be shown to be $\eta = 1-r^{1-\gamma}$. It is plotted in Fig. 2.

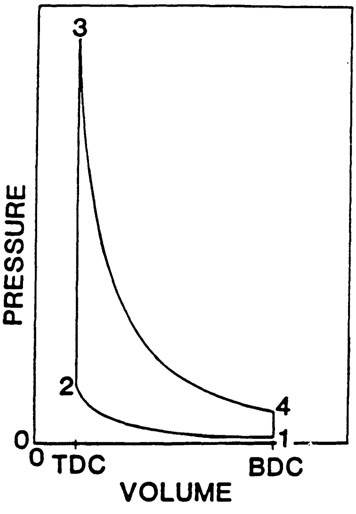

FIG. 1. Pressure-volume diagram for the air-standard Otto cycle.

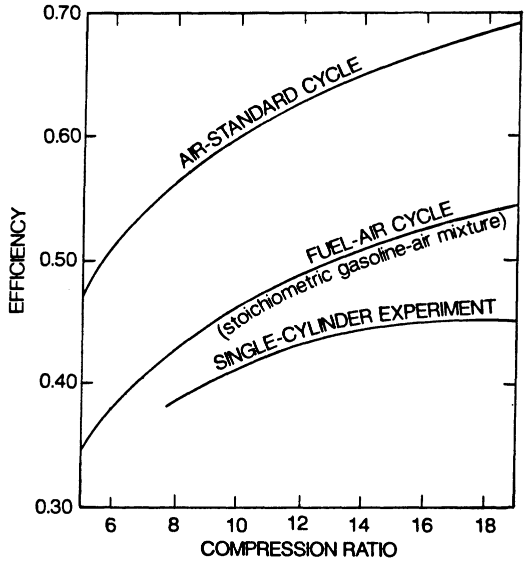

FIG. 2. Thermal efficiency as a function of compression ratio for the air-standard Otto cycle, for the fuel-air Otto cycle with a stoichiometric mixture of gasoline and air, and as determined experimentally from the indicated power of a single-cylinder engine.

1.2 Fuel-Air Cycle

The next level of thermodynamic approximation of the engine is the fuel-air Otto cycle. It recognizes that from 1 to 2, the working fluid is a mixture of air and fuel. From 2 to 3, the added heat is generated internally through combustion. From 3 to 4, the working fluid consists of combustion products. From 4 to 1, the products must be expelled from the cylinder to accommodate a fresh fuel-air charge. Throughout the cycle, specific heat varies with the temperature, pressure, and composition of the cylinder gas. During combustion the temperature is high enough to cause dissociation of the chemical species. The thermal efficiency of the fuel-air cycle, which accounts for these effects, is also shown in Fig. 2 for a stoichiometric (chemically correct) mixture. For mixtures richer than stoichiometric, the fuel-air cycle efficiency falls below that shown. Conversely, as the mixture is leaned from stoichiometric, the fuel-air cycle efficiency progressively increases, approaching the air-standard cycle as an upper limit.

2. MECHANICAL DESIGN

A broad variety of engine configurations has seen automotive use, including versions operating on both four-stroke and two-stroke cycles. The fuel system and the ignition system are key aspects of engine operation. Although most automotive engines are naturally aspirated, some use forced induction.

2.1 Mechanical Configuration

The normal embodiment of the Otto cycle incorporates the slider-crank mechanism illustrated in the cylinder cross section of Fig. 3. The slider element is the piston, acted upon by the gas pressure within the cylinder working space above it. The crankshaft, which extends the length of the engine and is normal to the plane of Fig. 3, contains offset cranks for the individual cylinders. The connecting rod, which joins the piston pin to the crankpin, transforms the reciprocating motion of the piston into the rotary motion of the crankshaft. Engine power is delivered to the transmission input by the crankshaft. Features of the slider-crank mechanism evident in Fig. 3 are the crankshaft counterweight opposite the crankpin for maintaining engine balance and grooves in the piston for mounting expandable piston rings that seal the working-space pressure and control the lubricating-oil film on the cylinder wall.

The engine structure of Fig. 3 is comprised of three assemblies, stacked vertically. The block contains the cylinder bore in which the piston reciprocates. Coolant passages surrounding the bore are also seen, as is the camshaft, discussed below. (In the past a few automotive engines have seen use in which the liquid-cooling system is abandoned in favor of air cooling. In this case the exteriors of the cylinder and head are heavily finned, and the fins are subjected to a directed cooling-air stream for removal of excess heat.) Atop the block is the cylinder head, which contains poppet valves for controlling the flow of mixture into the cylinder and exhaust from it. The head contains additional coolant passages (not shown), as well as the intake and exhaust ports that communicate with the intake and exhaust manifolds, which fasten onto the head. The third element is the oil pan, which fastens onto the bottom of the block and contains the oil reservoir. The rotating end of the slider-crank mechanism splashes oil from this reservoir onto the cylinder walls. Crankshaft journal bearings are normally lubricated with pressurized oil conducted through passages drilled in the crankshaft. Lubrication of the piston-pin bushing is usually accomplished with splashed oil, although in some engines the oil is delivered under pressure through a hole running the length of the connecting rod.

The intake valve, mounted in the head, is shown in Fig. 3. Behind it is an exhaust valve. Both are held closed by springs until the valve-actuation mechanism applies sufficient force to overcome the spring load. In this engine, a camshaft rotates in the block at half crankshaft speed. The intake and exhaust cam lobes each raise and lower their respective tappets, which move push rods extending from the block into the head. There the upper end of each push rod bears against one end of a centrally pivoted rocker arm, the opposite end of which oscillates downward and upward to open and close the valve at the proper time.

Alternatively, the camshaft may be located in the head, providing an overhead cam

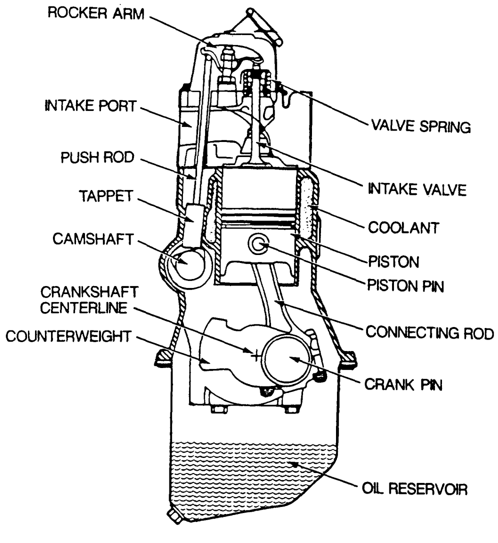

FIG. 3. Cross section through the cylinder of a four-stroke gasoline engine.

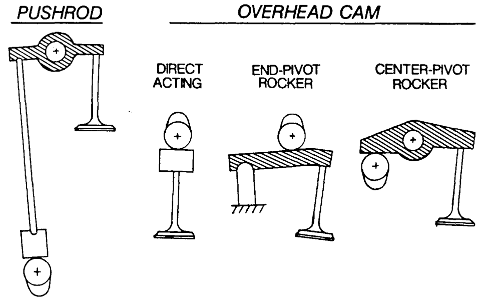

FIG. 4. Various overhead-cam arrangements for the automotive four-stroke engine.

(OHC). The camshaft is then driven from the crankshaft through a belt, a chain, or a gear train. In Fig. 4, several OHC arrangements are shown schematically alongside the pushrod arrangement. In some OHC engines, one camshaft is used for the intake valves and a second for the exhaust valves, resulting in a dual overhead cam (DOHC) engine.

Although only a single cylinder is shown in Fig. 3, the modern automotive engine normally uses a multiplicity of cylinders. Most common are four cylinders arranged in line, six cylinders either in line or in a "vee" arrangement, and eight cylinders in a vee. Variations include the in-line three-, five-, and eight-cylinder engines, horizontally opposed four- and six-cylinder engines, and vee engines with ten, twelve, and even sixteen cylinders.

2.2 Strokes per Cycle

Most automotive engines employ four complete piston strokes: compression, expansion, exhaust, and intake. The latter two strokes are not part of the ideal Otto cycle but have proven to be an effective addition for exchanging burned products for a fresh fuel-air charge. This four-stroke cycle is executed within the engine geometry of Fig. 3.

As an alternative, the Otto cycle can be completed in just two strokes of the piston, eliminating the two extra strokes dedicated to gas exchange. A variety of two-stroke engine arrangements exists. The two most common types are diagrammed in Fig. 5.

In the crankcase-scavenged configuration, the intake and exhaust processes are effected through ports in the cylinder wall. The fresh charge is first drawn into the crankcase through a check valve by the upward motion of the piston during its compression stroke. As the piston approaches TDC, the cylinder contents are ignited with a spark plug. As the piston descends on the expansion stoke, its upper edge first begins to uncover the exhaust port, allowing escape of the pressurized combustion products. Shortly thereafter, uncovering of the intake port begins and the downward piston motion forces the charge in the crankcase through a transfer passage into the cylinder. A portion of this incoming charge escapes directly through the exhaust port as it scavenges out the burned gas from the previous cycle, but the balance is trapped for compression and subsequent combustion.

This crankcase-compression version precludes the customary oil reservoir in the crankcase, leading to the use of rolling-element bearings that are more tolerant of sparse lubrication than the journal bearings normally found in four-stroke engines. If the fuel is added to the air prior to its entry into the crankcase, a substantial fraction of it es-

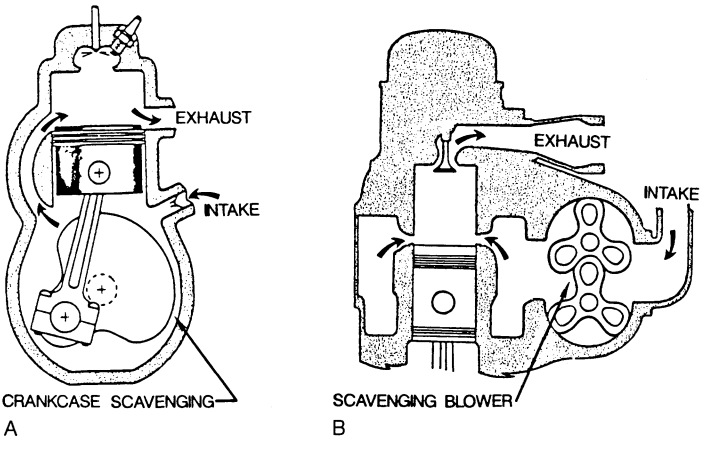

FIG. 5. Two-stroke engine arrangements: (a) crankcase-scavenged, (b) uniflow with blower scavenging.

capes unburned into the exhaust system during scavenging. This is intolerable if control of exhaust emissions is critical. In that case, introduction of fuel into the cylinder must be delayed until both ports have been closed. This can be accomplished by injecting the fuel directly into the cylinder.

In an alternative (not shown) to crankcase scavenging that allows oil in the crankcase, the incoming charge is compressed by an engine-driven blower and introduced through the intake port in the same manner as with crankcase scavenging.

The uniflow configuration, also shown in Fig. 5, uses an engine-driven scavenging blower to force the cylinder charge through intake ports surrounding the cylinder, but exhaust is accomplished through one or more poppet valves in the head. The unidirectional upward flow of the fresh charge offers more effective scavenging, and use of cam-actuated exhaust valves provides greater flexibility in timing the gas-exchange events.

2.3 Fuel System

In automotive engines, for many years the fuel was introduced into the air by means of a carburetor located at the entrance of the intake manifold. The simple carburetor is shown schematically in Fig. 6. A float-actuated inlet valve maintains a constant fuel level in the float bowl. An open-ended fuel tube emanating from the bottom of the bowl terminates in the throat of a venturi through which the engine air is drawn. With atmospheric pressure above the fuel in the float bowl and a depression in the venturi throat that increases as engine airflow increases, fuel exits the fuel tube in approximate proportion to engine airflow.

Although this simple sketch illustrates the central feature of the carburetor, many refinements (not shown) are required in a practical implementation. These include provisions for counteracting the surface tension of the fuel, inclusion of a special idling circuit, a means for enriching the mixture at heavy engine loads, and a means for temporary enrichment during sudden increases in demanded engine load.

Also shown in Fig. 6 are a choke valve upstream of the venturi and a throttle valve downstream of the venturi. Partially closing the choke during cold starts enriches the mixture fed to the engine to compensate for the loss in fuel evaporation within the intake manifold at low temperatures. Regulation of the throttle valve controls engine output. As the throttle is closed, the increasing pressure loss across it depresses intake-manifold pressure so that the compression stroke starts from a subatmospheric pressure. The resultant reduction in mass of the fresh charge trapped in the cylinder decreases engine output. Throttle-valve position is adjusted to match driver needs by means of the driver-actuated accelerator pedal.

As exhaust-emission standards have been tightened, the traditional carburetor is no longer capable of controlling air-fuel ratio within the necessary limits. That carburetor was originally replaced by a variation in which fuel flow was modulated by a pulsing solenoid valve. This approach has been largely supplanted by one of two forms of fuel injection. With single-point injection, one injector located above the throttle plate supplies several, if not all, cylinders. With multipoint fuel injection, an injector located in each intake port supplies the fuel needs of its own cylinder. The amount of fuel injected per stroke is controlled by an on-board computer.

2.4 Ignition System

In the automotive gasoline engine, the ignition system provides a spark for igniting the cylinder mixture at the proper time during the cycle in a reliable and repeatable manner. The traditional battery-ignition system,

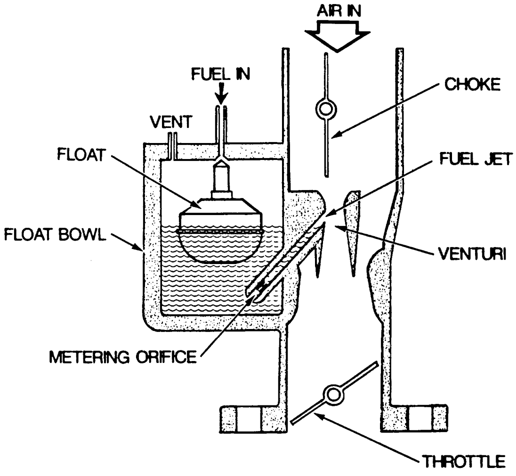

FIG. 6. Elements of the simple carburetor.

illustrated in Fig. 7, includes a battery, ignition switch, and coil. The primary side of the coil is grounded through mechanically actuated breaker points and a condenser, connected in parallel. The secondary side of the coil is grounded through a distributor switch and the individual spark plugs. In a four-stroke engine, the breaker-point cam and the distributor arm rotate at half crankshaft speed to provide a spark every other engine revolution.

When the breaker points are closed, current flows to the primary windings of the coil, building up a magnetic field. When the points are opened, the field collapses and the condenser is charged by the resulting induced current. When the condenser discharges back into the primary winding, the magnetic field quickly breaks down completely. This induces a high-voltage current in the secondary winding that is routed to the appropriate cylinder by the distributor, causing a spark to jump the spark-plug gap and ignite the mixture.

The time that elapses between occurrence of the spark and completion of combustion varies with engine speed and load. In the traditional ignition system of Fig. 7, this characteristic is accommodated by changing the phasing of breaker-point opening with respect to the crankshaft. This is accomplished with a speed-sensitive centrifugal mechanism and a diaphragm responding to intake-manifold vacuum.

The modern electronic ignition system is an improved embodiment of the same principles. It employs a pulse generator, which serves as a maintenance-free electronic circuit breaker, in place of the breaker points. The mechanical distributor may be replaced by a maintenance-free electronic version. The speed- and vacuum-sensitive signals formerly used to establish spark timing are replaced by commands from the engine control module (ECM). The ECM contains tabulations or algorithms for desired spark timing as a function of a broad range of measured operating parameters, including speed, manifold pressure, barometric pressure, coolant temperature, and throttle position.

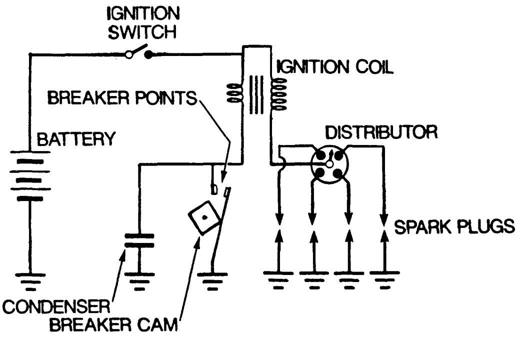

FIG. 7. Diagram of a battery-ignition system.

2.5 Forced Induction

Because engine power is dependent on mass airflow rate, power can be increased by pressurizing the intake manifold for increased intake-air density. This is accomplished either by supercharging or turbocharging.

In supercharging, an engine-driven blower is used to raise intake-air density. A common blower is the type illustrated in the uniflow two-stroke configuration of Fig. 5, in which air is pumped into the engine by the intermeshing lobes of two counter-rotating rotors. When such an engine is operated at partial engine load, a subatmospheric pressure is desired in the intake manifold and the blower becomes superfluous. Under these circumstances the blower must be either bypassed or disconnected to avoid its parasitic power drain, which would otherwise decrease engine thermal efficiency.

The turbocharger involves a centrifugal compressor and an exhaust turbine (usually of the radial-inflow type) mounted on a common high-speed shaft. The high-temperature gas exiting the exhaust manifold passes through the turbine, causing it to spin the compressor. The engine intake charge passes through that compressor, experiencing an increase in pressure on its way to the cylinders. For operation at part load, the turbocharger speed falls and the engine throttle valve, located upstream of the compressor, decreases cylinder inlet pressure to the desired level.

An intercooler (or aftercooler) is sometimes located between the compressor and the engine to lower the temperature of the compressed charge, hence increase its density, so that a greater charge mass can be inducted for increased power. The lower temperature also reduces the tendency for combustion knock to occur. The intercooler coolant is usually ambient air.

3. PERFORMANCE CHARACTERISTICS

The performance of the automotive engine is tied to the thermodynamic cycle on which it is based. One characteristic of normal interest is the relationship between its output, measured in terms of either power or torque, and its speed. Another is the effectiveness with which it converts fuel energy into power, normally measured in terms of either thermal efficiency or brake specific fuel consumption.

The actual pressure-volume diagram for a four-stroke Otto-cycle engine operated at part load is shown in Fig. 8 and may be contrasted to the air-standard full-load diagram of Fig. 1. In the actual engine, compression starts from subatmospheric pressure at *A*. Spark ignition occurs before TDC at *e*, with combustion continuing to point *f*. Clearly, heat addition does not occur at constant volume in a real engine. Neither the compression nor the expansion process is adiabatic, as it is in the ideal cycle. During both the compression and expansion strokes, there is a net heat loss to the coolant. Gas begins to leave the cylinder as the exhaust valve starts opening at *eo*. The exhaust valve remains open during the exhaust stroke (*CD*) and does not close completely until after TDC at *ec*. The intake valve starts to open before TDC at *io*, remains open during the intake stroke (*DhA*) and past BDC, closing during the compression stroke at *ic*.

The mean height of area *AgeBfC*, obtained by dividing the enclosed area by the stroke length *CD*, defines the indicated mean effective pressure (IMEP). The indicated power (P_i) developed at the piston during the compression and expansion stroke is

$$P_i = \bar{p}_i D(N/k),$$

where $\bar{p}_i$ equals IMEP, D is the total piston displacement, N is the crankshaft rotational speed, and k is the number of revolutions per cycle (equal to 2 for the four-stroke cycle, 1 for the two-stroke cycle). For a fixed air-fuel ratio and with optimized ignition timing, indicated power in a given engine tends to vary directly with the mass airflow rate.

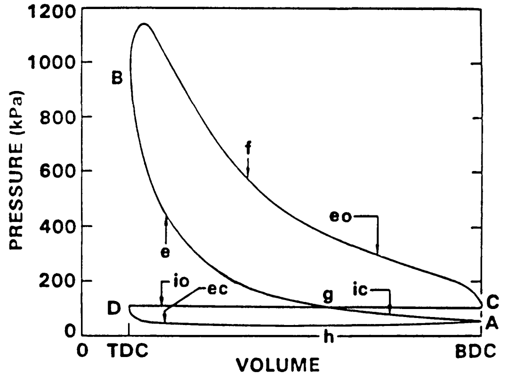

FIG. 8. Actual pressure-volume diagram for a four-stroke engine operating at part load.

The effect that variations from the ideal fuel-air cycle have on the efficiency of an actual engine, based on its indicated power at full throttle, is shown by the lowest curve in Fig. 2. This curve is from experimental data on a single-cylinder engine having a displacement of 0.66 L (Caris and Nelson, 1959). In this engine, maximum efficiency occurred at a compression ratio of about 17. Other experiments suggest that the benefit of high compression ratio diminishes as individual-cylinder displacement is decreased (Muranaka *et al.*, 1987). The principal factors causing the loss in efficiency in the real engine, compared to the fuel-air cycle, are heat loss to the coolant and departure from constant-volume combustion.

The output brake power (P_b) actually delivered by the engine is less than the indicated power by the power lost to mechanical friction plus that expended in pumping the working fluid through the engine. The associated pumping work is represented by area *CgDhA* in Fig. 8. As the throttle in the intake manifold is closed to decrease engine output, intake-manifold absolute pressure decreases, intake-stroke pressure *DhA* assumes a lower position on the diagram without a corresponding effect on exhaust-stroke pressure *CgD*, and the pumping work increases.

The mechanical efficiency accounting for the friction and pumping losses, $\eta_m (= P_b / P_i)$, reaches about 90% for a modern automotive engine at full load but approaches zero at the idle condition. Typical wide-open-throttle curves of indicated power, brake power, and mechanical efficiency are shown as a function of engine speed in Fig. 9.

Engine brake torque (τ) is given by $\tau = P_b / 2\pi N$. It tends to be proportional to the product of the air consumed per cycle and the me-

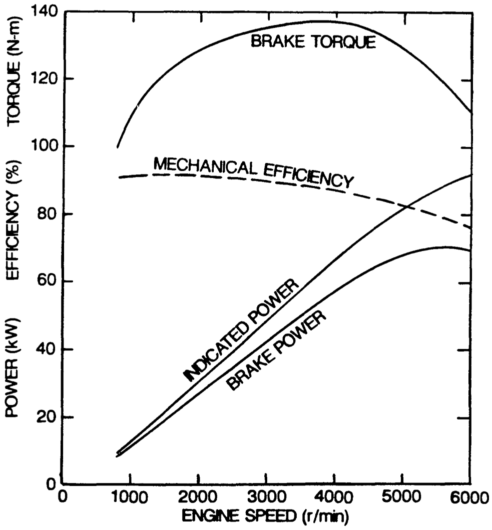

FIG. 9. Full-load characteristics of a typical gasoline engine.

chanical efficiency. A typical wide-open-throttle torque curve is included in Fig. 9.

The ratio of fuel-consumption rate to brake power, known as the brake specific fuel consumption (BSFC), is a frequently used measure of the effectiveness of energy conversion that is customarily expressed in units of g/kW h. Brake thermal efficiency (η_b), which is dimensionless, is equal to the reciprocal of the product of BSFC and the gravimetric heating value of the fuel, expressed in appropriate units.

A typical engine performance map is shown in Fig. 10. The upper boundary traces the maximum brake torque, and the isopleths show the variation in brake thermal efficiency. Maximum efficiency occurs within an island located at a fairly high fraction of engine load and an intermediate speed range. Above this island, efficiency falls because the mixture is enriched for maximum power. Below the island, efficiency falls primarily because mechanical friction and pumping losses consume an increasing proportion of the indicated power developed. Contributing to the fall in efficiency at high speeds is the associated reduction in mechanical efficiency. At low speeds, a factor tending to decrease brake thermal efficiency is increased heat loss, a result of there being more time for heat transfer.

4. TRANSMISSION

The transmission is located between the engine and the differential. ln the absence of losses, power, which is the product of rotational speed and torque, is conserved across the transmission. Thus, the transmission offers a means of trading a reduction in its output-shaft speed, relative to its input-shaft speed, for a multiplication of torque.

Geared transmissions may be classified according to whether shifting is accomplished manually or automatically. When the vehicle is standing, the engine operates at its idling speed, but the driving wheels of the vehicle are stationary. Consequently, with either transmission some provision must be included to accommodate this infinite input/output speed ratio.

4.1 Manual Transmission

For passenger cars, the manual transmission normally incorporates from three to six finite speed ratios, with five currently being the most common. These speed steps are effected by transmitting the power through various combinations of driver-selected gear pairs.

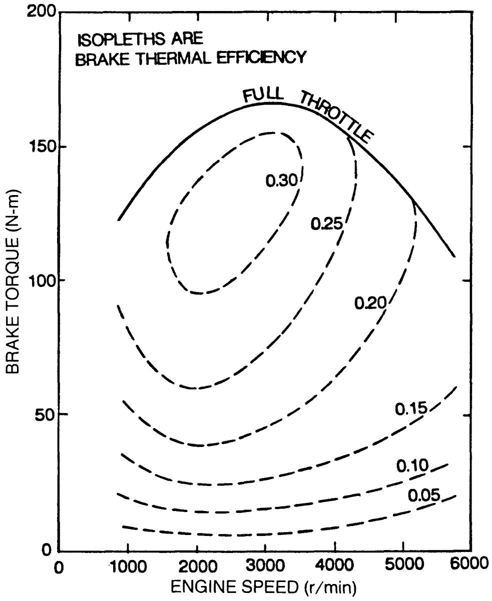

FIG. 10. Performance map of a typical gasoline engine.

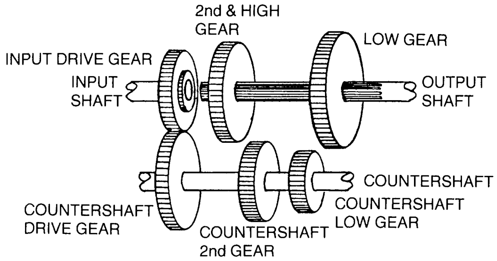

FIG. 11. Principles of a three-speed manual transmission, shown in neutral. In low, the low gear on the splined output shaft is slid axially along it into engagement with the countershaft low gear. In second, the two second gears are similarly engaged instead. In high, the gear at the left end of the output shaft is locked to the input drive gear to provide direct drive.

The principle of such a transmission system is illustrated in Fig. 11. The input and output shafts are coaxial and parallel to a countershaft. The input drive gear is permanently meshed with the countershaft drive gear, causing both shafts to rotate concurrently. The axial positions of the remaining gears on the countershaft are fixed, but the gears on the output shaft are internally splined so they can be moved axially along matching splines on the periphery of the output shaft. The position of the gear-selector lever determines which pair of gears on the countershaft and output shaft is engaged. Since the working diameters of meshed gears are proportional to the number of teeth they contain, the input/output shaft-speed ratio is $(N_i/N_{cd})(N_c/N_o)$, where N is the number of gear teeth, and the subscripts i, cd, c, and o denote the input drive gear, countershaft drive gear, and the countershaft and output-shaft gears that have been selected for engagement, respectively. For direct drive (input/output speed ratio equal to 1), teeth are provided on the gear at the left end of the output shaft so that it can be slid along the shaft into locked engagement with matching teeth added to the input drive gear.

To manage the infinite speed ratio in a standing vehicle, the transmission is shifted into neutral, which disengages all output-shaft gears from gears on the countershaft. When the transmission is shifted into reverse, an extra gear is interposed between the appropriate countershaft and output-shaft gears to reverse the rotation of the output shaft.

During shifting from one speed ratio to another, the driver depresses a clutch pedal. This opens a friction clutch between the engine crankshaft and the transmission-input shaft to sever that connection until the desired set of transmission gears has been engaged by manipulating the gear-selector lever. The clutch consists of two parallel coaxial circular plates, to one of which is attached a friction material. When the clutch pedal is released, these plates are pressed together by springs to lock the engine to the transmission input.

4.2 Automatic Transmission

The automatic transmission incorporates the same fundamental functions as the manual version, but there are some significant differences in implementation. For instance, the typical manual transmission employs spur gears in a countershaft arrangement, as illustrated in Fig. 11, but the automatic transmission usually employs planetary gears. The speed ratio across a planetary gear set, which is illustrated in Fig. 12, depends on which of its three elements—sun, planets, or ring gear—is prevented from rotating, i.e., grounded. Grounding is accomplished with clutches that are automatically engaged and disengaged by a shift-scheduling controller that works with such input signals as engine speed, throttle position, and intake manifold pressure.

There is a difference in the way manual and automatic transmissions normally interact with the engine. With the manual transmission, the typical driver releases the accelerator pedal (closes the throttle) while the clutch is disengaged for gear shifting. With the automatic transmission, however, the

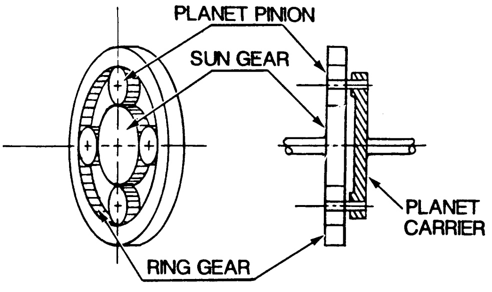

FIG. 12. Planetary gear set, used in most automatic transmissions.

shift is effected automatically without a correspondingly severe, temporary drop in engine power.

In the automatic transmission, the clutch of the manual transmission is typically replaced by a torque converter such as illustrated in Fig. 13. The basic torque converter consists of a torus filled with circulating automatic transmission fluid and containing three sets of blading—pump (or impeller), turbine, and stator (or reactor). The engine rotates the pump element, which pumps fluid radially outward. As that fluid then flows radially inward through the turbine, it transmits torque through the turbine blading to the gearbox input.

The stator blades are mounted on the transmission case through a one-way clutch. When a standing vehicle starts to move, the clutch is engaged and the stator blades are stationary. They redirect the fluid flowing through them en route to the pump inlet in a way that provides multiplication of torque across the torque converter. When the vehicle wheels are locked, this torque multiplication is normally in the range of 2.0–2.5, the input/output speed ratio across the torque converter is infinite, and both the power transmitted and the efficiency of transmission are zero. As the vehicle begins to move, the output/input torque ratio across the converter falls toward unity, the turbine/pump speed ratio rises toward unity, and the power transmitted and the efficiency of the torque converter both increase. As the turbine speed nears the pump speed, the changing reaction torque on the stator releases the one-way clutch through which it is grounded to the case and allows it to rotate (free-wheel). Torque multiplication ceases, and the pump and turbine act as a fluid coupling that transfers engine torque to the gearbox input through the action of the circulating transmission fluid on the blading of the torque converter.

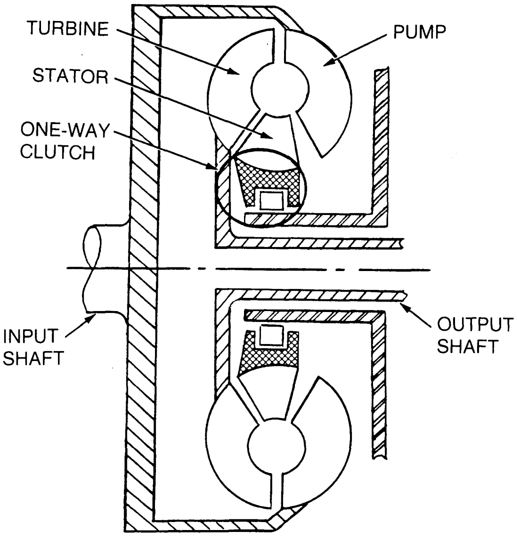

FIG. 13. Basic torque converter.

The turbine speed never quite reaches the pump speed. When increased power is demanded, this speed difference (slip) increases. To overcome the power loss associated with slip, many transmissions incorporate a clutch that mechanically joins the turbine to the pump during driving at constant speed and modest acceleration and deceleration. This clutch is released when the driver demands a large increase in power, allowing the torque converter to multiply input torque.

The torque-converter clutch is normally engaged only in the highest gear ratio(s), i.e., lowest input/output speed ratio(s). Engagement replaces the fluid joint of the torque converter with a solid mechanical connection. This defeats the damping characteristics of the fluid joint, allowing torque impulses from the crankshaft to be transmitted into the drive train, where they excite objectionable vibrations in the vehicle in the lowest gear(s).

Because of the torque-multiplication capability of the converter, the typical automatic transmission needs from one to two fewer speed ratios in its gearbox. Thus, today most automatic torque-converter transmissions have three or four forward speeds, compared to four or five in the manual transmission.

4.3 Continuously Variable Transmission

While common manual and automatic transmissions vary the input/output speed ratio in finite geared steps, over a limited range of speed ratios the continuously variable transmission (CVT) accomplishes such speed variation as a continuum. Current CVTs transmit torque through a specially designed belt or chain connecting driving and driven sheaves. One-half of each sheave can be moved axially a small distance with respect to its mating half, effectively varying the sheave working diameter. Thus the input/

output speed ratio can be decreased by increasing the diameter of the driving sheave while concurrently decreasing the diameter of the driven.

The torque-transmission capability of such a system currently limits its use to small cars with correspondingly low-output engines. Because of ratio-range limitations of the belt or chain, such additions as a two-speed gearbox or a torque converter have been considered to match the performance characteristics of existing transmissions.

5. VEHICLE CHARACTERISTICS

Vehicle performance and the distance traveled on a given quantity of fuel depend on the interaction between power-train characteristics and the power requirement of the vehicle.

5.1 Power Requirement

The power required (P_r) to propel a vehicle is

$$P_r = [C_r mg \cos\alpha + C_d A(\rho V^2/2) + m_e g a + mg \sin\alpha]\, V,$$

where C_r is the rolling-resistance coefficient of tires, m is the vehicle mass, m_e is the effective vehicle mass, including rotational inertias, C_d is the aerodynamic drag coefficient, A is the vehicle frontal area, V is the vehicle velocity, a is the vehicle acceleration, g is the gravitational constant, and α is the slope of road grade. On the right-hand side of this equation the first term within the brackets accounts for the rolling resistance of the tires, the second represents the aerodynamic drag, the third is the power consumed in accelerating the vehicle mass, and the fourth accounts for the extra burden when climbing a hill.

In Fig. 14 the power required by a typical car to overcome rolling resistance and the additional increment attributable to aerodynamic drag are shown shaded. The upper boundary of the shaded region is the constant-speed level-road power requirement. The dashed curve above it reflects the additional power required to climb a 5% grade. Above these power-required curves are the wide-open-throttle power-available curves in each gear of a five-speed transmission. The difference between the power available and the power required is the power reserve available for acceleration. At a given road speed, say 60 km/h, it is evident that less reserve power is available in the highest gears (lowest input/output speed ratio). Additional power reserve is made available by downshifting to a lower gear.

5.2 Fuel Economy

Not apparent from Fig. 14 is the fact that when driving at a given speed in a low gear, fuel economy suffers. This is illustrated in Fig. 15, where the level-road requirement is superimposed on the engine torque-speed map. It is evident that the higher the gear, the more favorable the brake thermal efficiency. However, again, the torque reserve is least in the highest gears, necessitating more frequent downshifting. For any point along one of the operating lines in Fig. 15, the fuel economy in km/L can be computed from

$$\text{km/L} = d/(\text{BSFC})V,$$

where d is the specific gravity of the fuel, BSFC can be calculated from the thermal efficiency at the point of interest and the heating value of the fuel, and vehicle velocity is obtained by dividing the engine speed on the abscissa by the engine-speed/vehicle-velocity

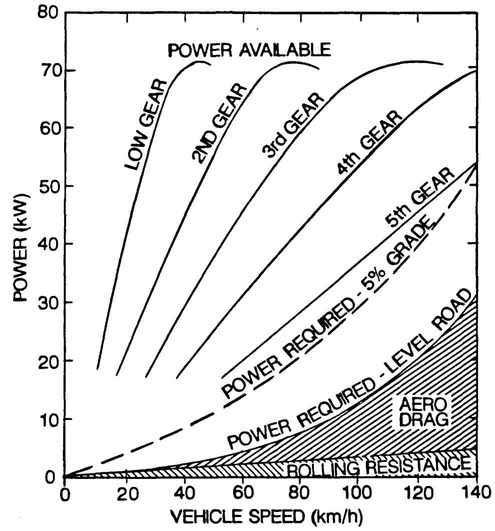

FIG. 14. Vehicle power requirement, and power available with a five-speed manual transmission.

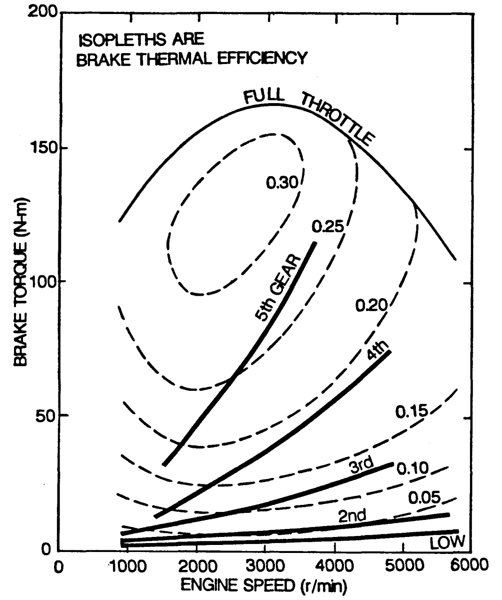

FIG. 15. Engine torque requirement at road load in various gears, superimposed on an engine map.

ratio provided by the drivetrain when the transmission is operated in the indicated gear.

6. ENVIRONMENTAL ASPECTS

At the turn of the century the fledgling automobile was welcomed as a relief from the problems of solid-waste disposal, odor, and flies associated with the ubiquitous horse. A half-century later the deteriorating air quality in southern California, fostered by climate, topography, and population density, initiated the era of environmentalism. Los Angeles smog correlated with atmospheric ozone concentration, and ozone formation was traced to the warm-weather action of sunlight on nitrogen dioxide and certain hydrocarbons mixed in proper proportions (see AIR POLLUTION: COMPONENTS, CAUSES, AND CURES). Automobile exhaust was identified as one of the anthropogenic sources of nitrogen oxides (NO_x) and hydrocarbons (HC). Legislated control of emissions from automotive vehicles and other sources followed.

An early improvement was to route hydrocarbon vapors in the crankcase, originally vented to the atmosphere, into the engine intake instead through a positive crankcase ventilation (PCV) system. This move eliminated about 20% of the HC emitted by an uncontrolled engine.

Initial regulation of tailpipe emissions limited only HC and carbon monoxide (CO), a toxic gas. About 60% of the HC from an uncontrolled car and all of the CO was coming from the tailpipe. Ultimately NO_x, which appears exclusively in the exhaust gas, was added to the list of regulated tailpipe emissions. The dominant oxide of nitrogen is nitric oxide (NO), but this later oxidizes in the atmosphere to nitrogen dioxide (NO_2). Consequently, all oxides of nitrogen in the exhaust are considered to have the molecular weight of nitrogen dioxide in measuring emissions gravimetrically for regulatory purposes.

The final 20% of the HC from an uncontrolled car comprised evaporative losses from the fuel system, notably the carburetor float bowl and the fuel tank. Vapor from the fuel system is now captured in a canister of activated charcoal for subsequent consumption by the engine.

6.1 Sources of Tailpipe Emissions

Hydrocarbon emissions exhausted from the engine consist primarily of unburned fuel. Lubricating oil can also contribute, although that is a minor source in an engine maintained in good mechanical condition.

If the mixture is rich, insufficient oxygen is available to burn all the fuel, so HC emissions would be expected. Even at stoichiometric and leaner mixtures, however, when the theoretically required amount of oxygen is present, unburned HC is found in the exhaust gas.

Originally, such unburned HC was believed to result primarily from the quenching of the cylinder flame as it approached the walls of the combustion chamber. Later work has suggested that under most conditions, this quenched air-fuel mixture diffuses into the hot burned gas and oxidizes. Regardless of the extent to which this occurs, the chamber walls are contributors to HC emissions through two established mechanisms. First, the oil film on the cylinder walls absorbs molecules of unburned fuel. These molecules are desorbed as the pressure in the cylinder falls during the expansion stroke, at a time when most of the mixture volume in the chamber has already been consumed by the flame. Second, porous combustion-chamber deposits formed on the cylinder head and piston crown also absorb fuel molecules, releasing them too late for their complete oxidation.

Another source of HC emissions is fuel trapped in crevices. That fuel escapes the normal combustion process because the flame is unable to penetrate into a crack. The most significant crevice is formed between the piston periphery and the cylinder wall, above the uppermost piston ring. Fresh air-fuel mixture is forced into this crevice as the piston ascends on the compression stroke, and additional unburned mixture enters early during the expansion stroke as the cylinder pressure continues to rise toward its maximum. Once cylinder pressure begins to fall, this unburned crevice gas starts to reenter the combustion chamber, but too late to take part in the normal combustion process.

One more source of unburned HC is flame extinction, which is most likely to be significant if the mixture is lean or is heavily diluted with residual burned gas from an earlier cycle. In such cases, the mixture ahead of the flame that is traveling across the chamber is subjected to a falling pressure and temperature as the piston descends on the expansion stroke. The last part of this unburned mixture to be consumed by the flame is also exposed to the cooling effect of the chamber walls. These circumstances are unfavorable to combustion, and the flame may simply be extinguished before the last small fraction of air-fuel mixture is consumed.

All of these unburned molecules of fuel have the opportunity to oxidize into innocuous carbon dioxide and water vapor as they mix with the hot burned products of combustion, but due to a combination of inadequate mixing and insufficient time to complete the oxidation process, a portion escapes into the exhaust system as HC emissions. The qualitative trend of these exhaust-HC emissions with air-fuel ratio is illustrated for gasoline in Fig. 16, where the vertical dashed line denotes the stoichiometric mixture ratio. The HC emission rises at an increasing rate as the mixture is enriched from stoichiometric because of the shortage of oxygen. HC persists on the lean side of stoichiometric and ultimately rises as the mixture is leaned, despite the increased presence of oxygen, because the lower cylinder temperatures accompanying lean combustion are less favorable for post-flame oxidation, and eventually because of the increased incidence of flame quenching before the flame has completed its travel across the chamber.

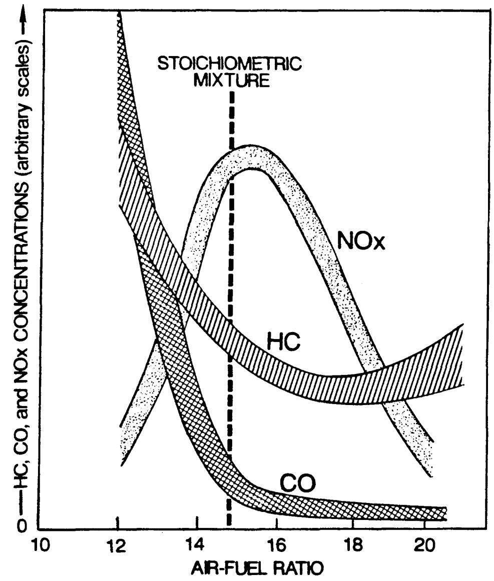

FIG. 16. Effect of air-fuel ratio on trends in engine-out emission concentrations. Fuel is gasoline.

Carbon monoxide also trends upward in Fig. 16 as the mixture is enriched, again because there is insufficient oxygen present for complete conversion of the fuel carbon to carbon dioxide. CO emissions are seen to be low in lean mixtures, but not zero. This product of incomplete combustion is to be expected as long as partial oxidation of HC is occurring late in the cycle and in the exhaust port.

The NO_x trend with mixture ratio is also shown in Fig. 16. NO_x, primarily nitric oxide, is an equilibrium constituent of air heated to a high temperature. The maximum combustion temperature is essentially reached at the stoichiometric ratio. Progressing richer from stoichiometric, temperature is falling because of incomplete combustion of fuel and because fuel carbon and hydrogen are competing with nitrogen for the short supply of oxygen present. Consequently, the NO_x concentration falls. On the lean side, dilution with excess air also lowers the temperature, but there is an excess of available oxygen. As the mixture is leaned from stoichiometric, the tradeoff between falling temperature and increasing availability of oxygen causes NO_x production to peak at a slightly lean mixture ratio.

6.2 Tailpipe-Emission Control

Nationwide regulation of tailpipe emissions began in the U.S. in 1968. Emissions are measured while driving the car on a chassis dynamometer over a prescribed transient schedule representative of urban operation. The dynamometer loads the driving wheels as a function of car speed and acceleration in a manner simulating driving on an actual road.

Fuel economy is evaluated on a second driving schedule, representative of highway driving. Fuel-economy measurements on the urban and highway schedules are combined to establish a vehicle fuel economy for regulatory purposes, but the highway schedule is not used in assigning emissions levels.

In the early years of emission regulation, tailpipe emissions were decreased by such measures as lowering compression ratio, retarding ignition timing, and departing from established air-fuel ratio schedules. When NO_x was added to HC and CO as a regulated emission in 1973, EGR (exhaust gas recirculation, the recycling of a fraction of the engine exhaust back into the intake manifold) was introduced to lower combustion temperature through dilution of the fuel-air charge. These techniques compromised fuel economy and drivability.

In 1975 the oxidizing catalytic converter was introduced on a broad scale. This converter consists of a sheet-metal container inserted in the exhaust system that exposes the engine exhaust gas to minute quantities of catalytic materials, typically platinum and palladium, which are capable of catalyzing the oxidation of HC and CO. The catalyst is dispersed on the surfaces of either pellets comprising a bed through which the exhaust gas flows, or a monolith structure of parallel passages through which the exhaust gas flows. Given the presence of oxygen and a temperature above 300–400 °C, such a catalyst can eliminate over 90% of the entering HC and CO. In some systems, an engine-driven air pump has been added to provide the required oxygen. Engineering the system to ensure that the catalyst is heated quickly to its functional temperature is important for achieving low tailpipe emissions. The availability of the catalytic converter eased the requirements on engine-out emissions, so engines could be retuned for better fuel economy and drivability.

In 1981 the federal NO_x standard was lowered to the point where its catalytic reduction became necessary. This led to addition of rhodium to the converter, making it a three-way device controlling HC, CO, and NO_x.

Catalytic reduction of NO_x becomes ineffective in the presence of excess oxygen, but oxidation of HC and CO cannot occur in the absence of oxygen. Consequently, air-fuel ratio had to be controlled within a very narrow window about the stoichiometric ratio to achieve high conversion efficiency of all three regulated emissions. This requirement is beyond the capability of the traditional carburetor.

The need for precise mixture regulation introduced the era of electronic engine control. An on-board computer tells the fuel system how much fuel is needed to provide the proper air-fuel ratio. The computer calculates this requirement either from stored tables of engine characteristics as a function primarily of engine speed and intake-manifold absolute pressure, or from the signal of an intake-airflow meter. An oxygen sensor in the exhaust stream, which responds too slowly to be used for real-time fuel control, signals the computer if the mixture ratio strays from the stoichiometric value. This facilitates a continuing calibration of the fuel-control system to guard against long-term drift.

In order to regulate the fuel rate electronically, its flow is controlled by a pulse-width-modulated solenoid. The solenoid-controlled fuel orifice may be incorporated in an electronic carburetor, but the growing preference is for replacing the carburetor with fuel injection. Two principal options are used. With single-point injection, the fuel nozzle is located at the entrance to the intake manifold, where the carburetor is normally placed. With multipoint injection, typically port injection, a separate nozzle is located in the intake port of each cylinder.

6.3 Efficacy of Controls

U.S. emissions standards have been lowered over time to the point where a new 1990 car must emit 96% less HC and CO, and 76%

less NO_x, than a 1960s precontrol car did. New U.S. cars are designed to satisfy emission standards at 80 500 km and are subject to recall for correction in the case of high failure rate.

From estimates by the Environmental Protection Agency (EPA) for 1970 and 1987 model-year cars in use at 80 500 km, aggregate HC and CO emissions were actually decreased by 80%, and NO_x by 70%, over that 17-year time interval after accounting for the 48% increase in vehicle miles traveled; yet over that same time span, the EPA composite average ozone and CO concentrations decreased by only about one-third (Atkinson *et al.*, 1990). Ozone depends on both HC and NO_x, but is not linearly related to them. The relationship between urban CO and CO sources is more direct, however.

There are a number of other reasons why average urban ozone and CO have not decreased in proportion to the reduction in tailpipe emissions from new cars. For example, for all of the listed emissions, the automobile is not the only source. Moreover, the atmospheric inventory depends on all cars on the road, not just those from a specified model year. Much of the in-use fleet consists of older cars built when emissions standards were less stringent, thus allowing them to emit more than newer cars. In this connection, the average age of the U.S. in-use fleet has increased steadily over recent years (Motor Vehicle Manufacturers Association, 1989).

Some cars on the road are improperly maintained or have been misfueled with leaded gasoline, which deactivates the catalytic converter and increases tailpipe emissions markedly. Just one such car can emit as much HC, CO, and NO_x as many properly maintained cars.

The possibility also exists that the test used to assess vehicle emissions is not representative of real-world driving. One known factor affecting total HC emissions has been the increase in gasoline vapor pressure over the past two decades (National Institute for Petroleum and Energy Research, 1989), which increases evaporative emissions. As a result, gasoline vapor pressure is destined for regulation.

7. FUELS

The performance, fuel economy, and emissions of the automotive propulsion system all depend on the fuel consumed. Gasoline derived from petroleum has long been the dominant automotive fuel, although petroleum-derived diesel fuel has been required for the compression-ignition diesel engine. Recently, interest has arisen in broadened use of gaseous fuels or alcohols because of anticipated environmental advantages.

7.1 Liquid Hydrocarbons

Commercial gasoline is a mixture of many different liquid-hydrocarbon compounds. It has an average atomic H/C ratio of 1.5–2.0, with a typical value of 1.85 and a lower heating value of 43.5 MJ/kg. The individual hydrocarbon compounds found in gasoline are classified by family.

Alkanes, or paraffins, are saturated hydrocarbons that have a chemical composition of C_nH_{2n+2}. In a normal-paraffin molecule, the carbon atoms are arranged in a straight chain. Isomers of paraffins are more compactly arranged molecules having carbon-containing branches attached to the main carbon chain. Naphthenes are cycloparaffins in which at least part of the carbon chain is arranged in the form of a closed ring. They have the chemical formula C_nH_{2n}.

In normal combustion of a homogeneous charge, as the flame progresses across the chamber, the unburned mixture ahead of it is compressed to a high pressure and temperature. If this unburned-mixture fraction is at these conditions too long before being consumed by the flame, it ignites spontaneously, causing a sudden rise in cylinder pressure and a noise known as combustion knock. For a specified fuel, knock limits the usable compression ratio, hence thermal efficiency.

The octane rating of a fuel marks its resistance to knock. Long-chain normal paraffins have comparatively low octane ratings, but a more compact isomer having the same chemical formula has a higher octane rating. By definition, an octane number of 100 is assigned to isooctane, an isomer containing eight carbon atoms. Normal-heptane, comprising a straight seven-carbon chain, has an octane number of zero. Commercial gasolines fall between these extremes. Two standardized tests are used to assess the knock resistance of gasoline, one giving the research octane number (RON) and the other the motor octane number (MON). In the U.S., the average of these, $(R+M)/2$, generally falls in the range 85–95.

For more than 60 years, tetraethyl lead was added to gasoline in small quantities to enhance its resistance to knock. That practice is being phased out in the U.S., both to avoid adding lead to the atmosphere and to preserve the exhaust catalyst, which is poisoned by lead.

Olefins resemble paraffins but are unsaturated, evidenced by a double bond between one pair of carbon atoms in the chain. Olefins are of the form C_nH_{2n}. Diolefins contain two double bonds and have the formula C_nH_{2n-2}. Double bonds characterize an unsaturated molecule that is more prone to gum formation than a saturated molecule.

In the aromatic family, which has the formula C_nH_{2n-6}, at least some of the carbon atoms are arranged in rings. Aromatics are unsaturated but have high octane ratings. Benzene, an aromatic, is considered toxic.

Like gasoline, diesel fuel is a mixture of hydrocarbons, but is less volatile. Because ignition in the diesel engine is caused by compression of the charge rather than a spark, a good diesel fuel should be autoignition prone. Thus, a good diesel fuel knocks too readily for use in a spark-ignition engine, and conversely, gasoline makes a poor diesel fuel. Cetane number is a measure of the propensity of a fuel to ignite when sprayed into air compressed in a standardized test engine. On average, U.S. automotive diesel fuels have a cetane number of about 45.

7.2 Gaseous Fuels

Spark-ignition engines can be adapted to operate on gaseous fuels. Those commonly used are natural gas and liquefied petroleum gas (LPG).

Natural gas is extracted from underground like petroleum. It varies somewhat in composition but is usually about 90% methane. Methane (CH_4) is the lightest member of the paraffin family. It has a high octane rating but is difficult to carry on board a vehicle. Normally it is stored at high pressure (165–200 atm) and called compressed natural gas (CNG). Even at these high pressures its volumetric energy density is so poor compared to gasoline that vehicle range is severely curtailed. Energy density is improved by storing it as a liquid (LNG), but the liquid is cryogenic, introducing a new set of problems for vehicular use.

LPG is a by-product of petroleum refining and natural gas production and, as such, is not as abundantly available as natural gas. LPG used as an engine fuel is mostly propane, a normal paraffin having the formula C_3H_8. It, too, has a high octane rating. Its volumetric energy density is higher than that of natural gas, but not as high as that of gasoline.

Hydrogen is the least dense of the gaseous fuels. After making appropriate engine changes, it can be burned in a spark-ignition engine. It is not presently available in sufficient quantity at a reasonable price to be used broadly as an engine fuel, and it has many handling and storage problems. As a compressed gas, its volumetric energy density is lower than that of natural gas. If liquefied, it is cryogenic. It has been stored in a metal hydride, being released when the hydride is heated, but this storage technique carries a heavy weight penalty.

7.3 Alcohols

The lowest-molecular-weight alcohols, methanol (CH_3OH) and ethanol (C_2H_5OH), are used as engine fuels. The volumetric energy densities are approximately 1/2 and 2/3 that of commercial gasoline for methanol and ethanol, respectively. Both alcohols have high octane ratings and high latent heats. The high latent heat cools the charge in the intake manifold during evaporation of the alcohol, enabling the engine to induct more air for increased output power. If the pure alcohols are used as fuels, this cooling effect combines with a low vapor pressure to make starting very difficult in even modestly cool weather. For this reason, a blend of 85% methanol and 15% gasoline, known as M85, has been advocated by some to ease the starting problem.

Methanol is made primarily from natural gas, although it can be made from biomass sources such as wood. Ethanol is biomass-sourced, being made from sugar cane in Brazil and from corn in the U.S. Under existing technology, the high cost of ethanol makes it unattractive in the U.S. as a primary fuel. However, it has been blended into gasoline in proportions up to 10% to enhance octane rating. This blend is commonly called gasohol. Methanol has also been blended into gasoline, but at a lower percentage. This requires addition of a cosolvent to avoid phase separation. If blends containing higher percentages of alcohol in gasoline, or if neat alcohols, are considered for use in automotive propulsion, the fuel system must be revised because of the damaging effect that alcohol, especially methanol, has on many commonly used materials.

7.4 Emissions Prospects of Alternative Fuels

Interest in alternatives to commercial gasoline and diesel fuel has been fostered by the failure of many urban areas to meet federal air-quality standards. Fuels receiving primary attention are methanol made from natural gas and natural gas itself.

It has been suggested by some that methanol would reduce smog in urban areas because engine emissions of unburned fuel should be mainly methanol, which has a relatively low reactivity in the chemical reactions responsible for smog compared to many constituents in gasoline exhaust. Unfortunately, however, the concentration of formaldehyde in the products of methanol combustion is many times that from gasoline combustion, and formaldebyde is very reactive. So far, formaldehyde has proven stubbornly resistant to catalytic elimination at high mileage. The ultimate result of the use of methanol fuel, or the more practical M85, on urban air quality remains unsettled.

During any transition to methanol as an automotive fuel, limited availability favors the flexible- or variable-fuel vehicle capable of operating on M85, neat gasoline, or any mixture between these extremes. The vapor pressure of a blend of 10% methanol in commercial gasoline is higher than the vapor pressure of either the gasoline itself or M85, creating concerns about meeting more stringent evaporative-emission standards. In addition, in short-trip and winter driving, upper-cylinder wear has proven more severe with methanol and its blends than with gasoline.

Some suggest that it is foolish to convert natural gas to methanol and suffer significant energy loss in the conversion process when natural gas itself is a suitable fuel for spark-ignition engines. The primary unburned-fuel constituent in the exhaust is methane, which has such a low reactivity that for regulatory purposes it is often excluded from the exhaust-hydrocarbon inventory. Moreover, the formaldehyde emission is low, and evaporative emissions are eliminated. Natural gas has a major problem with on-board storage, however. It is customarily stored as a compressed gas at 165–200 atm, but even at such high pressures its energy density is such that vehicle range is cut to 20%–25% of its value on gasoline if the vehicle space allotted to fuel storage is fixed. For this reason, natural gas is more often favored for light- or medium-duty trucks, where it is easier to find space for additional tankage, than for passenger cars.

8. ALTERNATIVE ENGINES

Despite the dominance of the spark-ignition engine in the automotive field, alternative engines exist and either are being used to a lesser extent or are the subjects of research and development in the interest of improved fuel economy and/or lower exhaust emissions.

8.1 Diesel Engine

The cycle of events employed by the diesel engine duplicates that of the spark-ignition engine. Both the four-stroke and the two-stroke cycle are used, although the former predominates. The fundamental differences between spark-ignition and diesel engines center on the methods of charge preparation and ignition.

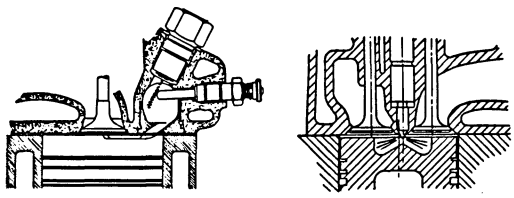
In the diesel engine, fuel is not introduced upstream of the intake valve. Instead it is sprayed into the combustion space through a high-pressure injection nozzle late during the compression stroke, shortly before the start of combustion is desired. Ignition occurs spontaneously at some point(s) in the fuel spray, without help from a spark plug, as a result of both the elevated compression temperature and the distinctive properties of diesel fuel. Combustion continues during injection of the remainder of the fuel. To ensure compression ignition of the fuel, the diesel engine uses a higher compression ratio than the spark-ignition engine, typically in the range 17–21.

The fuel economy of a diesel-powered vehicle, expressed as the distance traveled per unit volume of fuel consumed, exceeds that of a comparable vehicle with a spark-ignited gasoline engine for three reasons: the diesel employs a higher compression ratio than the knock-limited ratio tolerated by the traditional gasoline engine, typical diesel fuel contains about 13% more energy per unit volume than gasoline, and diesel-engine load is controlled by varying the fuel injected into the cylinder air rather than by throttling the intake air. The last feature replaces the part-load pumping penalty of the traditional automotive engine with the thermodynamic advantages of a lean average air-fuel ratio.

In contrast to the homogeneous air-fuel charge of the spark-ignition engine, the diesel operates with a stratified charge, the air-fuel ratio varying from zero at the injector-nozzle exit to infinity in the air surrounding the spray plume. Exposure of the very fuel-rich mixture in the core of a spray plume to the high combustion temperatures of the adjacent burning mixture promotes the formation of soot, minute particles comprised primarily of carbon atoms. Most of this soot oxidizes as combustion progresses, but a significant quantity escapes with the exhaust gas. In the process it attracts unburned HC. The exhaust soot and adsorbed HC, lubricating oil escaping from the cylinder, and sulfates formed from sulfur in the fuel, together with the water molecules associated with these sulfates, collectively comprise the exhaust particulate matter (PM). PM is a regulated exhaust emission in the U.S. Although the exhaust HC of the diesel is fairly low without aid from an exhaust catalyst and the CO is very low, simultaneous compliance with PM and NO_x standards is a challenge. For example, EGR (exhaust gas recirculation) is an effective means of lowering NO_x at part load, but its introduction increases PM.

Broadly speaking, there are two types of diesel engine in use: the indirect-injection (IDI) and the direct-injection (DI) versions. They are contrasted in Fig. 17.

In the IDI version, fuel is injected into an antechamber connected to the main chamber above the piston by a narrow passageway. Bulk air motion established in the antechamber fosters mixing of the air with the fuel spray. Upon ignition, the burning mixture expands through the passageway into the air-filled main chamber, where combustion is completed. The IDI engine is the type used in most diesel passenger cars because of advantages in emissions and noise production. It normally has a compression ratio greater than 20 to help compensate for the increased heat loss associated with the high surface/volume ratio of its combustion chamber. The antechamber also includes a glow plug for aid in starting.



INDIRECT INJECTION DIRECT INJECTION

FIG. 17. Two types of diesel engines.

In the DI version the fuel is injected directly into the cylinder. In the version of Fig. 17 the piston contains a deep bowl. Swirl induced in the intake air is intensified through conservation of angular momentum as the piston ascends on the compression stroke, creating bulk air motion in the bowl that promotes mixing of air and fuel. Such a DI diesel is being pursued for passenger cars because it has the potential for a 10%–15% increase in fuel economy compared to the IDI engine, but noise and emissions compliance have impeded its broad application.

In a variation on the DI engine of Fig. 17, the bowl is eliminated from the piston crown, providing a more quiescent field of air. Mixing is then promoted by using very high fuel-injection pressures, typically combined with a multiplume spray pattern. DI diesels of this type are common in heavy-duty trucks.

8.2 Spark-Ignition Stratified-Charge Engine

Spark-ignition versions of the compression-ignition stratified-charge diesel engine have been the subject of considerable attention over the years.

A divided-chamber stratified-charge engine bearing a family resemblance to the IDI diesel has seen limited production in passenger cars. A rich mixture is carbureted into the antechamber, a lean mixture into the main chamber. Spark ignition of the rich mixture sends a flaming torch of burning gases into

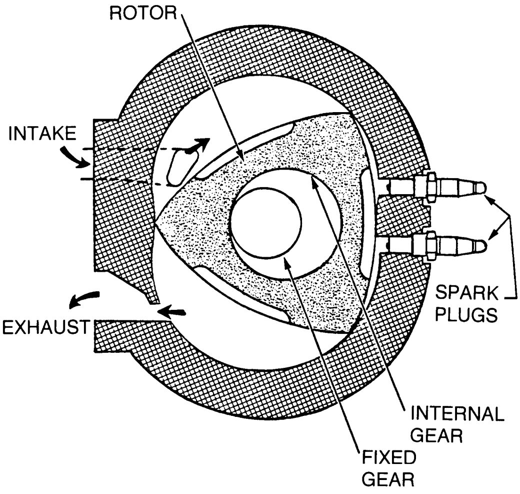


FIG. 18. Rotary engine.

the main chamber for ignition of the lean mixture. This approach has not shown sufficient advantage to earn widespread acceptance.

Two types of spark-ignited DI engines have been the subject of extensive research. Members of this class are frequently called DISC (direct-injection stratified-charge) engines. In the late-injection type, fuel is injected into the cylinder late during the compression stroke as in the diesel, and the spark plug has typically ignited the mixture before injection is completed. In the early-injection type, fuel is injected early during the compression stroke, and fuel injection is typically completed before the spark plug ignites the mixture. Both approaches have demonstrated fuel-economy advantages, but both have difficulty matching the exhaust emissions of competitive engines.

8.3 Rotary Engine

Many rotary engines with intermittent combustion have been invented over the years to avoid the vibration associated with the conversion from reciprocating to rotary motion accomplished by the slider-crank mechanism in the conventional reciprocating engine. However, only the one due to Wankel that is illustrated in Fig. 18 has achieved significant success commercially. A three-sided member rotates eccentrically within a specially shaped housing. Three chambers are enclosed between the flanks of the rotor and the interior of the housing. They change in volume as the central element rotates. Each of these variable-volume chambers is equivalent to a cylinder. The fresh mixture is inducted, and the burned gas exhausted, through ports in the housing. Two spark plugs are shown fixed in the housing, and the charge is swept past them by the rotor. The use of two spark plugs in a single combustion space reflects an effort to compensate for the undesirably long and narrow combustion chamber inherent with this configuration. The engine is compact and light, comparatively quiet, and vibration free, but generally has been unable to match the fuel economy of a comparable reciprocating engine.

8.4 Gas Turbine

The automotive gas turbine, diagrammed in Fig. 19, duplicates the compression, combustion, and expansion events of the reciprocating engine, but on a continuous rather than an intermittent basis. Intake air is compressed by a centrifugal compressor. The compressed air passes through a regenerative heat exchanger for preheating by the exhaust gas before entering the burner. There combustion of a fuel spray takes place on a continuous basis at an essentially constant pressure. The gas leaving the burner is at the peak temperature of the cycle, a parameter strongly influencing the thermal efficiency. This hot compressed gas expands first through a gasifier turbine that is connected on a common shaft to the compressor and provides the energy necessary to drive it. Expansion continues through a power turbine that is connected through a transmission to the vehicle-drive wheels. The hot gas leaving the power turbine, now at near-atmospheric

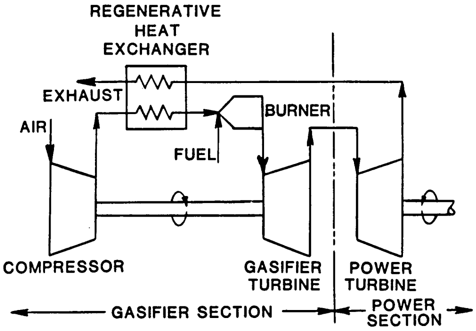

FIG. 19. Schematic diagram of a two-shaft regenerative gas turbine.

pressure, rejects heat to the compressor-discharge air in the heat exchanger before being exhausted to the atmosphere.

The regenerative heat exchanger usually takes the form of a porous matrix in a large-diameter thin disk. The opposite face areas of the disk are divided into high-pressure and low-pressure sectors by rubbing seals fixed to the housing and radiating from the disk center. As the disk slowly rotates on its axis, any given element of the matrix alternately passes through each of these two sectors. As the matrix element rotates through the low-pressure sector, hot gas exiting from the power turbine passes through it to the exhaust system, heating the matrix element in the process. When that matrix element rotates past the seals into the high-pressure sector, cooler compressor-discharge air passes through it in the opposite direction, extracting heat from the matrix en route to the burner.

The presence of the regenerator distinguishes the automotive gas turbine from its aircraft counterpart. The regenerator saves fuel by preheating the burner inlet air so that less fuel is required to achieve the peak cycle temperature. It cools the engine exhaust to a level more acceptable for disposal on streets and highways. It also helps to silence the exhaust noise.

The usual two-shaft automotive gas turbine has been illustrated in Fig. 19, but single-shaft versions have also been built experimentally in which the gasifier and power turbines have been combined into a single unit. This simplifies the engine but demands an efficient continuously variable transmission to accommodate the difference between the engine-shaft speed, which is related to the instantaneous power demand of the driver, and the vehicle speed, which is not proportionately related.

Past automotive gas turbines have been unable to match the fuel economy of existing piston engines, one reason being the limitation placed on peak cycle temperature by existing high-temperature alloys. Research is now directed toward use of structural ceramics in the hot sections of the engine in an effort to remove that barrier. Obstacles yet to be overcome include proof of reliable cost-competitive ceramic components, achievement of satisfactory efficiencies in the miniature turbomachinery that follows from the low engine airflow requirement attending high peak cycle temperature, and development of a burner that can meet low NO_x requirements at high operating temperature.

8.5 External-Combustion Engines

The foregoing engines all involve internal combustion, i.e., combustion in through-flowing air. The steam engine and the Stirling engine utilize external combustion, with the heat generated being transferred into the working fluid through a heat exchanger. The working fluid then circulates in a closed cycle.

In the steam engine, the working fluid is water in both its liquid and vapor phases. The steam engine works on the Rankine cycle. Water is pressurized by a pump, then passed into a steam generator or boiler, where it is heated to its boiling point, vaporized, and superheated, all at essentially constant pressure. The hot steam then passes through an expander of either the reciprocating or turbine type, although the former has proven more effective in automotive sizes. The expander extracts work from the steam, after which the low-pressure steam passes to the condenser. There the steam is condensed back into a liquid at constant pressure for passage to the pump and recirculation through the cycle. Condensation is accomplished by passing ambient air through the condensing heat exchanger.

The preferred working fluid for the Stirling engine is hydrogen, although helium has been used with some sacrifice in thermal efficiency. In contrast to the steam engine, no phase change is involved. In the ideal Stirling cycle, the gas is first compressed isothermally, then heated at constant volume (isochorically) to a still higher pressure, next expanded isothermally, and finally cooled to its original state isochorically. The heat rejected from the gas during isochoric cooling is stored in a regenerator for subsequent transfer into the gas during its isochoric heating. It can be shown that this ideal cycle has as high a thermal efficiency as can be achieved when operating between specified upper and lower temperature limits. In implementing this Stirling cycle in hardware, reciprocating pistons are employed, but the heat addition is accomplished through continuous combustion.

Being external-combustion engines, both of these alternatives can be operated on a broad spectrum of fuels. Because they are free of explosive combustion, both avoid the combustion noise of reciprocating internal-combustion engines. However, both of these closed-cycle engines share some common drawbacks for automotive application, although the more efficient Stirling engine comes the closer to meeting recognized needs. Both are large and heavy. Upon starting a cold engine, both require an annoying waiting period until the working fluid reaches an acceptable operating temperature. Especially in light-load operation, the brake efficiencies of both suffer because of the energy requirements of the large number of engine-required auxiliaries. The steam engine is poorly suited to operation in winter climates because of the freezing problem. The Stirling engine has an unsolved problem with leakage of the hydrogen working fluid.

9. ELECTRIC VEHICLES

Because of problems with local air quality in many urban areas, interest is strong in the electric vehicle. Leading candidates are the battery-electric, in which the conversion from fuel-stored energy into electricity is accomplished at a remote location, and fuel cells, in which that conversion takes place on board the vehicle.

9.1 Battery-Electric Vehicle

It has been estimated that use of an electric car in place of one powered by an internal-combustion engine would reduce HC and CO emissions by one to two orders of magnitude. On the other hand, a significant reduction in NO_x is unlikely, although the NO_x would usually be emitted at an electric generating plant remotely located from any urban center. In trade, a substantial increase in emissions of particulate matter and sulfur oxides is anticipated, even with expected environmental controls, because over half of the electricity generated in the U.S. will involve combustion of coal on into the 21st century.

Energy efficiency is high from the battery through the control system and electric motor to the drive wheels, but that figure is not of great significance. When the efficiency is reckoned from the primary-energy source through the steam power plant and its electric generator, the electricity delivery system, the battery charger, and into the battery, studies have suggested no significant energy advantage for the battery-electric vehicle.

Because of presently limited battery capabilities, the utility of the battery-electric vehicle is restricted. A maximum range between charges on the order of 150 km is typical. Range falls quickly if battery energy is used to provide heating or air conditioning, and it also falls with ambient temperature and with battery age. As the battery charge is consumed, vehicle performance deteriorates. When repeatedly deep discharged to utilize maximum range, battery life suffers. While an empty gasoline tank can be refilled in a matter of minutes, it takes hours to recharge a battery. Fast recharging also depreciates battery life. For this reason, the battery-electric approach is presently best suited to commuter cars and urban delivery vans.

Although energy cost for a battery-electric car can be competitive, battery replacement cost presently tilts economics away from this option. Future substantial increases in gasoline prices could reverse this balance. Clearly, what is needed is an improved battery.

Research and development are being conducted on many types of batteries. Some batteries are superior to others in terms of power density (W/kg), a measure of performance capability. Others are best in terms of energy density (W h/kg), indicative of range capability. All would benefit from the ability to accept more charge/discharge cycles before requiring replacement.

A candidate promising one of the best combinations of energy, power and life is the sodium/sulfur battery, which operates at about 350 °C with the elements in a molten state. Such high-temperature batteries employing reactive materials involve unresolved questions about safety in the event of serious accidents and about freezing after long periods out of service, especially in winter climates.

9.2 Engine/Electric Hybrid Vehicle

The engine/electric hybrid, which adds a combustion engine to the battery-electric system, can be used to overcome both the range handicap and the normally restricted performance capability of the battery-electric vehicle. The engine and the battery-electric system can be combined in a variety of arrangements.

The simplest involves addition to the battery-electric vehicle of a small engine driving a generator to recharge the batteries as energy is extracted from them. In such a range extender, vehicle range is determined by the size of the fuel tank rather than the energy capacity of the battery pack. Performance is still limited by the energy-delivery rate of the batteries, however.

At the expense of increased complexity, the engine can be linked to the drive wheels along with the electric motor, while still driving a generator to keep the batteries charged. While extending vehicle range as in the above case, this arrangement also enhances performance capability from a given battery pack by augmenting the propulsive power available.

A third arrangement is to link both the engine and the electric motor to the drive wheels as above, but to eliminate the engine-driven generator for battery recharging. This option also has the potential for increased range over the simple battery-electric vehicle, with range again being determined by the size of the fuel tank. A smaller engine is often proposed with this arrangement, allowing the engine to operate nearer full load, where it has a higher thermal efficiency. The shortfall in performance is then made up by the power available from the battery-electric system. Although this arrangement may offer an advantage in fuel economy over a vehicle of equal performance powered solely by an engine, some utility is sacrificed in the general case. For example, on a prolonged upgrade with partially discharged batteries, the electric motor may no longer be able to compensate for the performance shortfall of the undersized engine.

Many variations exist in the details of implementing the above schemes. In addition, hybrids have been demonstrated in which an engine is coupled with either mechanical-energy storage in a flywheel or hydraulic/pneumatic-energy storage in a hydraulic accumulator rather than in a battery. All of these possibilities share the burden of increased complexity, weight and cost, and of reduced carrying capacity because of the increased space requirement of the hybrid system. For the latter reason, such hybrid systems are often considered for vans and small trucks rather than for the severely space-restricted passenger car.

9.3 Fuel-Cell Vehicle

The fuel cell is not as developed as the battery for vehicular application. It offers a potential solution to the range problem of the battery-electric option. Currently, the leading approach is to break down methanol in an on-board reformer, extracting hydrogen. This fuel is then reacted in the fuel cell with oxygen from the air to make electricity for the electric drive motor(s). Because such a system is unable to follow the fast transients characterizing typical automotive power requirements, it must be combined with batteries for energy storage. The batteries also allow recovery of vehicle kinetic energy through regenerative braking. The energy density of such a system is presently too poor for serious consideration in automobiles, but the technology is relatively immature, leaving room for future improvement.

GLOSSARY

Brake Power: The power delivered by an engine at its output shaft.

Brake Specific Fuel Consumption (BSFC): The mass of fuel consumed per unit of brake power delivered.

Differential: The mechanism incorporated in the drive train to allow the vehicle drive wheels to rotate at different speeds, as when turning a corner.

Drive Train: The components connecting the engine output shaft and the drive wheels, normally including a transmission and a differential.

Dynamometer: A device, usually an electric generator, capable of loading an engine (an engine dynamometer) or vehicle (a chassis dynamometer) at various torques and speeds for test purposes. An electric dynamometer capable of operating also as a motor to rotate the engine or the vehicle drive wheels when the engine is not delivering power is called a motoring dynamometer.

Exhaust Gas Recirculation (EGR): Recycling of a fraction of the engine exhaust gas back into the intake manifold, done to control the emission of nitrogen oxides.

Exhaust Manifold: A branched conduit that collects the exhaust gas from the individual cylinders and delivers it to the exhaust pipe.

Four-Stroke Engine: A reciprocating piston engine that completes a thermodynamic cycle in any given cylinder during four strokes of its piston (two revolutions of the crankshaft).

Indicated Power: The power developed by the cylinder gas during the compression and expansion strokes of the piston.

Intake Manifold: A branched conduit that delivers the engine intake air to the individual cylinders. The air delivered may also contain fuel, depending on the type of engine and its fuel system.

Intercooler: A heat exchanger located between a supercharging compressor or a turbocharger compressor and the engine, used to cool the compressed cylinder charge. The cooling medium may be either engine coolant or ambient air.

Journal Bearing: A lubricated sleeve in which a shaft or pin rotates or oscillates.

Knock: In a spark-ignited homogeneous fuel-air charge confined by an enclosure, an abnormal combustion phenomenon in which part of the unburned charge remote from the spark plug and normally the last to be reached by the advancing flame front ignites spontaneously.

Lean Mixture: Fuel and air mixed in proportions such that there is an excess of air present compared to that required for complete combustion of the fuel.

Mechanical Efficiency: The ratio of brake power to indicated power, a measure of losses attributable to friction and pumping.

Multipoint Fuel Injection: Spraying of fuel into the engine air in the intake system at a multiplicity of points, normally at the entrance port to each cylinder.

Octane Number: A numerical rating given to a gasoline to indicate its resistance to combustion knock and determined by one of several standardized test procedures.

Overhead Cam (OHC): Indication that cams operating the intake and exhaust valves are mounted above the cylinder head, requiring that the camshaft be driven from the crankshaft by a belt, a chain, or gears.

Oxidizing Catalytic Converter: A device in the exhaust system through which the exhaust gas flows. It contains minute amounts of special metals that catalyze the oxidation of both unburned hydrocarbons and carbon monoxide.

Power Train: The combination of the engine and the drive train.

Pumping Loss: The parasitic loss associated with pumping engine air into the cylinder and exhaust gas out of the cylinder during the intake and exhaust strokes.

Rich Mixture: Fuel and air mixed in proportions such that there is an insufficiency of air present compared to that required for complete combustion of the fuel.

Scavenging: Removing burned gas from the cylinder during the exhaust process to make room for fresh charge for the next cycle.

Single-Point Fuel Injection: Spraying of fuel into the engine air at a single point at the entrance to the intake manifold. (In vee engines, one injector may be used for each bank of cylinders.)

Stratified Charge: A cylinder charge in which the local ratio of fuel to air spatially varies significantly within the chamber, normally by intent.

Supercharger: An engine-driven compressor upstream of the intake manifold used to compress the air above ambient pressure for increased engine power.

Thermal Efficiency: The dimensionless ratio of the output energy from an engine to the fuel input energy.

Three-Way Catalytic Converter: A device in the exhaust system through which the exhaust gas flows, that device containing minute amounts of special metals that catalyze the oxidation of both unburned hydrocarbons and carbon monoxide, and that simultaneously reduce the oxides of nitrogen.

Throttle-Body Fuel Injection: Another commonly used name for single-point fuel injection, denoting that the injector is mounted in the element housing the throttle plate.

Torque Converter: An element in the transmission that includes a centrifugal hydraulic pump on its input shaft, a radial-inflow hydraulic turbine on its output shaft, and at least one row of stator blades between them. It transmits power from the engine crankshaft to the vehicle drive wheels, smoothly accommodating a continuously variable speed ratio across it and multiplying engine torque when the speed of the output shaft is much less than that of the input shaft.

Transmission: An element placed in the drive train to facilitate changing the ratio of the engine rotational speed to the rotational speed of the vehicle drive wheels.

Turbocharger: A unit mechanically separate from the engine within which a turbine driven by engine exhaust spins a compressor mounted on a common shaft, that compressor delivering compressed air to the engine for increased power output.

Two-Stroke Engine: A reciprocating piston engine that completes a thermodynamic cycle in any given cylinder during two strokes of its piston (one revolution of the crankshaft).

INTRODUCTION

The early methods of producing high-energy electron beams for x-ray applications required generating the full voltage to give the final electron energy and then applying this voltage to a vacuum tube into which a source of electrons at the negative electrode injected the particles. Energies or voltages of one or two million electron volts were possible, but the techniques for holding such high voltages on a vacuum tube were very difficult to extend to higher voltages. At the same time the energies desired for exploring the energetic transformations within the nucleus of atoms were an order of magnitude higher, and such voltages could not be reached with the electron accelerators of the 1930s.

Higher voltages were also needed for the medical application to x-ray therapy since it was realized that there would be a buildup of secondary ionization, the "dose" responsible for biological action, below the surface of the body at a depth which increased with x-ray energy. High skin dose imposed an undesirable limit on the dose which could be delivered to the tissue to be treated deep below the skin if voltages below one million were used. Furthermore, if electrons of sufficient energy could be produced, these electrons could be used directly on deep tissue instead of using the secondary electron ionization produced by x rays. The energy loss of an electron in penetrating waterlike tissue is about 2 MeV per centimeter provided that the electron is relativistic, that is, provided its energy is well over the value of the electron's rest mass, 511 kV. Consequently a 20-MeV beam of electrons would penetrate about 10 cm and create an ionization dose along the way. Since the radiation therapist wants to deliver the dose to such depths, electron energies adjustable from 10 to 40 MeV would be desirable for either x-ray production or for direct electron beam application.

For radiographic examination of thick metal objects, such as iron castings, to discover flaws, the thickness that can be penetrated by x rays or gamma rays depends upon the atomic number of the metal's elements and on the energy of the x-ray photons. There is an optimum energy due to the decrease of Compton absorption with increasing x-ray energy and the increase of pair production with increased energy. For iron the most penetrating photon energy is around 25 MeV, and for lead it would be only about 3 MeV.

It is evident that for the applications mentioned it would be desirable to have beams of electrons of several tens of MeV. Since the electrons would be highly relativistic at these energies, the cyclotron could not be used. The cyclotron was very well adapted to the acceleration of ions to these energies in the 10-MeV range which are far below the rest mass of the ions used. Thus the betatron method of electron acceleration, which can operate at classical and at relativistic energies, had immediate application when it was developed in 1940.

The later development of the synchrotron principle by McMillan (1945) and Veksler (1945) made possible the acceleration of electrons by radio frequency means to energies far higher than betatrons can achieve. Betatron acceleration has been applied for experiments with mesons at meson-producing energies of about 300 MeV, but the loss of electron energy by centripetal acceleration radiation can become about 10% of the final energy there, and it rises rapidly with energy. Hence the synchrotron principle of radio frequency acceleration is used to take relativistic particles to higher energies since this radiation loss is conveniently supplied by synchrotron acceleration. It is for this reason that centripetal acceleration radiation is called "synchrotron radiation," and this radiation now has found extensive applications as a light source with polarization and high intensity over a spectral range not accessible by other means.

Experiments and studies of betatron acceleration date back to times well before any of these applications. Slepian, Wideröe, Walton, Breit and Tuve, and Steenbeck, to name a few, are among the early workers. Slepian imagined a closed iron transformer core with electrons circulating around it like the windings of the secondary coil of a transformer. The electrons were to be bent into the circulating orbit by the bending action of permanent magnets placed around the core with their magnetic field increasing with radius to provide for holding both low-energy electrons at small radii and later for more energetic accelerated electrons at a somewhat higher energy (Kerst, 1946). It is interesting to note that the evolution of betatrons eventually led to just such a structure after alternating-gradient focusing was discovered.

The experiments of Wideröe and especially of Breit and Tuve and Walton were directed toward nuclear disintegration attempts with the beams. All of the applications mentioned were evident as possibilities for electron beams by the late 1930s when experiments guided by detailed theoretical work resulted in a small model operating at 2 MeV which produced an x-ray intensity equivalent to the gamma rays from 1 g of radium (Kerst, 1941; Kerst and Serber, 1941). Yields from betatrons have been sufficient for many practical purposes, but electrostatic repulsion between particles in the orbit limits the current which can be held by focusing forces. By injecting at higher energies, and hence at higher magnetic fields, magnetic focusing forces are increased and the space charge limit can be raised. The possibility of holding larger currents by the addition of a toroidal field has often been attempted, and it has ultimately been accomplished with the aid of alternating gradient or strong focusing.

1. PHYSICAL PRINCIPLES

To increase the energy of a particle in an orbit of radius r in a magnetic field the particle must experience an electric field in the direction of its motion. The magnetic field can do no work on a particle because the force which it provides is at right angles to the motion. However, a transformer action providing an increase of a certain number of electron volts per turn comes not from the field at the orbit, but from the rate of change of the flux, Φ, linking the orbit which is due to the rate of change of the vector potential at the orbit. In a betatron a transformer core within a circular orbit provides the voltage, $d\Phi/dt$, volts per turn. Figure 1 shows the structural forms and the accelerating chamber which is placed between the poles of the magnet. The iron magnetic circuit must be laminated because of the time-varying field, although air-core betatrons can also be made. The inductance represented by the coil system is usually in a resonant circuit with a large capacitor to store the energy. Some betatrons are pulsed with the capacitor's energy discharged unidirectionally through the coils as in Figs. 1(c) and 6(b).

The particles circulating in orbit between the poles experience an electric field

$$E=\frac{1}{2\pi r}\frac{d\Phi}{dt}\ \text{V/m}$$

and the vector potential associated with the linked flux is then

$$A=\frac{\Phi}{2\pi r}\ \text{Wb/m.}$$

Since the field at the orbit is

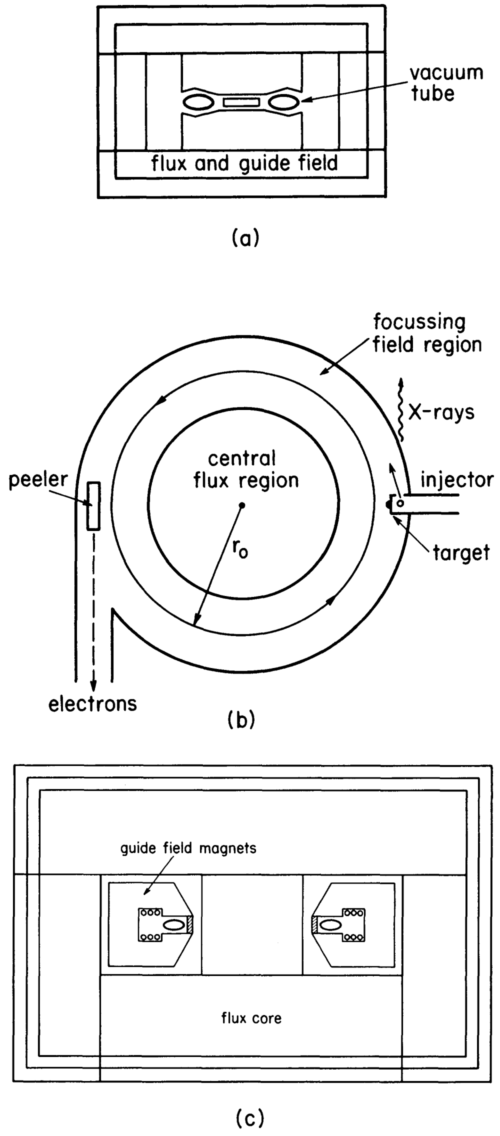

FIG. 1. (a) Magnet configuration of a 22-MeV betatron with the vacuum tube shown between the poles. (b) Toroidal vacuum tube. A resistive metallic interior coat prevents wall charge or *IR* voltage drops from deflecting the injected beam. (c) Configuration of unidirectionally pulsed magnets. The biased flux core links the orbit which circulates in a ring of focusing magnets.

$$\mathbf{B}=\mathrm{curl}(\mathbf{A}),$$

it is evident that in Fig. 1(c) the central portion of flux in the flux core will produce no magnetic field at the orbit because this core's vector potential has a $1/r$ dependence and thus its curl is zero and its contribution to B at the orbit is then zero.

However, the vector potential of the necessary focusing magnets in Fig. 1(c) at the orbit must have a nonvanishing curl(**A**) in order to give the focusing field **B**, but some electric field due to any orbital flux linkage from the focusing magnets is added to the electric field due to the accelerating flux of the central core producing the total electric field acting on the particles.

The momentum of a charged particle moving in an orbit of constant radius r is

$$p=eBr$$

and if this momentum was given to it by an electric field from a changing flux linkage within its orbit, then its rate of change of momentum was

$$\frac{dp}{dt}=eE.$$

Substituting

$$\frac{e}{r}\frac{dB}{dt}=\frac{e}{2\pi r}\frac{d\Phi}{dt}$$

and integrating, we find the flux condition

$$2\pi\, r_0^2 B=\Phi-\Phi_0.$$

We have assumed that the particle is started with $B=0$ and that the orbit maintained a fixed radius, and we find that the flux change within the orbit must be twice that for a uniform field within the orbit area.

The path of an electron in typical betatrons which require 1–4 ms to accelerate can be as long as 1000 km. Evaluation of beam loss by scattering on residual gas in the vacuum chamber and experimental observations have shown that a vacuum pressure of less than 10^{-5} Torr is required for these long paths. This vacuum is not difficult to obtain, but there must be focusing forces to keep the beam together stably. That there are such forces, under certain conditions, can be seen by a simple argument. For axial (vertical) focusing note that the centripetal force due to the bending magnetic field is directed inward radially at right angles to the magnetic line of force. Thus if the lines of force, which are vertical in the plane of the orbit, bend inward above and below this midplane, the force on the particle will acquire a component directed back toward the midplane when it strays out of that plane. This is the necessary restoring force to cause the particle to oscillate about the midplane. This field line curvature occurs when the strength of the magnetic field decreases in magnitude as the radial distance from the axis increases. This is the same vertical focusing action occurring in cyclotrons. If we describe this field dependence as

$$B \approx r^{-n},$$

then

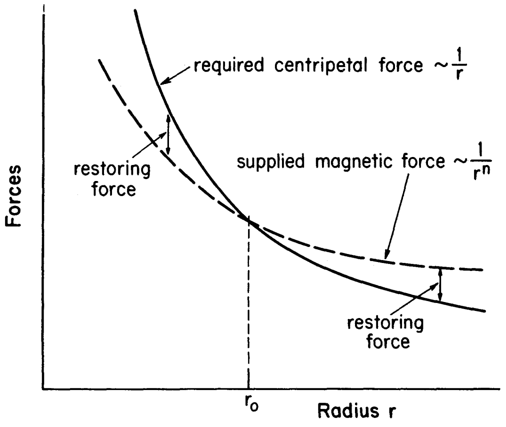
$$n \geqslant 0$$

for the necessary decrease of magnetic field with radius for axial focusing.

The requirement on n for radial focusing can be seen by noting that the centripetal force to keep a particle in a circular orbit decreases as $1/r$. Thus if the magnetic field which supplies this force decreases less rapidly than $1/r$, a particle displaced to a radius too large will find the magnetic force larger than needed to remain at the large radius and its path will curve inward to smaller radii. Likewise, a particle at too small a radius will find that the field is not strong enough to hold it at this radius. Hence n must be less than 1, and there is a fixed equilibrium radius where the centripetal force is equal to the magnetic force. Thus

$$0 \leqslant n \leqslant 1.$$

This is visualized in Fig. 2 where the required centripetal force to hold a particle in an orbit of radius r_0 is shown along with the radial dependence of magnetic force needed to accomplish focusing. The difference between the curves is available for focusing.



required centripetal force $\sim \frac{1}{r}$
restoring force
supplied magnetic force $\sim \frac{1}{r^n}$
restoring force
Forces
r_0
Radius r

FIG. 2. Radial forces. The required centripetal force to maintain a constant radius, $1/r$, is exceeded by the magnetic force for radii greater than r_0. Thus return toward r_0 is assured providing focusing.

The invention of alternating gradient focusing some years after the construction of the first betatrons removed this requirement on n and allowed magnetic field with much larger gradients, $n \gg 1$, but with n alternating in sign along the orbit. This led to the possibility of far smaller apertures and magnets and thus a great saving in cost.

It is now necessary to use the equations of motion to show the conditions for the fields to produce stable orbits.

2. EQUATIONS OF MOTION

For a circularly symmetric magnetic structure the vector potential describing the field has only a ϕ component. The relativistic Hamiltonian is

$$H = c\{m^2c^2 + P_r^2 + P_z^2 + [P_\phi/r - eA(t,r)]^2\}^{1/2} \tag{1}$$

and Hamilton's equations give

$$\frac{dH}{dP_r} = \frac{dr}{dt} = \frac{c^2}{H} P_r, \tag{2}$$

$$\frac{dH}{dr} = -\frac{dP_r}{dt} = -\frac{c^2}{H}\left(\frac{P_\phi}{r} - eA\right)\left(\frac{P_\phi}{r^2} + e\frac{dA}{dr}\right), \tag{3}$$

$$\frac{dH}{dP_z} = \frac{dz}{dt} = \frac{c^2}{H} P_z, \tag{4}$$

$$\frac{dH}{dz} = -\frac{dP_z}{dt} = -\frac{c^2}{H}\left(\frac{P_\phi}{r} - eA\right)\left(e\frac{dA}{dz}\right). \tag{5}$$

P_ϕ, P_r, and P_z are the canonical momenta with the ϕ component being a constant of the motion because of the lack of dependence of the problem on ϕ. P_r and P_z are the radial and axial momenta, respectively.

Taking $P_\phi = 0$, the classical and the relativistic cases will be treated separately, and then the case with $P_\phi \neq 0$ will be described. A more general treatment is in Kerst and Serber (1941).

When the particle's energy is far less than its rest mass energy, we have the classical case with $H \approx mc^2$ in (1), and (2) becomes $dr/dt = P_r/m$ and (3) becomes $dP_r/dt = -e^2A(dA/dr)/m$ giving

$$\frac{d^2r}{dt^2}=-\left(\frac{e}{m}\right)^2A\left(\frac{dA}{dr}\right) \tag{6}$$

for the radial acceleration. If the field is arranged so that there is a position where $dA/dr=0$, say at r_0, then that would be the radius for a fixed orbit with no radial acceleration. Furthermore if dA/dr is negative at $r\leqslant r_0$ and positive for $r\geqslant r_0$, then the radial acceleration, d^2r/dt^2, is always directed back toward r_0, an equilibrium orbit. Thus radial focusing is provided by such a field with the vector potential having a minimum at r_0.

The conditions just stated in (6) would describe an oscillatory motion with an angular frequency ω satisfying

$$\frac{d^2x}{dt^2}=-\omega^2x, \tag{7}$$

where

$$x=r-r_0$$

and

$$\omega^2x=\left(\frac{e}{m}\right)^2A\,\frac{dA}{dr}\,.$$

But since $dA/dr=0$ and A is minimum at r_0, expansion about r_0 gives

$$\frac{dA}{dr}=\frac{d^2A}{dr^2}\,x$$

and thus

$$\omega^2=\left(\frac{e}{m}\right)^2A\,\frac{d^2A}{dr^2}\,. \tag{8}$$

To evaluate (8) in terms of the magnetic field shape note that the curl equation gives $B_z=A_\phi/r+dA_\phi/dr$ and thus

$$\frac{dB_z}{dr}=\frac{d^2A}{dr^2}+\frac{dA/dr}{r}-\frac{A}{r^2}\,.$$

Then with $dA/dr=0$ at the equilibrium orbit and $\Omega=eB_z/m$, the circling angular velocity is

$$\omega_r=\Omega\left[1+r\frac{dB_z/dr}{B_z}\right]^{1/2}.$$

If the radial field dependence is $1/r^n$, then the familiar form results:

$$\omega_r=\Omega(1-n)^{1/2}, \tag{9}$$

with n less than 1 giving a real result.

For a differential equation like (7) with an adiabatically time-varying coefficient on the right-hand side which represents a stiffening spring, the amplitude of oscillation will vary as $1/\omega^{1/2}$ and this shows that the radial oscillation "damps" as the acceleration of the particles to higher energy progresses:

$$-\frac{\delta a}{a}=\frac{\delta B}{2B}=\frac{\delta E}{4E}, \tag{10}$$

where a is the amplitude of the orbital oscillation and E is the energy gain associated with the rising field B.

Finally on the equilibrium orbit $B_z=A/r_0$ and the accelerating electric field is

$$-\frac{1}{2\pi r}\frac{d\Phi}{dt}=-\frac{dA}{dt} \tag{11}$$

so

$$\Phi-\Phi_0=2\pi\, r_0^2B_z, \tag{12}$$

the equilibrium orbit flux condition with the possibility of a curl-free initial reverse bias flux Φ_0 through a portion of the iron within the orbit. Such a bias allows central iron flux to change twice as much as it could if it were unidirectional.

About this equilibrium orbit with damped radial motion of stray particles, axial motion out of the plane of the orbit should also be focused and damped. As mentioned the outward bulging of the magnetic field lines in the orbital plane provides this force with a component back toward the plane. The resulting axial acceleration is [like (6)]

$$\frac{d^2z}{dt^2}=-A\left(\frac{e}{m}\right)^2\frac{dA}{dz}\,. \tag{13}$$

In this case dA/dz is zero on the orbital plane by symmetry for positive and negative z.

Since $dA/dz=B_r$ and curl($\mathbf{B}$)=0 in the vacuum and $A=rB_z$, $dB_z/dr=dB_r/dz=B_r/z$, near $z=0$ (13) becomes

$$\frac{d^2z}{dt^2}=\left(\frac{eB_z}{m}\right)^2\left(\frac{r_0}{B_0}\right)\frac{dB_z}{dr}\,z \tag{14}$$

or

$$\frac{d^2z}{dt^2}=-\Omega^2nz \tag{15}$$

showing that the axial angular frequency is

$$\omega_z=\Omega n^{1/2}. \tag{16}$$

(16) and (9) substantiate that $0 \leqslant n \leqslant 1$. The time increase of B in (14) shows that the amplitude of axial oscillation is "damped" by the same factor as is the radial motion (10) for nonrelativistic particles.

For the relativistic case we ignore mc in the Hamiltonian (1) and find Hamilton's equations with small P_r and P_z to be

$$\frac{dr}{dt}=\frac{c}{eA}P_r,$$

$$\frac{dP_r}{dt}=-ce\frac{dA}{dr},$$

$$\frac{dz}{dt}=\frac{c}{eA}P_z,$$

$$\frac{dP_z}{dt}=-ce\frac{dA}{dz}.$$

The radial acceleration equation is

$$\frac{d^2r}{dt^2}+\frac{1}{A}\frac{dA}{dt}\frac{dr}{dt}=-\frac{c^2}{A}\frac{dA}{dr}$$

and the axial, or z, equation has the same form with z substituted for r. The reasons for dA/dr and dA/dz vanishing on the equilibrium orbit are the same as for the classical case giving a generic differential equation with x for $(r-r_0)$ or for z and $(d^2A/dx^2)x$ for dA/dx:

$$\frac{d^2x}{dt^2}+\frac{1}{A}\frac{dA}{dt}\frac{dx}{dt}=-\frac{c^2}{A}\frac{d^2A}{dx^2}x \tag{17}$$

with

$$\frac{d^2A}{dr^2}=\frac{dB_z}{dr}+\frac{A}{r^2}$$

for radial motion where $dA/dr=0$ and

$$\frac{d^2A}{dz^2}=-\frac{dB_r}{dz}=-\frac{dB_z}{dr}$$

for axial motion.

Since $A=Br_0$ on the equilibrium orbit, the right-hand side of (17) which is $-(\omega_x^2)\,x$ shows that

$$\omega_r^2=\left(\frac{c}{r}\right)^2\left(1+\frac{r}{B_z}\frac{dB_z}{dr}\right) \quad \text{or} \quad \Omega^2(1-n)$$

and that

$$\omega_z^2=-\left(\frac{c}{r}\right)^2\frac{r}{B_z}\frac{dB_z}{dr} \quad \text{or} \quad \Omega^2 n$$

as in the classical case if B has an r dependence $1/r^n$.

The constant rotational angular velocity Ω at the speed of light does not produce the spring-stiffening "damping" effect seen at classical energies but instead the differential equation (17) shows a damping term which is proportional to dx/dt producing an exponential amplitude factor on the solution for times of steady field rise, if dA/dt or dB/dt is constant and positive, of

$$\exp\left(-\frac{dA}{dt}\frac{t}{2A}\right).$$

This results in an orbit shift toward the equilibrium orbit and away from the injector at relativistic energies of

$$-\frac{\delta x}{x}=\frac{dB}{2B}=\frac{dE}{2E} \tag{18}$$

radially or axially in contrast to that for classical energies (10).

These amplitude changes result in a very small beam width when high energy is reached. This is very valuable for sharp radiographic purposes or beam manipulations. Together with influences of space charges and space currents of the beam, this damping made possible injection from a particle source very near the orbit in early accelerators.

A further transient motion after injection occurs if P_ϕ is not zero, that is, if the particle is injected tangentially but at an energy which is correct for the initial radius r_i but wrong for the equilibrium radius r_0,

$$P_\phi=(P_i-eA_i)r_i,$$

where P_i is mechanical angular momentum, and P_ϕ must be a constant in time. Thus if A changes with time,

$$d(P_ir_i)=d(er_iA_i).$$

But P_i on the instantaneous circle is

$$er_iB_i=er_i\left(\frac{A_i}{r_i}+\frac{dA}{dr}\right).$$

Combining we have $d(r^2dA_i/dr)=0$ giving

$$-\frac{dr_i}{dt}=\frac{\dfrac{\partial}{\partial t}\left(\dfrac{dA}{dr}\right)}{\dfrac{\partial^2A}{\partial r^2}+\dfrac{2}{r}\dfrac{\partial A}{\partial r}}.$$

Neglecting the small last term in the denominator near r_0 and noting that

$$\frac{\partial}{\partial t}\left(\frac{\partial A}{\partial r}\right)=\frac{\partial}{\partial t}\left(\frac{\partial^2 A}{\partial r^2}(r_i-r_0)\right)$$

gives

$$\delta r_i/(r_i-r_0)=-\delta B/B=-\delta E/E \tag{19}$$

for the shift in the instantaneous circle off-energy orbit radius with field or energy change.

These transient motions of injected particles all serve to move the particles to the equilibrium orbit and away from the injector as the energy rises.

3. THE RADIATION-LOSS ENERGY LIMITATION

A limitation of the betatron method of magnetic induction acceleration is that, with electrons, centripetal acceleration radiation loss of energy becomes so great at several hundred MeV that an iron-core flux with the ordinary rise time of a few milliseconds cannot sustain the loss rate. For example, a 300-MeV betatron with a 4-ms rise time has approximately 10% energy loss during acceleration. The loss in electron volts per second is

$$dE/dt=4.22[E\ (\text{MeV})]^4/[R\ (\text{m})]^2.$$

This radiation has a continuous spectrum described by Schwinger (1949) which makes energetic electrons very useful as a radiation source in the ultraviolet to soft x-ray region. However, the maximum in the spectral intensity occurs at the $(E/mc^2)^3$ harmonic of the orbit's revolution frequency. Consequently electron energies of interest are in a range up to 1000 MeV. This radiation, which is a serious obstacle for a betatron, was overcome elegantly by the invention of the synchrotron radio frequency accelerating method by McMillan (1945) and Veksler (1945). The radiation is consequently called synchrotron radiation, and the high-energy limit for electron synchrotrons is orders of magnitude higher than the limit for electron betatrons.

It can be said that synchrotron acceleration uses a very small amount of flux linking the orbit for induction acceleration but uses it again and again by reversing it when the particle is not at the accelerating gap of an rf-flux-containing cavity. Hence the particle experiences the electric field of a rising flux linkage only at the time it crosses the gap. The guide or focusing field configuration at the orbit can be the same as that for a betatron, but the synchrotron has in addition automatic ϕ or azimuthal phase focusing which maintains the equilibrium energy. With enough rf flux in the cavity the radiation loss can be supplied to energies more than an order of magnitude higher than electron betatron energies.

4. THE BEAM CURRENT LIMIT

If the electrostatic repulsion of the charge in the accelerated beam is sufficient to overcome the magnetic focusing forces, then more particles cannot be held in the beam. This space-charge limit can be estimated assuming the beam to be cylindrical with radius a. The electrostatic repulsion of a beam of I amperes for electrons of speed v at the edge of the beam is then

$$F_E=e\,I/(2\pi\epsilon_0 av)$$

and the axial force supplied by the magnetic field gradient is

$$F_m=evanB_z/r. \tag{20}$$

With the injection field B_i these are equal for a beam current limit of

$$I=2\pi\epsilon_0 a^2v^2nB_i/r_0. \tag{21}$$

This estimates limiting ring currents of 0.8 A for the betatrons which have been used for therapy and radiography, and this agrees approximately with observations. Since injection in such applications is at about one-third the speed of light, the final ring current rises to 2 or 3 A in the process of gaining speed.

This limit on current is altered when relativistic energies are approached since then the self-magnetic field of the beam adds a pinching force $F_m=v^2\mu_0\epsilon_0F_E$. The sum of the two forces is

$$F_E-F_m=F_E(1-\beta^2) \tag{22}$$

which vanishes if the speed of light is approached for the injection energy. Thus the limits on space charge and space current can be very high for high-energy injection. If the beam is not a straight cylinder, or if it has conducting walls with image currents and charges in the vicinity, then the cancellation is not quite as shown by (22). However, using the repulsion calculated by (22) balanced by the focusing force from (20), the limiting beam current is

$$I=\frac{2\pi\epsilon_0 nmc^3a^2\beta^3}{er^2(1-\beta^2)^{3/2}}$$

or

$$I=\frac{8.53n\beta^3a^2}{r^2(1-\beta^2)^{3/2}}\ \text{kA}. \tag{23}$$

This can be very large if the beam radius a fills the vacuum tube aperture at injection and if β is near its maximum of 1.

To raise the limit farther an additional magnetic field B_ϕ can be applied along the path of the particles. This accelerator is the "modified betatron" of Sprangle and Kapetanakos (1978), Rostoker (1980), Chernin and Sprangle (1982), and Kapetanakos *et al.* (1983). The effect of this field is to convert a velocity leading away from the beam bundle to a spiraling motion of the particles. This multiplies the limiting current in (23) by $(B_0/B_z)^2$. At the low field at injection time it is easy to make this ratio very large, thus raising the limit into the thousands of amperes. As acceleration progresses, B_ϕ is not to be increased as much as B_z since it is needed only at injection energies. If it could be increased proportionally with B_z, the difficulty to be described next would be avoided.

The B_ϕ field operating on the centroid of a beam traveling along (not across) the ϕ direction produces a drift velocity,

$$\mathbf{V}_d=-\mathbf{F}\times\mathbf{B}_\phi/eB_\phi^2.$$

F is any force such as a focusing force on the beam which has a component orthogonal to B_ϕ. This drift is like the drift of a particle in crossed electric and magnetic fields, $\mathbf{V}=\mathbf{E}\times\mathbf{B}/B^2$, but instead of the E field's force we have F composed of the magnet's focusing force on the beam centroid, plus wall image current repulsion, minus wall image charge attraction, so $F=F_{\text{focus}}-F_{\text{images}}$. The image force for very large currents can overwhelm the focusing force at low injection energies. But the current and charge image forces approach self-cancelation at relativistic energies and thus the magnet's focusing forces would dominate after some acceleration. Therefore, the drift velocity reverses after some energy is reached during acceleration for beams started in what is called the "high current range." There is a "low current range" in which the magnet's focusing forces exceed the wall images' defocusing attraction at all times and there would then be no reversal of drift during acceleration.

The beam centroid drift tends to follow along the wall if the beam is not in the center of the chamber since that is the $\mathbf{F}\times\mathbf{B}_\phi$ direction. To evaluate this drift circulation, or "bounce" frequency, first consider a low current case with negligible image forces. We had by (9) and (16)

$$\omega_r=\Omega(1-n)^{1/2}\ \text{and}\ \omega_z=\Omega n^{1/2}$$

or with $n=\frac{1}{2}$, for example, we have

$$F_{\text{focus}}=m\omega_r^2x\ \text{or}\ m\omega_z^2z;$$

then $V_d=m\omega_r^2x/eB_\phi$ or

$$\omega_{\text{drift}}=n^{1/2}\Omega n^{1/2}B_z/B_\phi.$$

If $n\neq\frac{1}{2}$, then the angular velocity of the drift is

$$\omega_{\text{drift}}=\pm[n(1-n)]^{1/2}\Omega B_z/B_\phi$$

and thus the drift frequency can be slow compared to the orbital revolution time when $B_z<B_\phi$.

We can now see what will happen if the current is raised to the high current regime where the wall image forces pull the centroid of the beam toward the wall and overcome the magnet's focusing forces. To do this consider the meaning of n and $1-n$. They are ordinarily used as the power on $1/z$ or $1/x$, respectively, for the displacement dependence of the magnetic focusing force which brings the beam back toward the center of the chamber. Now consider n to describe the power law for the combination of image and focusing magnet forces acting on the beam centroid as a whole in the z direction, and $1-n$, call it n', to be a similar exponent on $1/x$ which describes the whole force on the beam in the x or r direction. Then

$$\omega_{\text{drift}}=\pm[n\,n']^{1/2}\Omega B_z/B_\phi.$$

It is then evident that if these two exponents, n and n', are both positive, as in a conventional betatron or a modified betatron in the low current regime, the drift angular velocity is real giving a stable drift around the tube wall. It would be real also if n and n' were both negative and a stable drift would occur in the opposite direction. This is the case of the high current regime for image forces overwhelming the magnetic focusing forces and pulling the beam toward the wall. The beam is still contained but "bouncing" in the opposite direction around the wall.

Instability and an accompanying drift to the wall can occur when the low-energy injected beam is in the high current regime with n and n' thus both negative. Then subsequent acceleration increases magnetic focusing and decreases image forces leading to the low current regime. n and n' thus must turn positive but at slightly different energies causing n and n' to be opposite in sign at some energy thus making the drift angular velocity imaginary. This means instability and the beam is then lost.

Loss from this instability can be avoided by starting in the "low current regime" which is the final energy state. This conservative design choice does not gain from the factor B_ϕ^2/B_z^2 but uses the limit given in Eq. (23) which is the same as that for the conventional betatron—except that a is the chamber minor radius and except that injection of the order of 1 MeV is used (Kapetanakos *et al.*, 1983).

It is evident that the beam bounce drift instability could be moved to much higher currents if the magnetic field's focusing force could be increased. This can be accomplished by adding alternating-gradient or strong-focusing windings around the chamber. Roberson *et al.* (1983) call this the "stellatron" since the windings are similar to stellarator windings. With the strong-focusing modified betatron the limit on circulating current enables experiments to extend into the multi-kiloampere range. Nevertheless the added toroidal field brings in new beam trapping possibilities such as inductive trapping by raising B_ϕ during injection.

5. INJECTION

Space charge limits on the current which can be held in accelerators may be technically difficult to reach. From the single-particle equations of motion the shift away from the injecting structure during acceleration was evaluated. Our very high-energy accelerators follow such single-particle dynamics. Design is usually guided by Liouville's theorem which puts the limit of current on the phase space density achievable within the source or injector. This is invariant throughout acceleration. The actual limit allowed also depends on parameter changes which cause instabilities or resonances and which are influenced by charge density. The limit is not simply the space charge limit of the focusing forces which has just been discussed.

With the earliest betatrons, observations showed that orbit shifts, greater than those predicted by single-particle dynamics, aided particle capture into orbits that allowed acceleration to full energy. Subsequent measurements revealed that injecting a large beam current promoted capture. We can expect some such behavior since the electromagnetic energy associated with a circulating current is removed from the kinetic energy of the beam as the beam fills the chamber. This energy is proportional to the square of the number of turns the injected stream makes and thus some of the particles are trapped on a different instantaneous circle just by their energy change due to the incoming beam. Other beam-produced processes which can act to change untrapped orbits to trapped orbits immediately after injection have to do with the buildup of space charge, the sacrifice of space charge, the resistance of the wall coating, and the generation of radio frequency fields.

Purposeful parameter changes during injection are used very successfully to move particles to orbits which do not lead back to the injector structure—the main obstacle. Almost any field transient at that time will help, provided that the injector sprays an abundance of electrons in the right directions. A so-called orbit contractor is used on some betatrons to subtract a pulse of flux from the central flux at injection time, just as the injected beam current does. The contractor is very helpful in improving capture if a small beam is injected. However, if an intense beam is injected, the orbit contractor does not capture much more. In the latter case the reverse ampere turns of the beam itself have produced the contraction. See Kerst *et al.* (1950) and Kerst (1959).

The experience with betatrons has been to develop capture processes which put only a fraction of the injected particles into good orbits. The industrial betatrons approach the space charge limit at injection by using guns which can provide excess electrons that can be sacrificed. Not much current is needed at their injection energy to reach the space charge limit, and hence simple hot filament electron guns suffice. High current kiloampere range modified betatrons using a rising toroidal field for inductive charging or runaway plasma electrons for injection also trap by processes which sacrifice many electrons (Ishizuka *et al.*, 1985). However, injection technique with cold emission diodes seeks to minimize stray electrons and to put a directed beam on the proper orbit (Golden *et al.*, 1988).

The plasma runaway electron source for reaching high currents had been suggested by Budker (1956). He also pointed out that very strong focusing would result if charge neutralization occurred. Several groups experimented subsequently with this method and results are detailed in the CERN International Conference on High Energy Accelerators proceedings for 1959 and in Reynolds and Skarsgard (1960). At that time Linhart's group at CERN, which built five experimental betatrons, and Reynolds were able to inject and accelerate about 1 A to 2 MeV at a suitable pressure, although a conduction current orders of magnitude larger existed at the start of acceleration. These were what are now called "modified betatrons" in that they had toroidal fields. However, the later experiments of Rostoker and Kapetanakos produced circulating currents in their high-current modified betatrons of several hundred amperes which lasted about 100 ms during acceleration in the MeV range. The beam currents sometimes decayed and in some cases abruptly disappeared. Various instabilities associated with large beam currents or with field inhomogeneities are expected to cause such beam loss. Nevertheless, the plasma source used by Rostoker's group gave much more current than the plasma sources of the earlier similar betatrons. When strong focusing was added to these recent already modified betatrons, then with the plasma source the accelerated beam reached a ring current of 1 kA at 10 MeV (Ishizuka *et al.*, 1988), and with diode injection of directed electrons it reached about 1 kA at 16 MeV (Kapetanakos, 1989 and 1990). Figure 3 shows this betatron with its million volt injector, and vertical and toroidal coils. The alternating gradient strong focusing coils are not shown.

6. THE TARGET, BEAM EXTRACTION

To bring the beam to the target, extra flux is driven through the orbit's center to expand the orbit's radius to the target radius, or a field bump at some azimuth is pulsed on to distort the orbit toward the target. Practical application for radiography requires a target which, for the smallest source size, is inside the vacuum tube. This location benefits from the focusing and damping of orbital oscillations resulting in a beam size of a millimeter or less when high energy is reached. Furthermore, if a target smaller than the beam size is inserted, then electrons which pass above the

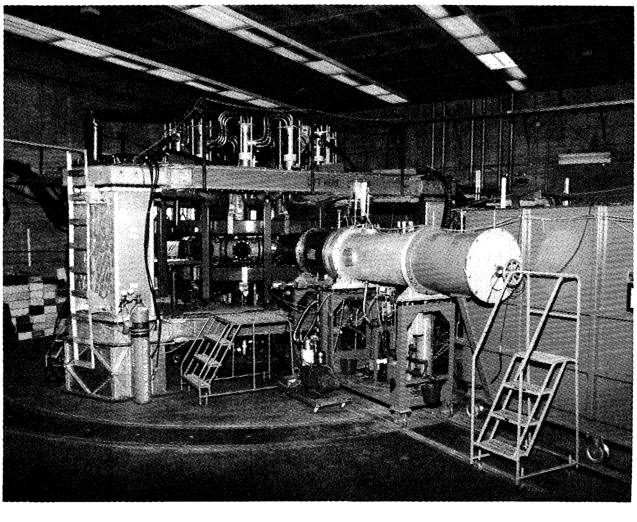


FIG. 3. High-energy injected modified betatron of the U.S. Naval Research Laboratory.

target on one pass will hit the target subsequently since the phase of their axial orbital oscillations should differ on each pass, and the source can thus be no bigger than the target. The radiographic definition possible with such targeting is unmatched making a betatron or synchrotron the choice for high definition work.

With a small target protruding on the injector structure, the obstacles interfering with injection are minimized. It is estimated that when the electron beam grazes the target, it scatters in less than 0.004 cm, and that more than half of the beam would scatter out before producing thick target radiation as indicated in Figs. 4 and 5. At the electron energy which produces the most penetrating x-ray spectrum for iron (20–30 MeV), the efficiency of x-ray production is more than 60% and target heating is not a problem.

Extraction of the electron beam for nuclear experiments or for electron beam therapy has been done by scattering off of the target or by expanding the beam into a magnetic shielding channel. In both cases a fine beam does not emerge. There is always a septum effect which spreads the beam extracted by a channel or "peeler."

There is a resonant process useful for beam extraction from accelerators in general which can be exemplified by the case of a magnetic peeler in a betatron where $n=\frac{3}{4}$ near the extraction radius. By Eq. (16) one-half of a radial oscillation will occur between passages of the peeler location. The magnetic field gradient caused by the peeler perturbation excites a half-integral resonance causing an exponential growth of radial oscillation and rapid steps into the shielded region of the peeler.

Modern high-energy accelerators handle beams far more efficiently than early betatrons did by properly designed pulsed inflectors or extractors which preserve the emittance of the beam and thus the particle density in phase space.

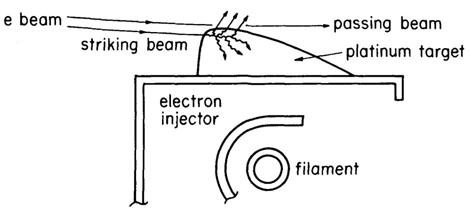

FIG. 4. Multiple and single scattering out of the target tip grazed by a slowly expanding orbit.

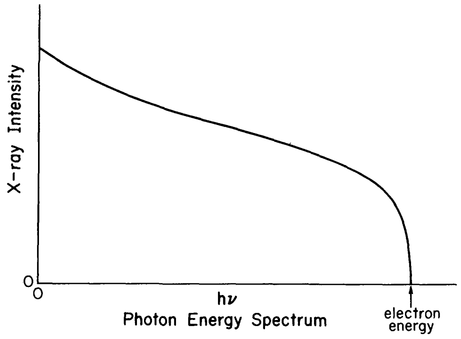

FIG. 5. Thin target photon intensity of bremsstrahlung spectrum.

7. FIELD ERRORS AND THEIR EFFECTS

Magnetic field distortion from the symmetry and uniformity implied by the equations of motion is caused by misplaced conductors, eddy currents in the conductors, or nearby objects in the magnet's fringing field, and phase shifts in alternating current magnets or the equivalent time lag for pulsed fields with some iron in the circuit.

The problem is to establish tolerances on allowed orbit distortion which results from field errors and then to evaluate the limits of structural error which must be met.

When a particle of momentum $p=eB_z r_0$ passes through a distortion δB of length L, it is given a perpendicular impulse $eL\delta B=\delta p$ so its angle of deflection is $\alpha=\delta p/p=(L/r_0)\delta B/B_z$. This deflection leads to a sinusoidal oscillation of amplitude a for which the angle at impulse is $(a/r_0)\times(1-n)^{1/2}=\alpha$, and thus the tolerance condition on length of error L and δB would be

$$(a_{\max})(1-n)^{1/2} \geqslant \delta B\, L/B. \qquad (24)$$

Here $1-n$ refers to radial motion and axial field strengths. For axial motion and radial field errors use n.

Since the particle returns to the field bump after one revolution, it has executed a fraction ω_r/Ω of a betatron radial oscillation at which time it receives a second impulse. The sum of all sine oscillations produced can be evaluated as done in optics for the Cornu spiral. The result can be described as a steady orbit displacement (because the average field strength along the orbit has been changed), a forced oscillation driven by repeated impulses which forms a new closed orbit which makes an angle $\alpha/2$ with the unperturbed closed orbit, and a free oscillation (Kerst, 1959). The aperture available would be decreased by the excursions of the forced oscillation of the distorted equilibrium orbit plus the free oscillation between passages, but the steady displacement can be offset by injecting at a different time. If the available aperture has width D, it will be decreased by the closed orbit excursion,

$$\delta D = \frac{\delta B}{B}\frac{\Omega}{\omega}\frac{L}{2}\tan\left[\frac{\pi}{2}\left(\frac{\omega}{\Omega}-Q\right)\right], \tag{25}$$

where Q is the integer less than the number of orbital oscillations once around the magnet if the case is an accelerator with stronger focusing than a conventional betatron. Note that resonance amplitude increase occurs when ω/Ω is integral. The tolerable δB and L can be determined with Eq. (25).

Sometimes resonances are to be passed due to parameter changes in an accelerator having more than one orbital oscillation per revolution, such as a modified betatron. In this case the tactic to avoid resonance blowup is to pass through the resonances quickly. However, the Cornu spiral for passage through a resonance leaves a residual vector of free oscillation having magnitude

$$A_f \approx \frac{2L}{\pi^{3/2}\left[\frac{d}{dt}\left(\frac{1}{\omega}\right)\right]^{1/2}}\left(\frac{\Omega}{\omega}\right)^2\frac{\delta B}{B}. \tag{26}$$

The speed of passage and the tolerances can be estimated for each resonance passed and the residual vectors can be summed (Kerst, 1983). Random relative phases between the residuals should lead to growth proportional to the square root of the number of resonances passed through, but programmed passages might be arranged to cancel the final resultant vector thereby succeeding in getting through a series of hazardous resonances.

In an ac magnet these errors are not easily seen with a search coil; but with a sliver of high permeability iron within a coil at the time of no saturation, close to zero field or injection time, a sharp voltage peak results. Relative phase shifts between two such peaking strips as a function of position in the field can be determined. From this the length L and the magnitude of δB for Eq. (24) are found.

Zero field strength has also been detected by collimated electron beam vacuum tubes which pass the beam only at the time when there is no field. The detector can be moved about over the pole face to test simultaneity of zero field.

Over an iron pole face a phase shift error can be corrected by a coil on the patch of length L or by a coil wound on the bundle of iron carrying the flux to that position. All that is needed is a small current which is either dc or picked up from a turn on the magnetic core and phase-shifted.

In the case of a pulsed guide field magnet, such as used in a flux-biased betatron, the field starts from its remnant value and rises in unison all over the pole unless some pole region has a different eddy current loss delaying its rise. Since the remnant field is approximately

$$B_{\text{rem}} = B_c(\text{air gap})/(\text{iron length}),$$

where B_c is the coercive force, the iron return paths for flux to all sectors of the pole face should have the same length so that they all start from the same remnant field magnitude, or else patch correcting coils would be needed to bring all regions of the guide field into synchronism.

In practice an accelerator with any beam can use its beam magnitude to help trim fields. For example, a method used on the first Cornell synchrotron is especially instructive. With long-wavelength betatron oscillations it is the first azimuthal harmonic of the field error that disturbs the orbit most. Consequently if correction coils are placed on the poles which produce a field distribution proportional to the sine of the azimuth ϕ, and if another set of coils produces corrections proportional to the cosine of ϕ, then a first harmonic correction can be moved to any angle around the orbit by controlling the magnitudes of the coil currents. The corrections can be used to cancel error effects by optimizing the beam.

8. APPLICATIONS

When electron energies of several million electron volts became available from betatrons, the order of magnitude increase of energy was the right range for nuclear binding research, x-ray radiography in iron, deep tumor therapy, and electron beam therapy.

The lowest binding energies are for beryllium and deuterium in the 2-MeV region, but the threshold for photo-disintegration of most of the elements in the periodic table is from 8 and upward to carbon near 19 MeV. The photoneutron reaction is usually prevalent giving a radioactive product. However, betatrons are not as good as cyclotrons for producing abundant radioactive samples for tracers or for therapy. One of the characteristics of the radiation is that the x-ray spectrum is continuous giving very few photons at the peak electron energy (Fig. 5). Although disintegration thresholds can be determined because the electron energy can be very accurately adjusted, the yield rises slowly with energy due to the few photons at the high-energy end of the spectrum. It requires a great effort to detect the true threshold to the precision achievable in the electron's energy. A pulse of extra flux is supplied within the orbit when the field at the orbit or the flux within the orbit reaches that for a precise energy. This expands the orbit radius at the desired energy and all the electrons are brought to the same target radius, and therefore the same energy, where a spectrum with the same high-energy limit is produced.

A fruitful use of the electron beam extracted through a magnetic channel is for the tagging of photons which subsequently produce a nuclear reaction. This is done by capturing, in an energy analyzer, the electron which has produced the photon that caused an observed coincident event. The photon energy is then the precisely known original energy of the electron minus its analyzed energy. The system is sometimes called a photon monochromator because only a very small section of the photon spectrum is used.

The betatrons for these studies were similar to the 20- to 25-MeV therapy or radiographic machines. It was clear that meson-producing energies could be reached without too much synchrotron radiation loss. 100 MeV was too low for making up the rest mass of the muon or the pion meson although there were some betatrons made and used for nuclear experiments in this range. 300 MeV or more was chosen for the meson-producing accelerators of the period. Several synchrotrons were made and one betatron for 320 MeV was finished in 1948 (Fig. 1). This structure had a separate biased flux core through the ring of field, or guiding, magnets. The ring of field magnets was very similar to the magnets of some synchrotrons, and its coils were connected in parallel with the core flux coil so that the equilibrium radius flux-field relation would be maintained throughout the acceleration pulse. The precision of fulfilling the flux relation, and hence the constancy of the orbit radius, depended on making the coil resistance low enough so that its resistive voltage drop was small compared to the inductive voltage on the coils. The six orbit magnets weighed 60 tons total and the flux magnet weighed 230 tons. The six pulses per second wave form is shown in Fig. 6(b). If flux biasing is used as shown in the figure, a choke coil is needed for keeping the pulse out of the dc generator which supplies the bias winding on the closed iron core. Since the flux magnetic circuit is all iron, very few bias

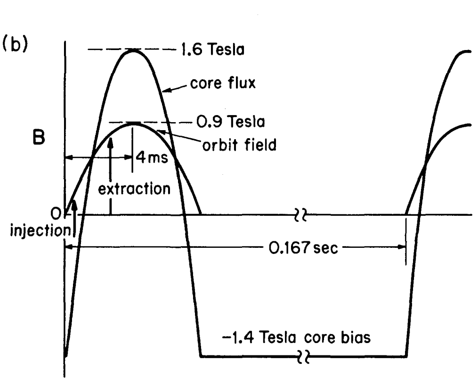

FIG. 6. (a) Accelerating field for sinusoidal commercial operation at 180 Hz. Three-fourths of the cycle is not used. (b) Six pulses per second unidirectional flux-biased wave form of the 320-MeV Illinois betatron.

ampere turns are needed. An alternate choice for biasing is to bias the field coils. In this case the bias current must be much larger.

The electron synchrotrons of the day tended to yield less output than the 320-MeV betatron. They used betatron action at injection with a very small flux core which soon saturated, and with the beam captured, synchrotron acceleration by radio frequency flux took over. In fact the first test of synchrotron acceleration was performed on a small 4.5-MeV betatron made by the University of Illinois group and given to the Woolwich arsenal in Britain where Goward and Barnes (1946) were able to penetrate the resistive wall coating with a radio frequency electric field and to continue the acceleration to 8 MeV.

Much later small FFAG betatrons played a role in the development of synchrotron acceleration manipulations. The purpose was to learn how to stack successively accelerated groups of particles in a ring current of sufficient magnitude for colliding beam experiments (Terwilliger *et al.*, 1957). The small betatron acted as a storage ring with beams started by betatron acceleration and then picked up by the rf cavity and brought to the stacking energy. It was necessary to determine the interference of successive group accelerations on the density of phase space in the stack. Although the stacking process could be modeled on a digital computer, the experiments provided confidence that one could carry out the required physical manipulations for synchrotron stacking and storing of beams.

Another small MURA FFAG betatron of the spiral sector type with all six sectors of the same polarity was applied to the establishment of experience with the wide variety of resonances which an alternating gradient focusing accelerator must avoid, to practice passage through the transition energy when synchrotron acceleration is employed, and to carry out the operation of producing a functioning physical structure. It accelerated only to one-third of the electron rest mass, but that was sufficient to exceed the transition energy (Haxby *et al.*, 1959). High-energy high-intensity sector-focused cyclotrons now use this spiraling pole structure to approach the rest mass energy.

Radiography of metal structures was the first commercial use of betatrons (Fig. 7). In

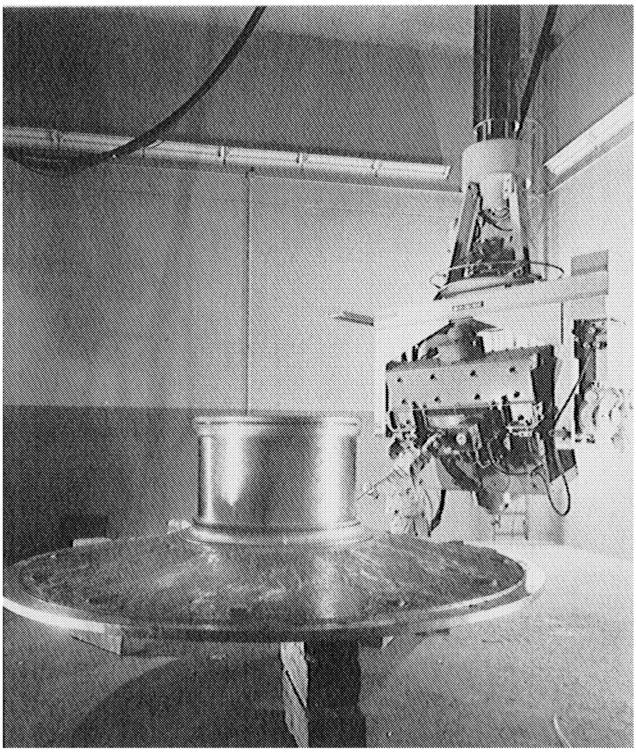

FIG. 7. Industrial radiography betatron. (From ATC Betatron Corp.)

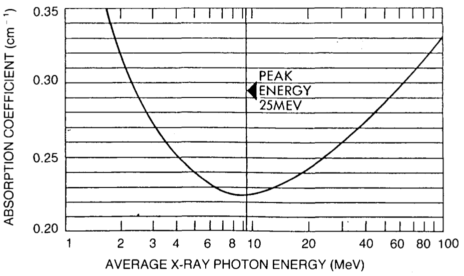

FIG. 8. Absorption coefficient for radiography of iron. (From ATC Betatron Corp.)

1943 they were installed in arsenals and at Los Alamos. The decrease of the Compton-effect absorption coefficient with photon energy is offset by the rise of electron pair production causing the most penetrating radiation to require about 25-MeV electrons (Fig. 8). If necessary fifteen to twenty inches of steel can be x-rayed in fifteen minutes to an hour.

As mentioned earlier the focal spot is vanishingly small because the beam naturally has small size and especially because the target can be a pointlike obstacle. A 0.002-cm platinum tip on the injector serves as a target. The high resolution possible with such a target has made betatrons especially suitable for certain high-resolution radiographic requirements.

Similar betatrons mounted differently became electron beam and x-ray beam deep therapy radiation sources (Fig. 9). Figure 10 shows how the ionization distribution in tissuelike material builds up beneath the surface for x rays from 20-MeV electrons. Since the tolerance of the patient for treatment is often limited by skin reactions at lower voltages, the minimizing of surface dose as well as the deeper penetration at voltages over 20 MeV has brought improved treatment possibilities.

A somewhat heroic effort was made to establish the physical means and techniques to adapt the order of magnitude increased radiation energy which became available in the 1940s for patient use (Quastler *et al.*, 1949). Collimation, dose measurement, beam flattening, aiming, and clearing away stray electrons required new methods of solution at 20 MeV. The requirement for beam flattening results from the target radiation being predominantly within an angle of mc^2/E of the forward direction of the electrons of energy E. Lengthwise cigar-shaped absorbers are needed to reduce the central intensity thereby flattening the dose distribution in the patient. Dose measurements were aided by passage of the applied radiation directly through foils which became radioactive and integrated the dose to the patient. Ultimately betatrons were used to develop a calorimetric method which made it possible to base radiation dose at these energies on the calorie to which intermediate standards could be referred.

Treatment by the accelerated particles themselves has some advantages, and therapeutic betatrons are arranged to provide both an x-ray and an electron beam. The ionization distribution along the path of an electron beam in tissue-like material is shown in Fig. 10. At relativistic energies electrons in tissue lose about 2 MeV/cm so a 22-MeV beam as

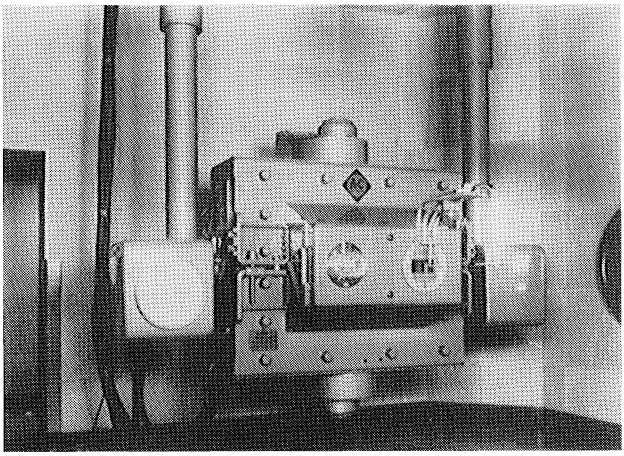

FIG. 9. Medical betatron used for deep therapy at 25 MeV.

shown in the figure would go as deep as 11 cm. It is evident that scattering has deflected many electrons before that depth. The finite range is advantageous because deeper tissue is not damaged. However, the multiple scattering and radiation straggling is much greater for electrons than it is for heavier particles, for example, for protons, so that a more sharply defined ionization distribution is possible with protons. It is necessary to use protons having an order of magnitude more energy to penetrate sufficiently.

9. CHRONOLOGICAL DEVELOPMENTS

The first description of an accelerator using magnetic induction seems to be Slepian's patent dated 1922. He described an accelerating flux core surrounded by permanent magnets for guiding electrons emitted from a filament. The bending field was to be greater at larger radii to accommodate the highest-energy electrons in the chamber. This is the wrong way for the gradient to focus axially, but it is interesting that direct current FFAG magnets can solve the focusing problem and a functioning betatron was made this way by Jones *et al.* (1956).

Experimenters who made attempts to accelerate electrons later in the 1920s are Breit and Tuve, Wideröe, and Walton. The full transient theory of single particle motion was not determined until much later (Kerst and Serber, 1941). This led to the design of an injection method capable of trapping injected particles. Quite a few other contributions to theory and experiments are summarized in a review by Kerst (1946).

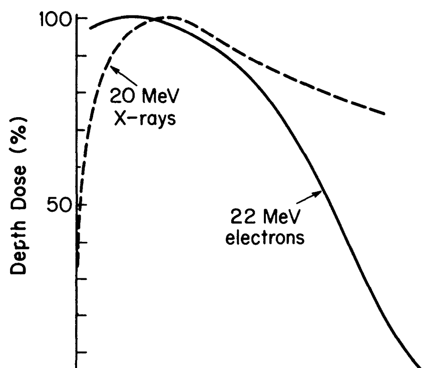

FIG. 10. Buildup of ionization below the skin for 22-MeV x rays, and range limitation of 22-MeV electrons inside the body. Depth dose curves.

The earliest commercial model was that of the Allis Chalmers company shown in Fig. 7 in its industrial support and in Fig. 9 as a therapeutic model. These operated at 25 MeV giving about 160 R/min at 1 m distance. Swiss Brown Boveri produced a 35-MeV unit developed by Wideröe and it was widely used for therapy. Siemens of Germany and General Electric of U.S.A. and the Japanese industries have also provided betatrons for therapy and radiography. Budker in the Soviet Union produced betatrons for commerce. The linear electron accelerator has replaced most of the betatrons, but there are still applications using the fine focal spot size that a betatron provides.

Interest in high current betatrons stems mainly from Budker (1956) with the series of experiments in the years immediately following. These efforts involved plasma injection which, as we have seen, awaited Rostoker's 1985 experiments for successful high current generation. The high currents in vacuum without the possibility of problems due to plasma were reached soon after at the U.S. Naval Research Laboratory by Kapetanakos's group. Almost all of these experiments used an added toroidal field, but the later work was greatly aided by the application of strong focusing or alternating gradient focusing.

In the interim in the Soviet Union Pavlevskii *et al.* (1977) did injection and capture experiments producing 100-A currents and brief acceleration sufficient to guarantee a good beam.

GLOSSARY

Bounce: The cyclic drift of the centroid of a beam traveling in the direction of a toroidal magnetic field. The drift is due to the forces perpendicular to this field. Its velocity is $\mathbf{V} = -\mathbf{F} \times \mathbf{B}/eB^2$.

CERN: European Organization for Nuclear Research.

Depth Dose: The ion density produced by x rays or charged particles penetrating tissue as a function of depth below the surface. It is usually expressed as percentage of surface dose.

Drift: See Bounce.

FFAG: Fixed field alternating gradient accelerator.

Injector: The source of particles sent into orbit for acceleration. An ion or electron gun or a boosting accelerator.

MURA: Midwestern Universities Research Association. A corporation of institutions for the advancement of high-energy facilities.

Peeler: A device to extract particles from the magnetic field in which they are in orbit—for example, a magnetic shield which prevents an entering particle from experiencing the accelerator's bending field.

Stacking: The process of building a large current in orbit by bringing successive small beams to adjacent orbits of similar energy. Phase space density invariance of injected beams determines the current possible in the final available phase space.

23.1
Introduction

The field to be treated in this article is wide and sometimes controversial. Radiation types encompass a large range of energies, and the interaction mechanisms differ considerably. Radiation biology *sensu strictu* deals with the effects of ionizing and ultraviolet (UV) radiations, and it is in this field where most information is available. Consequently, the article concentrates particularly on this aspect, also because the approaches used for the other radiation types were largely adopted from radiobiology.

The treatment follows the "classical way" from physics via chemistry to biology. The time course of events spans more than 30 orders of magnitude (see Figure 23.1), which illustrates the difficulty involved in solving the the task. Section 23.9.2 gives a few examples of radiation application, and protection principles are summarized in Section 23.9.2. Completeness is not intended and is impossible to achieve. Only fundamental problems are described, in a way that they can be understood also by the nonspecialist reader. For further reading, there are a few more general books covering more or less the whole field, for example Hall and Giaccia (2005) and Kiefer (1990). Reference reviews for special areas are given in each chapter.

23.2
Radiation Types and Sources

This section is restricted to those sources that present a possible biological hazard. Technical details have to be omitted here because of space limitations.

Under "optical radiations" are summarized those kinds that can be analyzed by means of optical instruments like prisms, gratings, and lenses. They are subdivided in terms of wavelength as follows:

1. UV: ≈100–380 nm
2. Visible (VIS): 380–800 nm
3. Infrared (IR): 800 nm to ≈100 μm

The UV region is often further characterized as

1. UV-A: 315–380 nm
2. UV-B: 280–315 nm
3. UV-C: 200–280 nm
4. Vacuum UV: <200 nm

Similar classifications have been suggested for the IR region:

The most important natural source of optical radiation is the Sun, whose emission spectrum closely resembles that of a blackbody with a temperature of about 6000 K. Its radiation is attenuated by the atmosphere. In the short-wavelength part, ozone (O_3) absorption causes not only a reduction in fluence but also a shift to longer wavelengths, which is very important for the maintenance of life since the damaging part of the spectrum is largely eliminated on the surface of the Earth. Water and carbon dioxide are mainly responsible for the absorption in the IR region. The energy fluence rate outside the atmosphere (commonly called the *solar constant*) is 1394 $W\,m^{-2}$, which is reduced to about 1/10th at sea level depending on geographical latitude. Technical UV sources include gas-discharge lamps (mercury, hydrogen, and noble-gas lamps), incandescent sources, and fluorescent lamps. Examples of emission spectra can be found in the World Health Organization report (WHO, 1982). Lasers present an exceptional case, also with regard to possible hazards (see Section 23.9.2.2).

Radiofrequency (RF) and microwave (MW) radiations are characterized by the electric and magnetic field strengths at the place of interactions. Ideally, the two vectors are in phase and perpendicular to each other. In this case, the "power intensity" is given by their product, usually expressed in watts per square meters. One has to note, however, that the simple situation is only found at some distance from the emitting source and that great distortions may occur upon interaction with matter. High-power sources are somewhat arbitrarily defined as those that can produce a mainbeam power density of at least 1 $W\,m^{-2}$ at a distance of 100 m. They include broadcast transmitters, tracking and acquisition radar, and communication systems such as satellite communications earth terminals. Low-power sources (<1 W m^{-2} at 100 m distance) include traffic radar and MW relay systems as well as MW ovens. Particularly, the last example may be of public concern because of its ubiquitous use in many countries. Although these appliances are enclosed and leakage is not intended, it cannot always be avoided. With an assumed level of 50 W m^{-2} at a distance of 50 mm, the power density will fall to less than 15 W m^{-2} at 30 cm and to about 0.1 W m^{-2} at 1 m. Traffic radar leads to an exposure of 10 mW m^{-2} at distances of 10 m.

Mobile communication by cellular phones has increased tremendously in recent years. There are two frequency bands used, both in the MW range, namely around 900 and 1800 MHz. Typical emissions by base stations lie in the order of 10–50 W but the field strengths decrease rapidly with distance. The signals are received and amplified by the phone so that the main source of exposure is from the handheld mobile phone with values up to 2 W near the head of the user. The emission powers of TV transmitters are considerably higher than that of base stations for mobile communication.

Natural ionizing radiation originates either from outer space or from terrestrial sources. Space radiation consists essentially of protons, helium ions, and a few heavier nuclei of which iron plays the most important role. Primary cosmic radiation does not reach the surface of the Earth. The particles are, depending on their energy, deflected by the magnetic field, or they react with the constituents of the atmosphere to create cosmogenic radionuclides and other secondary products, mainly mesons, neutrons, and electrons. The charged components are captured in the two Van Allen belts at heights of about 2.8 (mainly electrons) and up to 12 Earth radii (electrons and protons). Since the magnetic field is not exactly collinear with the Earth's axis and the dipole field is distorted, the height of the radiation belts varies with geographical locations with the lowest altitude in the South Atlantic ("South Atlantic Anomaly"). The intensity of cosmic rays is also modulated by solar activity, being highest at solar minimum and vice versa. The most important cosmogenic radionuclides are ^{14}C, ^{7}Be, ^{22}Na, and ^{3}H. Terrestrial radiation sources are the so-called primordial radionuclides, which survived from the formation of our planet because of their long half-life, and their daughter products. The most important are ^{40}K, ^{87}Rb, ^{238}U, ^{235}U, and ^{232}Th. The last three are starting products of decay series whose members contribute also to natural radiation. The more relevant among them are ^{226}Ra and ^{222}Rn. Particularly, the latter and its immediate daughter products are now considered to be the most important part of the natural radiation burden.

The cosmic component varies with altitude while the terrestrial contribution depends especially on soil composition. Some areas in India (Kerala coast), Brazil (monazite sands), and China display radiation levels that are at least one order of magnitude higher than the average. The relative contribution from natural sources to human radiation burden is discussed in Section 23.9.2.

Technical sources of ionizing radiations include nuclear energy production plants, medical applications in diagnosis and therapy, the use of γ irradiation, mainly for sterilization purposes, and of X-rays for quality control in industry.

The unit of activity is the Becquerel (Bq):

$$1\text{Bq} = 1\ \text{s}^{-1} \tag{1}$$

The older unit – no longer to be used in official or legal documents – was the Curie (Ci), originally based on the activity of 1 g of ^{226}Ra and later defined by

$$1\text{Ci} = 3.7 \times 10^{10}\ \text{Bq} \tag{2}$$

For radioactive gases like ^{222}Rn (radon) and ^{220}Rn (thoron), "working levels" (WL) are still widely used as units of activity concentrations, although they also are not part of the now-accepted international system. Without further derivation, the relations are given here, which are different for the two nuclides mentioned:

$$1\text{WL}(^{222}\text{Rn}) = 100\text{pCi}\,\text{l}^{-1} = 3.7\ \text{Bq}\,\text{l}^{-1} \tag{3}$$

and

$$\begin{aligned}1\text{WL}(^{220}\text{Rn}) &= 7.5\ \text{pCi}\,\text{l}^{-1}\\ &= 0.2775\ \text{Bq}\,\text{l}^{-1}\end{aligned} \tag{4}$$

23.3
Interaction with Biosystems at the Physical Level

23.3.1
Ionizing Radiation

23.3.1.1 Electromagnetic Radiation

When electromagnetic radiation traverses matter it is attenuated in an exponential manner:

$$I/I_0 = \exp(-\mu x) \tag{5}$$

where I_0 is the intensity at the entrance, I is the intensity after passing through a layer of thickness x, and μ is the attenuation coefficient. Equation (5) applies only to monochromatic radiation and homogeneous material; in the case of composite matter and radiation it has to be replaced by appropriate integral expressions. It is customary to use the mass attenuation coefficient μ/ρ instead of μ, with ρ being the density of the absorber. Attenuation is brought about by scattering (without energy loss) and energy transfer to the exposed medium. With regard to radiation action, the distinction must be made between "energy transferred" and "energy (locally) absorbed," which are taken into account by introducing the energy transfer coefficient μ_k and the energy absorption coefficient μ_{en}, respectively. The first signifies the complete energy transferred to secondary particles in the form of kinetic energy by the initial ionization event, while the second includes only the fraction that is locally absorbed.

All photon interactions (photoabsorption, Compton scattering, and pair formation) lead to the formation of electrons (and positrons that play, however, a less important role since they combine readily after short distances). They are responsible for the actual energy deposition in the medium; the initial processes contribute directly only to a very small extent to the total number of ionizations.

23.3.1.2 Particle Radiation

Ions The main interaction process in terms of energy deposition in exposed matter is the collision with atomic electrons. The energy loss per distance traveled is given by the Bethe–Bloch formula. Energy loss is commonly given as "mass stopping power," which is related – but not equal – to linear energy transfer (LET) (Section 23.5.4). The ICRU has compiled data for protons and heavier ions (ICRU, 2000, 2005). For ions with the same velocity, the energy loss may be calculated from proton data with the effective charge as scaling parameter.

Electrons Electrons play an essential role in the ultimate deposition of energy with all kinds of ionizing radiation since they are always formed in the ionization process. There are three types of interactions that are important in the present context: collisions with shell electrons, bremsstrahlung production, and emission of Cherenkov radiation. In terms of energy deposition, the first process is the most relevant. Bremsstrahlung production becomes important only at higher energies. It must be taken into account for dose calculations since the generated electromagnetic radiation may transport a great fraction of the originally transferred energy out of the exposed body (see also the discussion of "dose" and "kinetic energy released per mass" (KERMA) in Section 23.5). Cherenkov radiation is generated if the speed of a charged particle passing through matter exceeds that of light in the medium. This criterion sets a lower limit below which this process does not occur (about 500 keV for water). In terms of energy loss, it is usually not important, but it may lead to the generation of UV light, which may then be responsible for a certain biological radiation damage.

Neutrons The most important interaction with regard to biological damage by neutrons is the collision with atomic nuclei in the exposed medium. As would be expected from classical collision dynamics, protons are the most relevant constituents here; other nuclei contribute significantly to energy transfer only with higher neutron energies. The actual deposition in the medium is via these charged secondary particles that are displaced by the collision, a situation similar to the that of electrons with electromagnetic radiation. Nuclear processes initiated by neutron interactions do not contribute to a large extent in common energy ranges.

Mesons π^- mesons have, for some time, been used in radiation therapy because of their favorable depth dose distribution but this technique is no longer applied and been superseded by proton and carbon ion therapy. Mesons are, however, an important part of secondary cosmic radiation. The main interaction of π^- mesons occurs with atomic nuclei in the exposed biological material, resulting in highly excited states. The energy gained is deactivated by nuclear spallation, resulting in a number of charged fragments that deposit their energy over short distances with high ionization density. Interactions with oxygen and nitrogen play the most important role in biological matter.

23.3.2
Optical Radiation

Optical radiation is absorbed selectively by certain compounds, called *chromophores*, in the exposed medium. Energy deposition from optical radiation hence depends entirely on the absorption properties of the exposed medium.

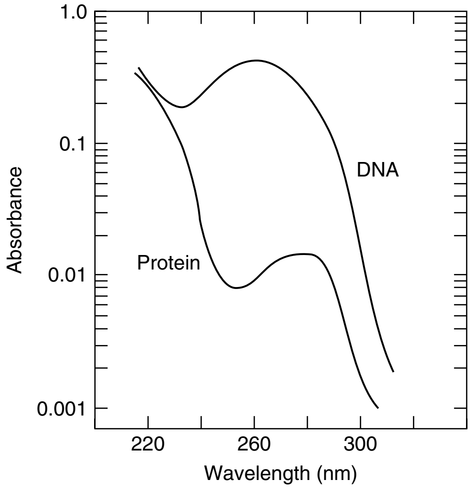

Fig. 23.2 Absorption spectra of DNA and proteins (bovine serum albumin) (after Harm, 1980).

Spectra for materials of biological interest are given in Figure 23.2.

With intense laser pulses two quantum excitations may take place, which can lead to photoionization. Whether they are biologically relevant is not yet clear. Excited molecules – particularly in the triplet state – are the starting points for photochemical reactions (see Section 23.6). If the absorption takes place in short times and is locally concentrated as with lasers, heat effects become the most prominent type of damage.

IR radiation causes excitation of vibrational and rotational molecular states, which is dissipated by heat production. This kind of damage, which is less localized and specific than that caused by UV and visible radiation, may then act as starting point of further tissue destruction.

23.3.3
Radio Frequency and Microwaves

RF and MW interact with matter by inducing electric and magnetic fields. A perfect dipole does not remove any energy, and the impinging radiation is not attenuated. In a medium of finite conductivity – as is all biological material – charge motion in the form of free ions (conductive loss) and molecular rotations (dielectric loss) is caused. The energy absorbed is finally dissipated as heat, leading to local or global temperature increase. The relative contributions depend on the electric properties of the medium, which in turn are frequency dependent. In principle, it should be possible to calculate the energy absorption for any biological object, but the practical restrictions are such that only very simple geometries can be adequately treated. Consequently, one has to rely on experimental determinations.

23.4
Deposition of Energy

23.4.1
Ionizing Radiation

As pointed out in the previous section, energy deposition by ionizing radiations is exclusively due to charged particles created in the exposed medium via the primary interaction processes. In most cases these are electrons, but with neutrons incident, protons and even other nuclei may also contribute. In the case of charged-particle irradiation, energy is deposited by their primary interactions and those of the secondary species. Both undergo further interactions by which the initial energy distribution is modified. This process is called *slowing down.* The resultant spectra may be calculated by Monte Carlo simulations taking into account the cross-sections of all relevant process for the medium under investigation. After a certain depth, a steady state is reached, called *secondary-particle equilibrium,* which is characterized as a situation where in a given mass element each particle leaving it is replaced by an incoming one of exactly the same kind and energy. Secondary-particle equilibrium can never be attained close to interfaces. The theory of slowing down is well established for electrons in water (see, e.g. Kiefer, 1990 for further references); more recently, the computations were also extended to materials of biological interest.

The biological activity of different kinds of ionizing radiations depends on the spatial pattern of energy deposition. A macroscopic parameter that is used to describe it is the LET, which is defined as the energy deposited *locally* per path length traveled. LET applies to the *charged* components only, since they are almost exclusively responsible for energy deposition. The term *locally* requires some specification. It depends obviously on the size of the site under consideration. If it is larger than the range of the most energetic particle, all interactions are included and LET becomes numerically equal to the stopping power, which gives the *energy loss* per unit distance of the incoming particle. It has become customary to use energy restrictions (in electronvolts) for the LET, indicated by suffixes. Thus, LET_{100} means that only those energy deposits are included where the energy of the electrons formed does not exceed 100 eV, corresponding to a range of about 5 nm in water.

Since energy deposition is always due to the interaction of a whole spectrum of primary and secondary particles (even in the case of monoenergetic ions) there is always a *distribution* of LETs. They may be characterized by certain average values, the simplest one being the "track" or "number average" $\overline{L}_T$, defined as the expectation value of the distribution $f(L)\,dL$:

$$\overline{L}_T = \int Lf(L)\,dL \tag{6}$$

Here, each event is counted with equal weight. If one is interested in the relative contribution to the total energy deposition, the "dose" or "energy average" $\overline{L}_D$ is used:

$$\overline{L}_D = \frac{\int L^2 f(L)\,dL}{L_T} \tag{7}$$

where each event is weighted by its energy deposition. The denominator is just a normalization factor. The two averages are only equal if the variance of the distribution vanishes.

LET is usually measured in kiloelectronvolt per micrometer, but megaelectronvolt square centimeters per gram is also widely used. Examples of LET distributions are shown in Figure 23.3.

The most important quantity to describe energy deposition by ionizing

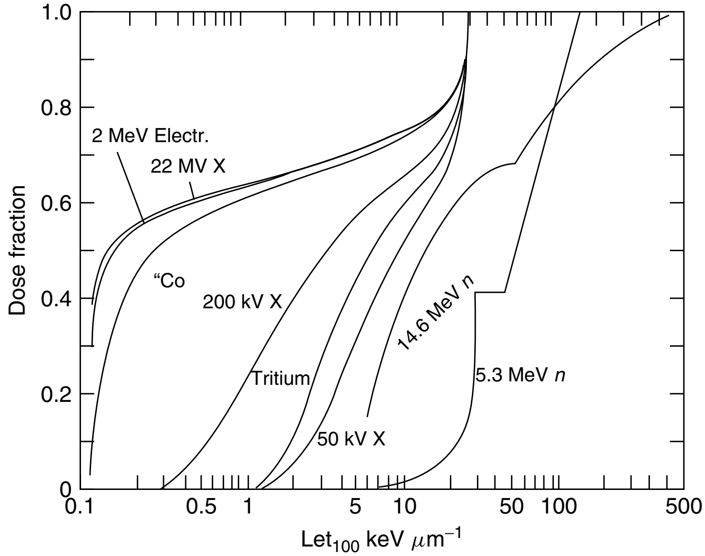

Fig. 23.3 LET distributions of several radiation types in water (after ICRU, 1970).

radiations is “dose,” which is defined as absorbed energy per mass. In sites of microscopic dimensions, which are relevant for biological targets, however, it loses its well-defined meaning because of the statistical nature of interactions (“microdosimetry” Rossi and Zaider, 1996). To account for this, another quantity has been introduced termed as *specific energy* z, which is the microscopical counterpart of dose. It is a *stochastic* quantity that is characterized by a distribution function $f(z)\ dz$ whose actual form depends on, among other things, the size of the mass element, the kind of particle, the particle's energy, and the medium exposed. Similarly, as with LET (see above), certain averages may be used for shorthand characterization, namely the track average or frequency mean $\bar{z}_F$:

$$\bar{z}_F = \int z f(z) dz \tag{8}$$

and the energy average or dose mean $\bar{z}_D$:

$$\bar{z}_D = \frac{1}{\bar{z}_F} \int z^2 f(z) dz \tag{9}$$

Generally, both the distribution and the expectation values depend on dose. The microdosimetric approach just introduced allows a clear and meaningful definition of this quantity: *Dose is the expectation value of specific energy* and hence equal to $\bar{z}_F$. Macroscopically speaking, one can also say that it is the mean energy absorbed per mass element; this used to be the classical definition.

The microdosimetric counterpart to LET is “lineal energy” y, defined as the energy deposited *by single traversals* in the given site (assumed to be spherical) divided by the average path length.

Mainly for reasons of practical measurement, another “dose” quantity had formerly been widely used, namely “charge liberated per unit mass,” which is now called *exposure*. By convention, only charged particles of one sign are counted, and the medium in which it is determined has to be air. Exposure is thus not really a dose but rather a characterization of the radiation field at a given position.

The international unit for dose is joules per kilogram with the special name "gray" (Gy). An older, no longer sanctioned, unit is the radians:

$$1\text{Gy} = 100\text{ rad} \tag{10}$$

The new unit for exposure is coloumb per kilogram; no special name has been suggested. The old one was the roentgen (R):

$$1\text{R} = 2.58 \times 10^{-4}\text{C}^{-1}\text{kg} \tag{11}$$

For a given type of radiation and a specified medium, conversion factors between dose and exposure can be given (Table 23.1).

Dose D, particle fluence ϕ, and track average LET L_T are related in a simple way:

$$D = L_T\phi/\rho \tag{12}$$

where ρ is the density of the medium.

The quantity "dose" as defined above refers to the energy actually absorbed in the medium and does not necessarily equal the energy lost by the interacting particle or quantum. The secondary particles produced by the primary collisions may gain sufficient kinetic energy to travel considerable distances before they are finally stopped. This situation is taken into account by another quantity called *KERMA*, which has the same dimensions as dose but relates to the energy loss of the incoming species. For photons, the difference between KERMA and dose is reflected in the coefficients μ_K and μ_{en}, respectively. KERMA and dose are only equal under the conditions of secondary-particle equilibrium *and* in the absence of bremsstrahlung losses. It is clear from this that they are always different at interfaces.

In an exposed body, the dose varies with penetration depth. With photon radiations, energy is deposited by electrons with ranges depending on the quantum energy. The dose maximum is thus shifted toward larger depth with increasing energy (Figure 23.4). This behavior plays an important role in the radiation therapy of deep-seated tumors (see Section 23.8.3.2)

Tab. 23.1 Relation between dose and exposure for various substances and photon energies (after ICRU, 1979).

Photon energy [keV]	Water [Gy/(C kg^{-1})]	Bone [Gy/(C kg^{-1})]	Muscle [Gy/(C kg^{-1})]
10	35.0	140	34
50	34.7	134	34.3
100	36.9	56.1	36.5
200	37.4	37.9	37.0
400	37.5	36.1	37.0
600	37.5	35.9	37.0
1000	37.5	35.8	37.0
2000	37.5	35.6	37.0

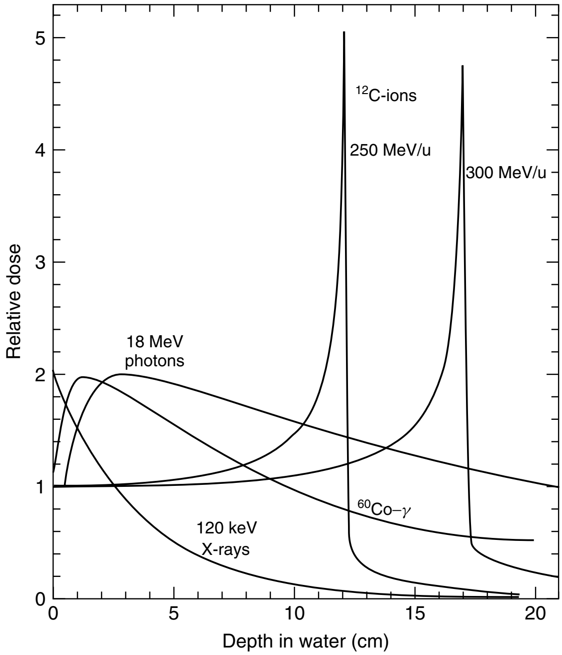

Fig. 23.4 Depth dose distributions for various types of ionizing radiations (GSI Darmstadt, with permission).

Depth dose distributions of protons and heavier nuclei are characterized by very sharp maxima ("Bragg peak"), which is one of the reasons for their increasing application in radiation therapy.

23.4.2
UV and Visible Radiation

Energy deposition by UV and visible radiation depends on the absorption properties of the molecular and atomic constituents of the exposed medium. Photobiological effects can only be caused if there is an overlap between the source emission and the tissue absorption spectrum for the wavelength range considered. This constitutes, however, only a *necessary* but not a sufficient condition for photobiological actions. Only if essential structures are altered via photochemical reactions will biological effects be seen. They may be caused by a direct destruction of the absorbing species or via secondary processes where light absorption creates intermediate reactive species, which in turn then may damage other constituents. This second case is called a *photosensitized reaction*. An important example is the formation of singlet oxygen, which is the mediator of the "photodynamical action." Primary chromophores may be identified by measuring an "action spectrum" (see Section 23.9).

Because of the dependence of energy deposition on the specific absorbing properties, "dose" as used for ionizing radiation cannot be defined in a reasonable way for UV and visible light although the term is still widely but wrongly used. The quantity normally applied is "energy fluence" (impinging energy per unit area, measured in joules per square meter), often called *dose*. In some cases, particularly in photochemistry, the "quantum fluence" (number of photons per unit area, unit m^{-2}) is also used. In some instances, particularly in conjunction with radiation protection, energy fluences are weighted by applying "sensitivity function" (see Section 23.9.2.2 for details). As the units used are identical (J/m^2) there is a definite danger of misinterpretation, and careful cross-checking is advisable.

23.4.3
Infrared

Energy deposition by IR is determined by the absorption properties of the exposed tissue, with local heating being the main result. It is not clear at present whether nonthermal effects on molecules and cells play a significant role, although they cannot be generally excluded.

23.4.4
Radio Frequency and Microwaves

Energy is deposited by the induction of currents where freely movable charge carriers are available and by the induction of molecular rotations.

The absorption of RF and MW radiation is related to the complex permittivity ε^* of the material to be considered:

$$\varepsilon^* = \varepsilon'(\nu) + j\varepsilon''(\nu) \tag{13}$$

The power absorbed, P, is given by

$$P = 2\pi\nu\varepsilon_0\varepsilon'' E^2 V \tag{14}$$

Here $\varepsilon'(\nu)$ and $\varepsilon''(\nu)$ are the real and the imaginary part of the complex permittivity, respectively, both being dependent on frequency ν, ε_0 is the electric field constant, E the electric field strength at the point of interaction, V the volume, and i the imaginary unit ($\sqrt{-1}$).

The coefficients have been measured for a number of materials of biological interest in the frequency range from 10 Hz to 20 GHz (Gabriel, Gabriel, and Corthout, 1996a; Gabriel, Lau, and Gabriel, 1996b, 1996c)

The quantity used to describe the amount of interaction is "specific absorption rate" (SAR), measured in watts per kilogram.

Depending on the geometrical dimensions of the exposed body, resonance phenomena must be taken into account. Although the energy absorbed will ultimately be dissipated in the form of heat, leading to local or global temperature increases, this is not necessarily the only cause of biological effects. Changes in charge distribution at membranes and possible resonances at the molecular level also have to be taken into account, at least theoretically. It is, however, not at all clear whether they play a role at subthermal powers.

23.5
Effects on Molecules of Biological Importance and Cell Organelles

Biological systems contain a plethora of molecules at different levels of complexity. All of them may be altered by radiation action. It is obviously necessary to make a choice here, which is guided either by the relative abundance of a particular species or by its biological importance. The discussion is, therefore, restricted to water, as the most abundant molecule type, and deoxyribonucleic acid (DNA), as the carrier of genetic information. This selection is, of course, somewhat arbitrary. Similar deliberations may be made with regard to subcellular structures. Chromosomal aberrations are dealt with because of their fundamental and also practical importance, as are membranes because they are often implicated as targets for radiation action and also since they constitute the interface between the biological system and its environment.

For the quantitative description of radiation-induced molecular alterations in photochemistry the quantum yield Q has been introduced, which is defined as the mean number of altered molecules per quantum absorbed. Its radiation-chemical counterpart is the G value, originally used as the number of altered entities (molecules or atoms) produced per 100 eV absorbed energy. With the introduction of the new SI units this has been changed to molar concentration of species produced per unit dose. The numerical relationship is given by the following expression:

$$G/(100\ \mathrm{eV})^{-1} = 9.64 \times 10^6 \frac{c/(\mathrm{mol\ dm^{-3}})}{(D/Gy)^{\rho/(\mathrm{kg\ dm^{-3}})}} \qquad (15)$$

where c is the molar concentration and ρ the density of the medium.

23.5.1
Water

Biological systems contain up to 80% water, so it must be considered as a major primary target for interaction with radiation. Its interaction with optical radiation depends on the absorption spectrum, which shows complete transparency between 200 and 800 nm. No effects are thus to be expected in this region. In the far UV, excitations may lead to radical formation, as with ionizing radiation (see below), while IR absorption causes heat production. The photochemistry of water does not play an important role under normal circumstances. Radiation-chemical processes, on the other hand, are considered to be responsible for a great part of biological damage at the cellular level, at least with sparsely ionizing radiation. The initial products formed are H and OH radicals and electrons. The latter interact electrostatically with surrounding water dipoles to form a transient hydration shell, which is indicated by the suffix "aq." Because of interradical reactions, the initial yields are always higher than the final ones, even in ultrapure water.

The hydrated electron possesses interesting properties. Because of the shielding by the hydration shell, its reaction probability with solutes is smaller than that for the other species; this results in a comparatively long lifetime (about 600 μs in pure water). The positive potential created by the surrounding water dipoles leads to a quantization of the possible energy states and hence to light absorption. The specific properties described have made the hydrated electron a key product in radiation chemistry.

The primary radicals react with each other to form the molecular products, molecular hydrogen (H_2) and hydrogen peroxide (H_2O_2). Oxygen, if present, is an important reaction partner that must be taken into account when discussing the radiobiological oxygen effect (Section 23.7). The probability of interradical reactions depends, of course, on the proximity of their initial formation and is hence increased in the tracks of high-LET radiations. The biological importance of radiation-induced water radicals lies in the fact that they react readily with solutes in their vicinity and are thus able to damage DNA or other critical biomolecules. This *indirect radiation effect* plays a significant role in dilute solutions and even in cells, where its existence can be demonstrated by the protective action of radical scavengers (see Section 23.6.2).

23.5.2
Photochemistry and Radiation Chemistry of DNA

DNA is the carrier of cellular genetic information. This justifies the special interest in radiation-induced alterations of this molecule, which may ultimately lead to loss of viability, induction of mutations, and initiation of cancer.

The absorption spectrum of DNA is shown in Figure 23.2, where it is seen that in the far UV range the region around 260 nm is expected to be most relevant for damage production. The most important products are pyrimidine dimers, pyrimidine adducts, single-strand breaks (SSBs), and crosslinks with adjacent proteins. Dimers are most important in microorganisms; their role in higher systems is less clear. They are the unique substrates for photoreactivation (see Section 23.6.2.3) and are also subject to other repair processes. Pyrimidine adducts have recently been implied to be the starting points for mutations, but this requires further substantiation. The other types play a lesser role in the far UV but may become more relevant with longer wavelengths. SSBs are produced only with low yield directly upon UV irradiation but are introduced during repair processes (Kiefer, 2007)

The radiation chemistry of DNA is less transparent than its photochemistry. Very many effects have been identified; some of the more relevant ones are SSBs, double-strand breaks (DSBs), base damage, base loss, denatured zones, intramolecular cross-links, and DNA–protein cross-links. Most of them have only been identified in aqueous solutions; data for cellular systems are scarce. DSBs have received the greatest attention, and it has been claimed that they are the main causes of cell inactivation. In dilute DNA solutions they are produced with a linear-quadratic dependence on dose, intracellularly in strict proportionality. (This statement has recently been called into question; clarification must await further experimentation.) DSB may be repaired (see Section 23.6.2.3) although not necessarily correctly. Presumably there is no single damage type that can be held responsible for the biological action of ionizing radiation. DNA damage may also be produced indirectly via the reaction of water radicals (see above) where OH seems to be the most important species (von Sonntag, 2007).

The dependence on LET has only been studied in some detail for strand breaks. It is seen that the yield of SSB decreases while that for DSB increases. This finding is important since it may serve to explain the higher biological effectivity of high-LET radiations. It is also taken as an indirect proof of the relevance of DSB.

23.5.3
Chromosomal Aberrations

The genetic material of higher cells is organized in supramolecular structures consisting of DNA and proteins, which are called *chromosomes*. They may be seen visually during the division process in the microscopic picture after appropriate staining. Radiation absorption can cause aberrations, broadly classified into two categories: numerical and structural. In the first class the number of chromosomes, which is a constant for a given species (e.g. 46 in man), is changed. Loss of a chromosome is normally lethal; a supernumerary one is often related to severe genetic diseases, the best known being Down’s syndrome (commonly called “mongolism”), which is caused by an extra chromosome 21 (“trisomy 21”). The role of radiation in its etiology is not quite clear. Generally it appears that radiation is a weak agent for the production of numerical chromosome aberrations.

Structural aberrations are more important. Some of them are diagrammatically depicted in Figure 23.5. They may be formed as a direct consequence of one initial event (“break”) but in most cases they are caused by the interaction of two primary lesions. Not all of them are directly visible – for example, if only the position of a piece is changed as in inversions or translocations. This does not, however, mean that they are harmless; quite to the contrary, it is now well established that translocations are connected with a number of cancer types. Practically, *dicentrics (dics)* play the most important role. They are caused by the interaction of two “breaks” in separate chromosomes and subsequent rejoining, leading to a chromosome with two centromeres. They are lethal alterations since they cannot be disentangled

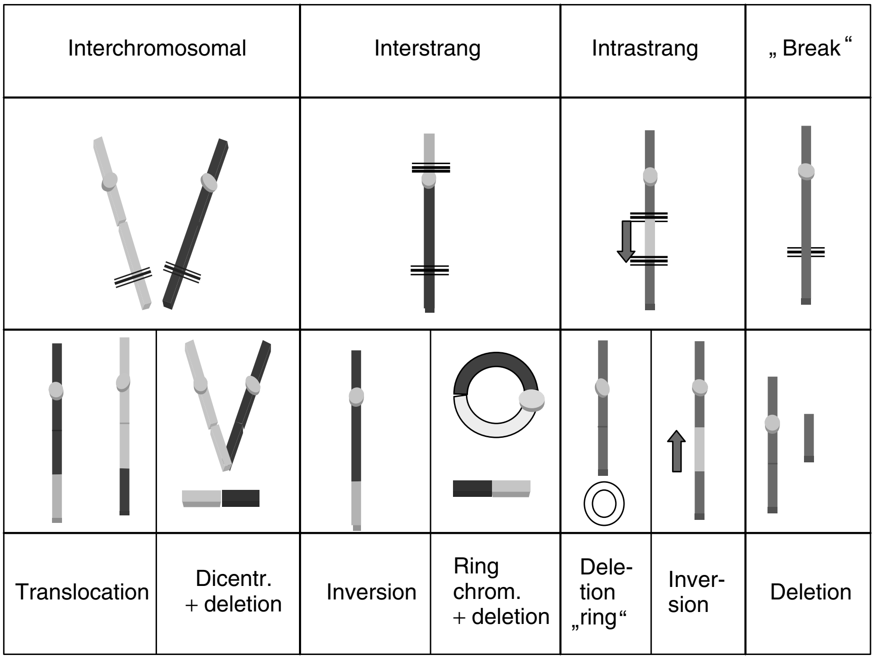

Fig. 23.5 Schematic representation of some chromosome aberrations (after Savage, 1978).

in division. More importantly, they can be recognized with comparative ease and thus serve as a convenient indicator of radiation damage. They even play a role in practical radiation protection. If lymphocytes of the peripheral blood are extracorporally stimulated into division, dicentrics can be scored and their relative number can be used as "biological dosimeter."

Radiation-induced breaks if not rejoined leave chromosomal fragments that are also replicated but usually not correctly distributed at mitosis. Quite often these fragments are encapsulated in membranes, thus forming "micronuclei." They can be easily scored in interphase and are also used for biological dosimetry (Fenech, 2007; Hayashi, 2007)

If replication is stalled, for example, under the influence of mutagens, chromatids may be exchanged between the sister chromosomes. These "sister chromatids exchanges (SCEs)" are thus sensitive indicators of disturbances of replication. Their detection requires special staining techniques (Wojcik and Obe, 2007).

Modern immunofluorescence staining techniques allow the detection and scoring of translocations and even inversions and other intrachromosomal alterations. Monoclonal antibodies coupled to fluorescent dyes can be raised against human chromosomes or parts of them so that every chromosome can be selectively "painted." Translocations are then visualized by color changes along the chromosomal structures. Studies have shown that they persist indeed much longer than dicentrics. Their dose dependence is similar to that of dicentrics and their detection limit lies in the same range (about 100 mGy for γ-rays).

Compared to other cellular endpoints (like loss of viability or mutations), chromosome aberrations constitute a relatively early event that can be assessed a few hours after exposure and may be less subject to postirradiation modification. They are induced by both UV and ionizing radiation. Dicentrics and translocations are formed according to a linear-quadratic relationship to dose with low-LET radiations. This functional dependence changes to straight linear for high-LET radiations.

As chromosomal aberrations can be seen only in mitosis they do not really reflect the original damage because they are the results of interactions at DNA level and possibly of repair and msirepair. Cells in the G_1, S, and G_2 phases of the cell's cycle may be stimulated into mitosis by fusion with mitotic cells. This technique of "premature chromosome condensation (PCC)" offers the possibility to study the formation of chromosomal aberrations in more detail.

Radiation exposure leads to genomic instability in many cell lines. New types of chromosomal alterations may appear many cell generations after exposure and persist in the progeny. It is speculated that this phenomenon may be an important step in radiation carcinogenesis.

A survey of recent developments in the field of chromosomal changes is given by Obe and Vijayalaxmi (2007).

23.5.4
Membranes

Membranes not only act as interfaces between the cell and its exterior or between different compartments, but also contain a number of enzymes whose functions depend critically on their integrity. The most sensitive components are the lipids. Radiation-induced radicals react readily with oxygen to form peroxides with high yields. The most interesting feature of this process is that the yield increases with lower dose rates, which is contrary to most other radiation reactions. Membrane damage does not seem to play a role in reproductive cell death but may be relevant in "interphase death," which is found, for example, in lymphocytes and spermatogonia.

23.5.5
Effects of Heat Treatment

Exposure to IR as well as to RF and MWs increases the temperature of the treated specimen. A biological effect may be caused by heat damage to critical constituents of the system. This possibility has to be carefully excluded if a claim is made for "specific actions." Hyperthermia in the sense of controlled heating has already made its way into cancer therapy. There is no doubt that cells are killed at elevated temperature (see Section 23.6.3), but the search for the target molecule or structure has been elusive. Proteins appear to be one of the prime candidates since they can be denatured, that is, change their molecular structure, at temperatures around 45 °C, with an accompanying loss in enzyme activity. There are, however, large differences, and the rate of inactivation depends not only on the particular protein but also on the presence of other molecules in the immediate vicinity, which may exert protective or sensitizing influences. If ordinary water is replaced by deuterium oxide (D_2O), cells and enzymes become more heat resistant, while they are sensitized in the presence of SH compounds (i.e. chemicals containing a free sulfhydric group), in contrast to the case for ionizing radiation where the same chemicals act as protectors.

Nucleic acids are comparatively heat resistant. DNA undergoes "melting," that is, unfolding of the double-stranded structure, in the temperature region 85–95 °C, depending on the relative proportion of guanine–cytosine pairs. It has been shown that chromosomal aberrations are formed in mammalian cells if they are heated to 45 °C during the DNA-synthesis phase, but this does not prove a direct action on DNA and suggests rather an interference with the synthesis process.

Membranes may play a more important role. They undergo phase transitions at certain temperatures, which can be demonstrated by electron spin resonance (ESR) of incorporated spin labels or by Raman spectroscopy. Also, the activity of membrane-bound proteins is changed after moderate heat treatment. These effects may be translated into impairment of cellular functions, considering the eminent role these structures play not only for transport processes but also for energy metabolism and the general integrity of the complex interrelationships in the cell's life. In spite of a great number of investigations, there is yet no consensus about "critical targets;" details of the ongoing discussion are found in Hahn (1982).

23.5.6
Specific Molecular Aspects of Radio Frequency and Microwave Actions

Experimental situations to address this question have to be designed in such a way that heat effects are excluded. This is not easy on a macroscopic scale and is virtually impossible at the microscopic or molecular level. Molecular vibrations or rotations may lead to local temperature differences that in turn cause structural alterations.

Thermal effects are well understood, current interest thus concentrates on "athermal biological effects." There is presently no accepted mechanism on how they may be caused, and the experimental evidence is quite ambiguous. Most studies deal with genotoxic actions, that is, effects on DNA. Recent reviews (Vijayalaxmi and Obe 2004; SSK, 2006) come to the conclusion that there is no convincing evidence for genotoxic effects of RF or MW fields.

23.6
Cellular Effects

All biological systems are composed of cells. The human body contains about 10^{14} of these elementary units. Most radiation actions on the organism as a whole can be traced back to cellular effects. This holds true for UV and ionizing radiations, but not exclusively for IR, RFs, and MWs. Nevertheless, a thorough discussion of cellular radiation effects is needed to pave the way for understanding tissue and organ malfunction.

23.6.1
Experimental Endpoints of Cellular Radiation Action

23.6.1.1 Survival

Survival in the present context is defined as the ability of a cell to divide indefinitely. It is experimentally determined by the "colony-formation assay," where single cells are plated on suitable nutrient media and incubated at the appropriate temperature. Cells are scored as "survivors" if they grow and form visible colonies. This method, which has been used for a long time with microorganisms like bacteria, yeast, and algae, has also been adapted for mammalian cells in the 1950s and is now a standard technique in many laboratories. In most cases so-called established cell lines are employed, derived from a variety of animal and human tissues. Nearly all of them have undergone transformation, that is, they have the properties of tumor cells, even if they were originally taken from healthy organs. There are only a few exceptions to this rule.

Mammalian cells in culture do not all grow to colonies, even in the absence of damaging agents. The "plating efficiency" is normally quite high (between 70 and 90%) for established cell lines but may be as low as only a few percent for freshly excised tissue.

Survival in the sense of colony-forming ability (cfa) as defined earlier is usually plotted on a logarithmic scale versus radiation dose (or any other physical parameter related to it) on a linear scale. Figure 23.6 gives typical examples of commonly obtained shapes. In curve A, survival decreases with increasing dose in an exponential fashion, which is quantitatively characterized by the dose D_0 reducing cfa to $1/e$. In the majority of cases "shouldered" survival curves are found (types B or C). If the terminal part is again exponential (curve B), the "shoulder width" may be given either by the intercept of its back-extrapolation with the ordinate, which is then called

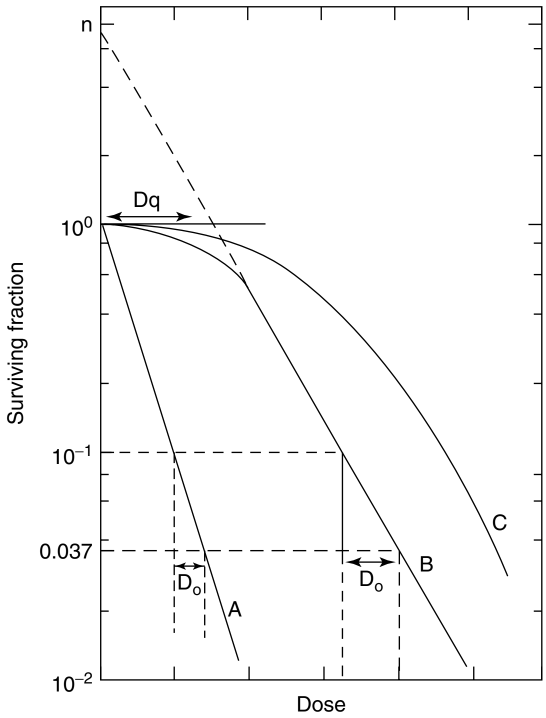

Fig. 23.6 Typical survival curve shapes.

the extrapolation number n, or by the quasithreshold dose D_q, which is obtained from the intercept with the 100% line as shown. Continuously bending curves (type C) are often found especially with mammalian cells. They may be satisfactorily approximated – at least in the initial part – by the expression:

$$y = \exp(-\alpha D + \beta D^2) \qquad (16)$$

commonly referred to as the *linear-quadratic* or "α/β relationship"; y stands for survival, D for dose, and α and β are the system-characterizing parameters.

For low-LET ionizing radiations it has been found for all cellular systems that the sensitivity as given, for example, by the D_0 values depends within certain margins on the mean DNA content per average chromosome. It is calculated by dividing the total mass of DNA per cell by the number of chromosomes. A useful rule of thumb is

$$D_0/\mathrm{Gy} = 3 \times 10^{-16}/(\text{kg of DNA per average chromosome}) \qquad (17)$$

which neglects, of course, differences due to repair deficiencies and may be assumed to be correct within about half an order of magnitude. No such simple relationship exists for other kinds of radiation. Table 23.2 lists the X-ray and UV sensitivities of a few cell types. The apparently simple shapes of survival curves prompted numerous attempts at theoretical interpretations, but there is yet no general agreement (see, e.g. Kiefer, 1990 for further references).

Tab. 23.2 D_0 values and cell nucleus factors for various systems.

Name	Species	DNA/cell[a] (kg)	Chromosome number	DNA/ chromosome[a] (kg)	D_0(UV)[b] (J m^{-2})	D_0(X-ray)[a] (Gy)
T_1 phage	Virus	8.1×10^{-20}	1	8.1×10^{-20}	41	2600
Escherichia coli B/r	Bacteria	1.9×10^{-17}	1	1.9×10^{-17}	85	30
Bacillus subtilis	Bacteria	7.7×10^{-18}	1	7.7×10^{-18}	50	33
Charomyces cerevisiae	Yeast	2.8×10^{-17}	36	7.8×10^{-19}	1150	150
Chlamydomonas	Alga	1.4×10^{-16}	16	8.8×10^{-18}	2500	24
Hamster cells	Mammal	1.5×10^{-14}	22	6.8×10^{-16}	50	1.4
Hela cells	Human	1.2×10^{-14}	78	1.5×10^{-16}	108	1.4

[a] After Underbrink, Sparrow, and Pond (1968).
[b] After Kiefer and Wienhard (1977).

The present preference of the linear-quadratic formula for mammalian cells is rather based on practicability than on theoretical considerations.

With UV, the effectivity to cause loss of cfa depends on wavelength. The action spectrum for mammalian cells in the far UV range coincides largely with the absorption of DNA. Deviations are seen in the region above 320 nm, which suggests that other chromophores, and possibly sensitized reactions, may also contribute here.

The inactivation by ionizing radiations depends also on the radiation type. The effectiveness of charged particles can be given as the inactivation cross-section σ_i. In the lower LET range, σ_i increases almost linearly with all systems. Around 100 keV/μm a supralinear rise is found (corresponding to relative biological effectiveness values greater than 1; see Section 23.6.2) before a transient plateau region is reached. For very high LETs (attainable only by very heavy ions), the unique relationship breaks down, and each ion has to be represented by a separate curve. Here LET is no longer a useful parameter. This is due to the influence of long-range δ electrons, as discussed in more detail elsewhere (Kiefer, 2008). In most cases – most obviously for mammalian cells – σ_i is smaller than the cross-sectional area of the cell nucleus, assumed to be the critical target. This means that a cell cannot be killed by the traversal of single particle through its nucleus, which is very surprising, taking into account the large amounts of energy that are deposited – far exceeding the D_0 values found with low-LET radiations. This finding has implications also for the production of mutant or transformed cells as discussed subsequently. The reason for this behavior cannot yet be fully explained.

The loss of cfa is commonly caused by mitotic failure, that is, the cells die when they attempt to divide. There is another mode of cell death, termed *apopotosis.* This constitutes a physiological process for cells to be eliminated because of age or loss of function. It may be important for cell killing at low radiation doses.

It is commonly assumed that cells surviving a radiation exposure and that are able to form a colony do not carry any remaining damage, except for mutations. This is not generally the case. If cells from colonies grown from irradiated cells are cultivated further they display very often a decline in cfa, which depends on the first dose. This ''delayed reproductive death'' is presumably related to ''chromosomal instability'' (see Section 23.6.2.5).

23.6.1.2 Mutations

Mutations are changes in genetic information that are stably transmitted from one cell generation to the next. On a cellular level they are expressed either as resistance to certain toxic drugs or biochemical deficiencies, resulting in the obligatory dependence on certain nutrients. At the molecular level a mutation represents a change or a complete loss of the function of a particular protein. Since in most cells the chromosome complement is diploid, that is, there are *two* genetic loci for a given protein, a mutation in only one chromosome is usually masked because the information for the protein is provided by the remaining undamaged one. Special test systems have to be developed to overcome this problem, which in classical genetics is called *recessivity*.

All mutation tests require the mutant cell to grow into a colony to be scorable. This means that cell killing, which occurs simultaneously, has to be adequately taken into account. For this it is usually assumed that the survival probability is the same for the mutant and the unmutated cell. This presumption is nearly impossible to prove but must be made for practical reasons. The ''mutant yield,'' that is, the total number of mutants in a cell population, not corrected for cell killing, invariably approaches very low values with high doses – not because they are not mutagenic but because all mutants are killed before they can be detected. It is dangerous to extrapolate from the action of high doses to that of low exposure levels – a situation well known in radiation protection but not always sufficiently appreciated.

Mutation induction curves may depend on dose linearly or (in most cases) in a linear-quadratic manner. UV is considerably more mutagenic than X-rays. The action spectrum for mutant induction resembles very closely that for cell inactivation and hence also that for the absorption of DNA, which is to be expected. The identification by action spectroscopy of nucleic acids as the carrier of genetic information preceded the biochemical experiments by nearly a decade, but remained almost unnoticed in the scientific community.

With ionizing radiations, mutations may also appear delayed after several cell generations. The mutation types may be quite different from those which are seen soon after exposure, a phenomenon linked to delayed reproductive death and genomic instability (Section 23.6.2.5).

23.6.1.3 Neoplastic Transformation

Cancer induction is generally considered to be one of the most important hazards of radiation. Although it is clearly a systemic disease, some of the initial stages can be studied at the cellular level by *in vitro* techniques. They require the use of untransformed cells, which are not readily available since most of the established laboratory strains are essentially tumor cells. They may be taken from fresh preparations (e.g. hamster embryonic tissue), but there are also a few permanent lines, mainly from mice, that grow like untransformed cells.

Whether they are true representatives of "normal" cells is still under debate.

Untransformed mammalian cells grow attached to the surface of the culture dish in a thin unicellular layer ("monolayer"). After transformation into tumor cells they build up to densely packed aggregates, called *foci,* and can be easily recognized after staining. That they really are tumor cells has been proved by injecting them into isogenic animals that do not react immunologically to them, where they inevitably cause tumors while the "nonfocal" cells do not. This comparatively simple approach allows assessment of the cancerogenic potential of radiation. Figure 23.7 shows the transformation "yield," that is, the number of transformants per cell at risk after X-ray or neutron exposure. After an initial rise it declines again with higher doses, which is due to the killing of potential transformants. The situation is quite similar to mutation induction. This graph demonstrates impressively the problems with which one is confronted if risk estimates for low doses have to be derived from measurements at high doses, as is frequently the case in practical radiation protection. In *in vitro* systems, cell killing can be separately assessed and corrected for by plotting "transformants per survivor," but this is hardly possible in tissues and organs.

The probability of transformation after a given dose increases considerably if "tumor promoters" are added to the culture medium. This is taken as evidence that tumor formation is a multistep process that may be modified by special conditions after radiation exposure.

23.6.2
Modifications of Cellular Radiation Effects

23.6.2.1 The Temporal Pattern of Exposure

As pointed out in the general introduction, the temporal evolution of biological radiation effects may span more than 30 orders of magnitude from the initial physical event until its final clinical expression. It is obvious that the time during which a dose is applied must play an important role. Generally, it is found that cell killing with sparsely ionizing radiation is reduced if a dose is split

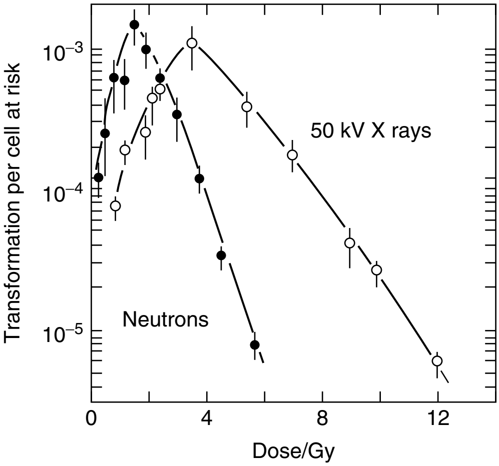

Fig. 23.7 Yield of transformed cells (that is, number of transformants per cell at risk) after X-ray or neutron irradiation (after Han and Elkind, 1979).

into two or more fractions (“split-dose effect”) with an interval comparable to the generation time of the cell type under investigation. A similar result is obtained if the dose rate is lowered and thereby the exposure is spread over a longer time period. In actively growing cells there is an additional influence of the cell growth phases having different radiation sensitivities, so that a rather complex pattern evolves, which, however, does not invalidate the general statement. With mutation and transformation as experimental endpoints, the influence of dose rate has not been studied to the same extent. There appears to be agreement that there is a reduction similar to cell killing if the dose rate is lowered, but there are also reports in the literature claiming an actual increase if growing cell populations are exposed for extended periods of weeks or months. There are only very few dose–rate studies with nonionizing radiations so that a general statement is not possible, although it appears that also in this case reduced killing is found with lower dose rates. Dose–rate effects are absent with densely ionizing radiations. In some instances, even a higher effectiveness of long-term exposures has been claimed, but this requires further confirmation.

The influence of very high dose rates has so far not received much attention. They may be important with laser sources where multiphoton excitations may occur.

23.6.2.2 Chemical Protectors and Sensitizers

Optical Radiations Photosensitized reactions play an important role for the damage of cells by near UV and visible radiation. In most cases, the excitation of the chromophore is transferred to oxygen to form singlet oxygen, which is the damaging species. This mechanism is called *photodynamic action.* The point of attack appears to be mostly membranes, but other targets cannot be excluded. Important examples of photosensitizers include riboflavin, acridine orange, acriflavin, bengal red, and thiopyramine.

Two substances have also recently gained practical importance for the treatment of certain diseases; psoralen and hematoporphyrine. The first interacts with DNA and on light absorption causes interstrand crosslinks in a two-step process, thus leading to cell killing. It is widely used for the treatment of psoriasis and (less frequently) vitiligo. In practice, the derivative 8-methoxypsoralen (8-MOP) is mostly used. The effective wavelength region is in the UV-A around 365 nm. Hematoporphyrin has been claimed to be a potent anticancer agent since it binds with some selectivity to tumor cells. It is used in a preparation, not very well defined chemically, called *hematoporphyrine derivative* (HpD), which has two absorption bands around 400 and 600 nm. Excitation leads to the formation of singlet oxygen, which causes cell killing mainly via membrane damage.

Ionizing Radiation The damaging action of sparsely ionizing radiations to cells can be reduced by the presence of chemical radioprotectors during exposure. There are essentially two classes: radical scavengers and the so-called SH substances. In the first case, the action is via the suppression of the indirect effect (see Section 23.5); typical representatives are alcohols like ethanol, butanol, and glycerol but also dimethylsulfoxide (DMSO). They all react readily with OH radicals to form less aggressive products. SH compounds exert their protective action via the donation of a hydrogen atom to a site whence it was abstracted by radiation, either by direct absorption or by primary radicals. Cells contain already naturally protective substances of which glutathion is the most important. The practical relevance of radioprotectors is small since appreciable effects require rather high, already toxic concentrations. They are considered as possible adjuvants in radiation therapy for the sparing of healthy tissues.

The most potent radiosensitizer is molecular oxygen. If cells are exposed in its absence to X or γ-rays, the doses necessary to achieve a given effect have to be increased by a factor between 2 and 3. The general shape of the dose–effect curves is not altered; oxygen acts in a "dose-modifying" way, that is, the curves are superimposable by application of an appropriate dose-scaling factor. This is commonly called the *oxygen enhancement ratio* (OER), defined as

$$\mathrm{OER} = \frac{\text{dose in the absence of } O_2}{\text{dose in the presence of } O_2} \quad (18)$$

for equal effect

The radiobiological oxygen effect is considered to play an important role in radiotherapy since many tumors contain regions with low oxygen contents. To overcome this problem, agents that act as sensitizers similarly to oxygen without being metabolized so that they may be evenly distributed in the tumors have been developed. The most important examples are metronidazole (also known as *flagyl*) and misonidazole. Their sensitizing action is less than that of O_2 and their applicability *in vivo* is limited by severe side reactions.

The oxygen effect is due to a reaction with transient radiation-induced intermediates in DNA by which they are stabilized and no longer accessible to H donation by intrinsic SH protectors. This is clearly a radiochemical process and has nothing to do with the physiological role of oxygen in cellular respiration. Support for this notion comes from the time dependence. In order to sensitize, oxygen has to reach the sensitive site within less than a millisecond, which is much too fast for any physiological intervention.

23.6.2.3 **Repair Processes**

There are quite a number of processes by which radiation-induced damage to genetic material can be repaired. The molecular mechanisms are quite well known – at least in bacteria, but more and more also in mammalian cells – but space does not permit description of them in detail. *Photoreactivation* is specific for the *in situ* monomerization of pyrimidine dimers and hence only relevant for UV-induced damage. The protein photophospholyase binds to the altered site in a dark reaction. Upon light absorption (effective wavelength region 350–500 nm) the dimer is split and the protein released. Photoreactivation has been demonstrated in bacteria, lower eukaryotes, birds, and amphibians but not without doubt in higher mammals. *Excision repair* is a multistep process in which the damage is first excised from one strand of the DNA, and the resulting gap is filled by repair–replication where the opposite undamaged strand is used as a template. It is operative in all cell types including humans. Excision repair was shown to work preferentially in active genes via a coupling with transcription. Apart from this, "general" excision is also operative. *Postreplication repair* operates if damaged DNA enters replication. The lesions stop the formation of new strands and the resulting gaps are filled either by recombination from the old complementary strand (bacteria) or by translesion synthesis (mammalian cells). In this way it is ensured that at least the newly formed strands are free of lesions although the lesions are not removed from the old ones. In bacteria the process is error-free, that is, it does not lead to mutations, while it is thought to be error prone in mammalian cells since the translesion synthesis may cause the insertion of wrong, that is, noncomplementary, nucleotides.

If the lesion density is too high, repair–replication would lead to DSBs because of overlapping gaps. In this case translesion synthesis occurs also in bacteria, which is normally prevented by a "proofreading" activity ensuring that only correctly matching nucleotides are inserted. Under special circumstances this safeguarding mechanism is "switched off" to allow DNA replication to proceed, although at the expense of possible errors. This process has been termed *SOS repair*. It is only induced if daughter strand gaps are present that cannot be filled by recombination, and is repressed again after completion. Obviously SOS repair is error prone and thought to be the main mechanism for mutation induction in bacteria.

SSBs do not present a problem for the cell under normal circumstances since they are formed also during ordinary replication and can be sealed by special enzymes called ligases. If they are produced by ionizing radiation the chemical configuration may be different so that processing by nucleases may be necessary before final ligation.

DSBs can also be repaired. They were formerly assumed to be lethal but it is known now that they are also the origin of mutations that are formed through misrepair. In mammalian cells, DSBs are handled by two repair systems, namely "nonhomologous endjoining (NHEJ)" and "homologous recombination (HR)." The first one is prone to misrepair while the second is essentially error free.

Repair processes are genetically determined. Many of the genes responsible have been identified, often cloned, both in bacteria and lower eukaryotes like yeast as well as in mammalian cells. Hereditary diseases causing repair deficiencies are also known in man; most of them are inherited recessively so that their prevalence in the population is quite small. Nevertheless, they pose a severe problem for the individuals affected, leading to death at an early age in many cases. This fact demonstrates the importance of repair processes for the integrity of life. UNSCEAR (2000) has discussed the issue of repair in some detail; an older, but still very useful, intoduction was provided by Friedberg, Walker, and Siede (1995).

23.6.2.4 **Radiation Quality**

The effectiveness of ionizing radiations in causing biological damage depends on the spatial pattern of energy deposition at a microscopic or submicroscopic level. This means that dose is not the only determinant to describe a certain effect level in a given system. Examples have been given before for the various endpoints. To account for this dependence on radiation quality, the term *relative biological effectiveness* (RBE) has been introduced. It is defined as

$$\mathrm{RBE} = \frac{D(\text{reference radiation})}{D(\text{test radiation}),\ \text{isoeffect}} \quad (19)$$

that is, it gives the ratio of doses that cause a given effect with a test radiation compared with a reference source. For the latter, ^{60}Co γ-rays are normally used but sometimes 250 kV radiation is also used. Even for a given system, RBE is not constant but depends on the effect level. The reason for this is that the dose–effect curves do not have the same shape with different radiation qualities. One finds a shouldered curve for X- or γ-rays but an exponential type for densely ionizing radiations. RBE obviously increases for low doses and may approach very high values. This makes the determination of the initial part of the curve crucial. A constant limiting RBE would be found if there was an initial exponential component. Since in radiation protection one is usually concerned with low doses, the problem is of great practical relevance. RBE increases with LET up to a maximum around 200 keV μm^{-1}, from where it declines. The reason for this fall is presumably the existence of saturation processes for the formation of primary lesions with very high ionization densities. All cellular endpoints have similar RBE/LET dependences although they differ quantitatively with different parameters, systems, and effect levels. A typical example for mutation induction is shown in Figure 23.8.

23.6.2.5 "Nonclassical" Effects in Cellular Radiobiology: Bystander Effect, Genomic Instability, Low Dose Sensitivity, and Adaptive Response

Classical radiation biology is governed by the "hit hypothesis" (which led to the "target theory") where it is assumed that cellular radiation effects are caused by photon or particle energy deposition in the cell nucleus. Present technical achievements made it possible to target cell nuclei by single particles to check the hypothesis. The experiments led to unexpected results: cells can also be inactivated or mutated if they did not receive a hit but if only neighbors were exposed.

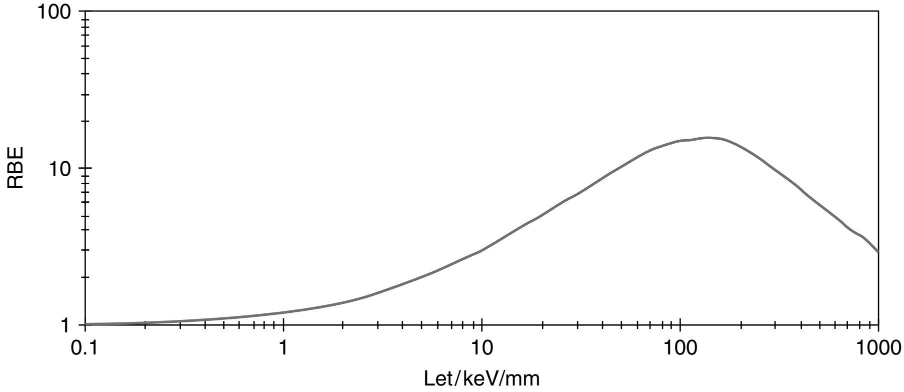

Fig. 23.8 Relative biological effectiveness for mutation induction in mammalian cells as a function of LET (after Kiefer, 2002).

This phenomenon has been termed *bystander effect*. It plays a role particularly at low doses and is not yet fully understood. The current assumption is that hit cells secrete "factors" that are taken up by other cells. It has been shown that the "bystander effect" is also related to genomic instability and delayed reproductive death.

The response of cells to low doses of ionizing radiation has received increased attention also in another respect. It is now clear that gene activity and its regulation can be influenced by X-rays as well as by UV. Studies using single-cell observations suggest that mammalian cells may be more sensitive to killing by low doses of X-rays than anticipated from an extrapolation from the overall survival curve. At the same time, it has been reported by several groups that the yield of chromosomal aberration after high doses is reduced if the cell received "priming doses" in the order of a few hundred milligrays several hours before. This "adaptive response" (which is not found in all cells) depends on an active cellular metabolism and may be related to inducible repair processes, but there is presently no proof for this supposition.

Whether the phenomena described here play a role in the evaluation of radiation hazard is a matter of intense discussion as mirrored for instance in a chapter "Nontargeted and delayed effects of exposure to ionizing radiations" in UNSCEAR (2009).

23.6.3
Heat Effects at the Cellular Level

It is commonly known that cells can be killed by exposing them to high temperatures. This forms the basis for heat sterilization. There are, however, drastic differences between species and strains; thermophilic prokaryotes like *Sulfolobus*, able to sustain growth even at 97 °C, may be mentioned as an extreme example. The more recent interest in thermal effects on cells comes from the application in the therapy of tumors. This section will, therefore, concentrate on mammalian cells only.

Thermal damage shows survival curve shapes similar to those found with UV or ionizing radiation and split-dose recovery similar to X-rays, but there is an additional feature not found with ionizing radiation or UV called *thermotolerance*. This is a transient phenomenon (and hence not due to the selection of genetically heat-resistant substrains) that can be induced by holding cells continuously at elevated but sublethal temperatures (around 42.5 °C) or by a fractionated treatment for shorter times at higher temperatures (up to 47 °C, depending on duration). It has been shown that even after 4-hours cells are more resistant than expected just from the recovery from sublethal damage (see Hahn, 1982). Thermotolerance is most clearly expressed in about 12–48 hours and declines after 72 hours, although not completely. This behavior is of great fundamental and practical importance, particularly in tumor thermotherapy, since in clinical practice treatments are always given in fractionated schedules. The mechanism is not known. It seems that two steps – induction and development – are required, and it has been shown that the second one requires protein synthesis. Heat treatment induces the synthesis of very specific stress proteins ("hsp" for heat stress proteins) but it has not yet been demonstrated unequivocally that they are involved in the expression of thermotolerance. Membranous structures like the cytoskeleton may also participate.

Heat sensitivity depends on a number of factors, which, in most cases cannot be easily separated, for example, cell cycle state, pH, oxygen tension, or glucose concentration. Although it has often been claimed, there is no evidence that tumor cells are *generally* more heat sensitive than their normal counterparts, but it may well be the case under specific conditions. The cytotoxic action of other agents – and ionizing radiations have to be especially mentioned here – is increased in combination with treatment at higher temperatures.

It does not seem that heat induces mutations directly but it may modify synthesis or repair processes in such a way that mutants are produced. This has been found in a number of instances, but more data are required. The issue is even more controversial with regard to neoplastic transformations: some researchers have found an increase, others a decrease in transformation rates with heat treatment. Obviously the particular cell strain and the special experimental protocol are critically important.

23.6.4
Specific Cellular Effects of Radio Frequency and Microwaves

Because of the rising use of mobile communication the influence of MWs has been studied extensively in recent years. In spite of this, no clear picture emerges. Most papers deal with cytogenetic parameters that were already discussed in Section 23.5.6. As pointed out, genotoxic actions with intensities below current International Commission on Nonionizing Radiation Protection (ICNIRP) recommendations cannot be unequivocally demonstrated. Mutation induction was only rarely investigated and not found. There are only very few experiments on neoplastic transformation, which also yielded mostly negative results (Meltz, 2003). Interestingly, cell inactivation was only very rarely included in the study protocol. The present state may be summarized by stating that the great majority of authors were not able to demonstrate cellular effect of MW and RF radiations below currently recommended limits in a reproducible manner.

23.7
Organ and Whole-Body Effects

It has become customary – essentially based on experience with ionizing radiation – to classify organismic damage into two groups, namely, *acute* and *late* effects. Although it is not always applicable in a clear-cut manner, this concept proves to be useful for other types of radiations also and will be followed here.

Acute damage may start, depending on dose, very shortly after exposure and is terminated within weeks or months. In most cases, its degree can be functionally related to dose, and it does not develop below certain threshold doses that depend, of course, on the particular endpoint and may be sometimes quite low. For this kind of behavior the term *nonstochastic* has been coined.

Late effects may take from months to years, or even generations in the case of genetic hazards, to become evident, and severity cannot be defined in a quantitative way. Only the *probability* of their occurrence is a function of dose. They are, therefore, summarized under the heading "stochastic damage." It is commonly assumed that there are no threshold doses although there is no general agreement about this at least for cancer induction, and this supposition is not inherent to the concept. An important difference between nonstochastic and stochastic damage is that the former is, within quantitative variations, predictable in an exposed individuum while the latter occurs in a random manner and is only governed by statistical rules.

For UV and ionizing radiation acute effects can be related to the inactivation of cells in critical tissues, but for other types of electromagnetic radiation the reaction is not so simple. Late effects are linked to the cellular parameters, mutation (for the genetic risk) and transformation (for cancer induction).

Tissue and whole-body effects have been most extensively studied with ionizing radiations and UV. In these cases links to cellular and molecular alterations can be shown so that a framework of explanation may be established. With other radiation types the situation is less clear. To facilitate presentation, the next sections describe in more detail what is known with ionizing radiations and UV while IR, RF, and MW are treated in separate subsections at the end.

23.7.1
Acute Effects

The impairment of cell division is the reason for most acute radiation effects. It is clear from this that the organs expected to be particularly failure-prone are those that depend critically on functioning of cell replacement. These are all surfaces (external and internal) and also the blood-forming system. They constitute "renewal systems" that are all functionally structured as follows: mature cells responsible for proper organ function have only a limited life span in the body, which varies widely. Cell loss is compensated by the entry of newly formed cells from the proliferating "stem cell" compartment into the process of differentiation during which the ability to divide is gradually lost and the specific function attained. This process requires time so that acute cell loss cannot immediately be compensated. The proliferative fraction is the main target for radiation action, which explains why even "acute" effects develop with a certain time lag.

23.7.1.1 **Skin**

The skin is the entry organ for all kinds of external radiation and hence is particularly at risk. The sensitive part is the *stratum germinativum*, consisting of proliferating epithelial cells. In man it lies at a depth of about 150–200 μm and is shielded by other epidermal layers whose absorption properties determine the amount of optical radiation reaching the proliferative compartment. Figure 23.9 gives the relevant information. As a function of dose the following stages of skin damage may be recorded: erythema (reddening, "sunburn"), inflammation, ulceration, and necrosis. Apart from this, skin cancer may develop later (see following text). The minimal erythema dose depends on wavelength and the time of recording. The action spectrum differs also

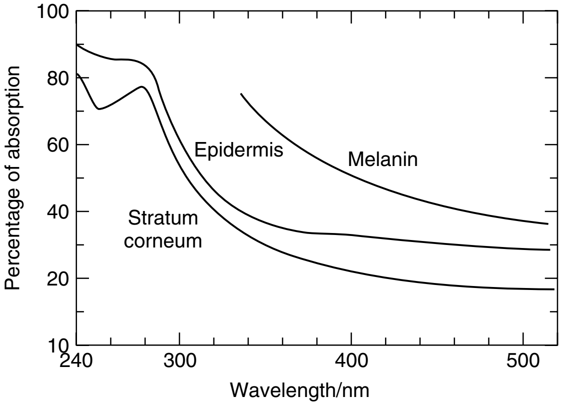

Fig. 23.9 Optical absorption of skin constituents in the UV and visible region (after Parrish *et al.*, 1978).

for different degrees of damage with an increased efficiency around 320 nm for causing more severe effects.

The skin also represents an important immune barrier of the body. Animal experiments show that this protective property is reduced after UV exposure because of damage to Langerhans cells, which comprise about 3% of the epithelial population and play an important role in the immune system. There may also be additional hormonal factors. The wavelength dependence of this effect has not yet been established, and it is not clear whether immune suppression occurs in man.

The skin is also very sensitive to ionizing radiations. It can even be reached by less penetrating kinds like β or even α particles. Effects and their severity depend on dose and the affected area. An abridged summary (after UNSCEAR, 1988) is as follows:

- Erythema develops in 50% of cases after an X-ray dose of 5.7 Gy to a field of $10 \times 10\ \text{cm}^2$.
- Epilation and abnormal hair growth are seen after about 1.5 Gy with 50% probability and may be permanent after more than 7 Gy.
- Desquamation occurs with more than 12 Gy.
- Effects on sebaceous glands also have to be considered. Reductions in size can be recorded after 3 Gy, and severe atrophy is found after 15 Gy.

23.7.1.2 **Eye**

UV effects on parts of the eye depend on the transmission properties, which are depicted in Figure 23.10, and the fluences applied. With lower levels, the main symptoms are photokeratitis and conjunctivitis, which appear a few hours after exposure and last usually not longer than about five days without leaving permanent damage. The threshold fluence for photokeratitis is lowest at 270 nm ($50\ \text{J/m}^2$). Lens damage in the form of cataracts (opacity) may be produced by UV-B and by extended exposures to UV-A. At 300 nm the threshold for transient opacities was found to be about $1500\ \text{J/m}^2$. It is not clear at present whether retinal damage may be caused in humans by excessive fluences in the UV

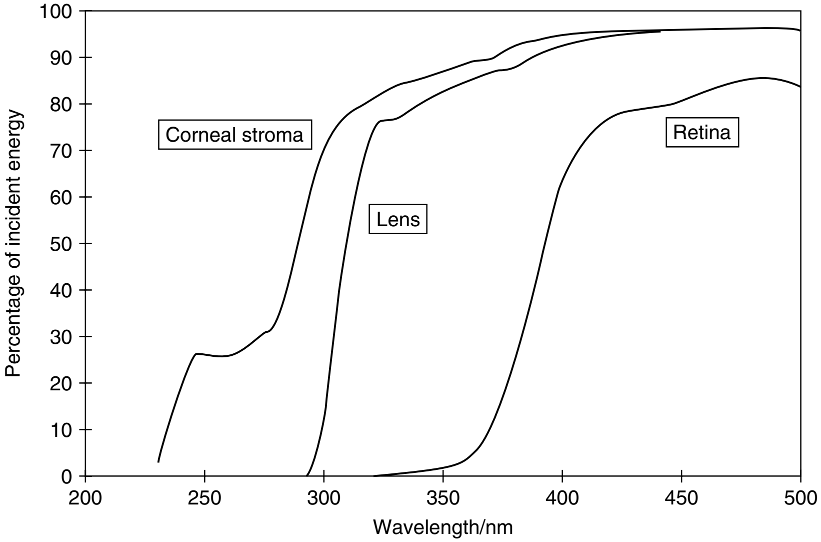

Fig. 23.10 Percentage of energy incident on the cornea that impinges on the anterior surface of various ocular media (after Kinsey, 1948).

region. Acute effects by ionizing radiation include (threshold dose in parentheses) (from UNSCEAR, 1988) erythema of the sensitive conjunctiva (2 Gy), hyperemia and hyperpigmentation of the lid (4–6 Gy), keratitis (4–10 Gy), and epilation of the eyebrows and necrosis (>10 Gy). Apart from these, cataract formation has to be taken into account, which is not clearly an acute effect since it may develop, depending on exposure level, a long time after irradiation. The doses required may be quite low, and rather large RBE values for neutrons have been reported. The eye therefore must be considered as a critical target organ even under circumstances of "normal" working conditions.

23.7.1.3 Nervous System and Other Organs

Direct effects on the nervous system have been found only with very high doses of ionizing radiation and may then lead to very early death as part of the radiation syndrome. Epithelial parts of other organs are also sensitive to the action of penetrating ionizing radiation. Injuries in the mucosa of the mouth and throat cause inflammation, swelling, and necrosis. The salivary glands react to 6–10 Gy within 48 hours. Pneumonitis of the lung can be recorded after one to three months after about 8 Gy.

23.7.1.4 Radiation Syndromes and Lethality

The human body reacts to radiation in a systemic way by developing a number of interrelated symptoms that are commonly called *radiation syndrome.* Its time course and expression depend on the dose level. With more than 50 Gy (always whole-body exposure) there is a direct effect on the central nervous system (which is not related to cell killing) leading to death within 48 hours after periods of lethargy and coma. In the dose range of 10–15 Gy the small intestine is most affected; death will occur with a probability of 90–100% within about two weeks, during which the persons suffer from severe diarrhea, fever, and electrolyte imbalance. With lower dose levels the critical organ is the blood-forming system, mainly the bone marrow. The symptoms for a midline dose range of 2–3.5 Gy are shown in Figure 23.11. It is obvious from this that the radiation syndrome shows a rather complex pattern and that a number of organs are affected.

Damage to the blood-forming system shows up in a reduction of the cellular constituents in the peripheral blood. This is most pronounced for the white blood cells, and less so with erythrocytes because of their comparatively long lifetime (110 days in man). The lymphocyte count is reduced to about 50% after 1–2 Gy within 48 hours. This causes severe impairment of the immune response and favors infections that, in many cases, constitute the ultimate cause of radiation-induced death. Thrombocytes are also reduced in number, thus increasing the danger of hemorrhages and internal bleeding. Even if the bone marrow is the critical organ with intermediate doses, this must not be taken to mean that damage to other organs does not contribute. Apart from the special effects described earlier, the alimentary tract, especially the small intestine, has to be mentioned. Even a "mild" syndrome is always accompanied by diarrhea, nausea, and gut malfunction.

If the doses are not too high the stem-cell system is able to recover, and there will be no remaining acute damage. There is (fortunately) considerable uncertainty about the dose–response curve for radiation-induced death in humans. The mean lethal dose observed within two months, abbreviated $LD_{50,60}$, depends on the health status, age, and amount of medical aftercare. According to recent experience, $LD_{50,60}$ ranges from 2.5 Gy (without medical care) to about 5 Gy and may be sometimes as high as 9 Gy if successful marrow transplantation can be performed. All these values apply to low-LET radiations. Very little is known in this respect for densely ionizing radiation, even for neutrons.

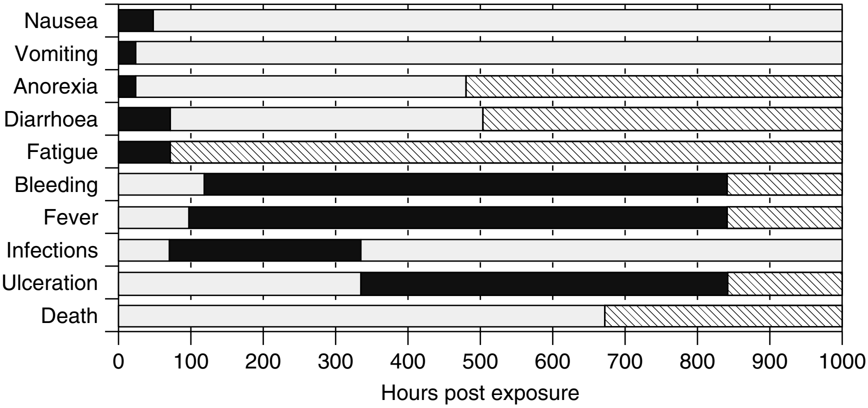

Fig. 23.11 Symptoms of radiation syndrome after whole-body exposure to 2–3.5 Gy (after UNSCEAR, 1988). Filled bars: 50–100% of all cases, hatched bars: 5–50% of all cases.

23.7.2
Radiation and Progeny

23.7.2.1 Fertility

Germ cell production in males represents a good example of a renewal system. The stem cells – type A spermatogonia – are particularly sensitive to ionizing radiation and may not only be killed at mitosis but also suffer interphase death. Moderate reduction in fertility, which is, however, fully reversible, may be brought about by doses as low as 0.15 Gy. Prolonged sterility is caused by more than 6 Gy.

In women the situation is different since the mature germ cells are derived from follicles that are not replenished via a renewal system. There are about 2 million of them at birth and about 8300 left at an age of 45 years. During the reproduction period about 400 mature oocytes are formed; the remainder degenerate by a process called *atresia*. Doses up to about 4 Gy cause temporary sterility, higher ones permanent sterility. Even after lower doses fertility is not fully recoverable.

23.7.2.2 Teratogenic Effects

The embryo, being a vigorously proliferating tissue, constitutes a very sensitive target for radiation action, and teratogenic effects are a matter of grave concern. Embryogenesis in humans may be roughly subdivided into three phases. Before the fertilized egg is nested in the ovary (preimplantation phase), radiation leads to failure of nidation, absorption of the fertilized egg, and hence premature termination of pregnancy. Animal experiments suggest that doses between 1 and 2 Gy are sufficient. There are no data for humans.

Most effects on the growing embryo are characterized by threshold doses (which may be quite low) but there is also the possibility of tumor induction (Table 23.3). Radiation action in embryogenesis displays a distinct temporal pattern (Figure 23.12). Organogenesis, especially its earlier parts (second to sixth week of gestation), is the most critical period in terms of possible teratogenic effects of radiation exposure. The most sensitive organs are those derived early in development from very few determined cells. The central nervous system, eye, skeleton, and spine belong to this category. Severe malformations were found in children exposed *in utero* by the atomic bombs in Japan 1945.

At later stages of development (weeks 8–16) irradiation may cause functional

Tab. 23.3 Threshold doses for radiation effects on embryonic development (modified after ICRP, 2003).

Effect	Critical period (weeks of gestation)	Estimated threshold dose to uterus (mGy)
Intrauterine death	0–2	1000
Malformations	2–6	50–100
Mental retardation	8–16	300
Tumor induction	Complete period	40–60 (doubling dose, no threshold)

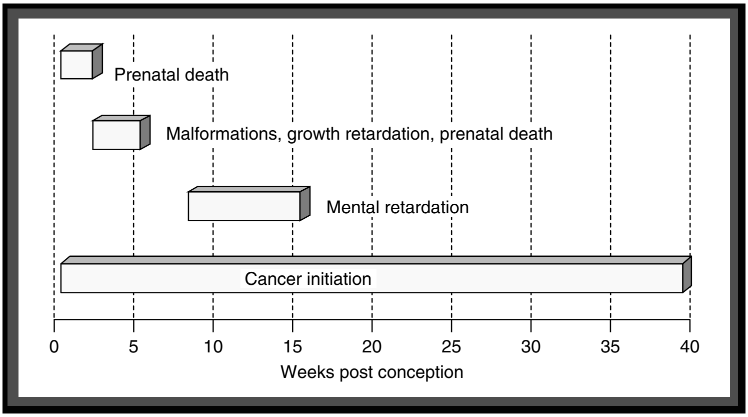

Fig. 23.12 Prenatal radiation effects.

impairment of the brain, leading to mental retardation. Threshold doses are higher in this case.

Tumors may be initiated at any time during embryonic and fetal development, leading to the expression of cancer in early childhood. The evidence is less clear here. No statistically significant increases of childhood cancers after exposure *in utero* were recorded in Hiroshima and Nagasaki but an extensive study of children whose mothers underwent X-ray diagnosis for obstetric reasons while pregnant showed increased numbers of childhood cancers (mainly but not exclusively leukemia). This Oxford Survey of Childhood Cancer (Bithell and Stewart, 1975) suffers from uncertain dosimetry but gives sufficient evidence for an increased rate of childhood cancers. There are, of course, no dose thresholds; the doubling dose may be estimated to be around 50 mGy to the uterus but with large uncertainties (Wakeford and Little, 2003).

The later stages in embryo development (fetal period) appear to be comparatively resistant to the action of ionizing radiation in contrast to the action of many teratogenic chemicals.

23.7.2.3 **Genetic Effects**

Germ cell mutations are transmitted to the progeny of exposed parents and hence present a serious potential hazard to future generations. To define it in quantitative terms, however, is very difficult for various reasons. Most mutations are recessive, that is, they are only phenotypically expressed if present on both homologous chromosomes. The probability for this increases, of course, with their proportion in the total gene pool. On the other hand, not all mutations will persist indefinitely in the population since they may be eliminated because of reduced fitness of the affected individuals, so that eventually equilibrium may be reached. Our present knowledge about genetically caused diseases is still rudimentary in spite of considerable progress in human genetics. A statistically increased rate of genetically caused diseases due to the exposure of the parents before conception has so far not been shown in any population. Quantitative data on genetic effects of radiation in man are thus not available so that one must refer to animal experiments. They have been performed extensively, mainly with mice, involving many millions of animals, providing a large database.

The now accepted approach to quantify the results is the "doubling dose method." It is based on the determination of the dose that increases the rate of spontaneous mutations by a factor of 2 (hence the name). UNSCEAR (2001) considered all available data extensively and derived an estimate of the doubling dose based on the frequencies of radiation-induced mutations in mice and spontaneous mutations in man. Its value is slightly less than 1 Gy for low-dose rate low-LET radiations like X- or γ-rays; for risk estimation it is rounded to 1 Gy.

Table 23.4 summarizes the results obtained for chronic X- or γ-irradiation.

There is no easy direct relationship between the (genetic) risk for a disease and the frequency of induced mutations. The "mutational component," that is, the relative increase in disease frequency (relative to the baseline incidence) per unit relative increase in mutation rate (relative to the spontaneous rate), depends both on the type of mutations and the disease. This complex problem is extensively discussed in UNSCEAR (2001).

Multifactorial genetic diseases form the great majority. They were not always appropriately taken into account in past analyses. They are observed as congenital abnormalities at birth (about 6% spontaneous rate) but are also present in about 65% of the population and only rarely directly observable. With the advent of more sophisticated methods in human genetics it became clear that many diseases like, for example, cancer, diabetes, or coronary heart disease have genetic traits. The mutational component is considered to be low so that the expected risk is of the same order of magnitude as for autosomal and X-linked diseases in spite of the high frequency in the population.

Careful examinations of the bomb survivors in Hiroshima and Nagasaki using a number of approaches did not reveal any significant increase in germ

Tab. 23.4 Risk estimates for radiation-induced genetically caused diseases based on a doubling dose of 1 Gy (chronic low dose rate low-LET radiations) (UNSCEAR, 2001).

Disease class	Baseline frequency per million livebirths	Risk per gray per million progeny	
		First generation	Second generation
Mendelian			
Autosomal dominant and X linked	16 500	750–1500	1300–2500
Autosomal recessive	7500	0	0
Chromosomal	4000	–	–
Multifactorial			
Congenital abnormalities	60 000	2000	2400–3000
Chronic	650 000	250–1200	250–1200
Total	**738 000**	**3000–4700**	**3930–6700**

cell mutations compared with unexposed control groups. This must not be taken to mean that the genetic risk to humans is negligible, since the groups involved were not large enough. The estimates based on the methods described above are fully in line with this conclusion.

23.7.3
Radiation Cancerogenesis

23.7.3.1 Ultraviolet Radiation

With UV radiation the only tissue at risk in terms of cancer formation is the skin. The majority of tumors are of the nonmelanoma type and comparatively easy to cure if treated at any early stage. Indirect information on humans may be obtained by comparing skin tumor incidences for different geographical latitudes where the UV-B component of sunlight varies. Such a compilation is depicted in Figure 23.13 for nonmelanoma skin cancers, demonstrating clearly the increased cancerogenic potency of short-wavelength UV.

All types of skin cancer show a worldwide dramatic increase. This is not only the case for the comparatively harmless basal and squamous cell carcinoma but also for the very aggressive melanoma. Figure 23.14 summarizes data obtained in British Columbia illustrating this alarming development. It is certainly not due to the reduction in stratospheric ozone but presumably to changed leisure habits and possibly also the increased use of sunbeds and other tanning devices.

Ozone depletion will add to this situation. Evidence is mounting that this is not a theoretical possibility only. It can now be seen worldwide, although the most dramatic effect has been registered in Antarctica. Future trends are difficult to predict and depend essentially on the use of chlorofluorocarbon compounds. It has to be kept in mind, however, that atmospheric chemistry operates at long timescales. A comprehensive review of all problems involved can be found in SSK, 1996.

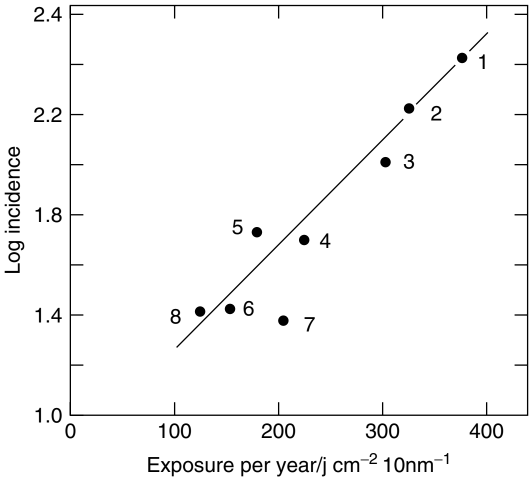

Fig. 23.13 Skin cancer as a function of UV-B exposure in different countries (after Gordon and Silverstein, 1980): 1, Australia; 2, Texas; 3, South Africa; 4, Nevada; 5, Canada; 6, England; 7, Germany; 8, Scotland.

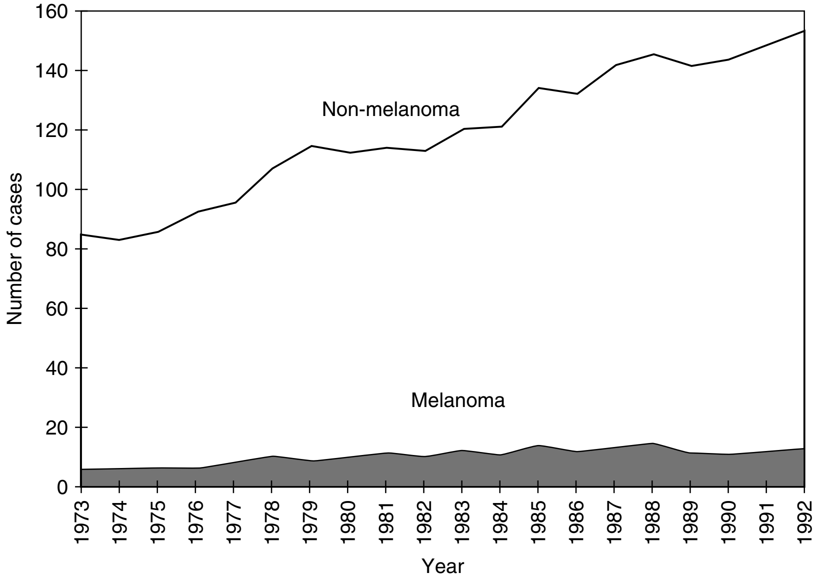

Fig. 23.14 Increase in nonmelanoma and melanoma skin cancer in British Columbia from 1973 to 1992 (Philips *et al.*, 1996).

23.7.3.2 **Ionizing Radiation**

With ionizing radiations no organ is spared from possible tumor formation although the probabilities vary. So do the latency times, that is, the period that elapses between exposure and the clinical manifestation. They span a wide range, which is considerably larger than the mean lifetime of common experimental animals like mice or rats. This means that for a quantitative assessment one can only have recourse to retrospective human data. They are available from a number of groups that received radiation either occupationally, accidentally, or as part of medical treatment. UNSCEAR continuously reviews all available studies and provides actual updates (the last one in UNSCEAR, 2008).

The most important source is still the follow-up of survivors of Hiroshima and Nagasaki, commonly called the *Life Span Study* (LSS). They constitute a cohort of about 100 000 people for which complete medical records are available. The determination of dose presents a problem. Approximate values were initially calculated in 1965 from the then-accessible bomb data and the evaluation of the exact location of each single victim relative to the epicenter. The doses thus obtained were termed *T65D* ("tentative doses 1965"). The calculations gave a higher neutron component for Hiroshima, and the comparison of leukemia cases in both cities provided thus an estimate for neutron RBE, which formed the basis for the recommendation of quality factors in radiation protection (see Section 23.9.2). A reevaluation led to a revision of the original estimates with the main results that the doses were slightly (by about a factor of 1.5) lower than previously thought and, more seriously, that the previously postulated difference in neutron contribution is only very small and insufficient

Tab. 23.5 Recent major epidemiological studies on cancer risk by ionizing radiations.

	Time period	No. of people	Person years	Reference
LSS incidence solid tumors	1958–1998	105 427	2 764 730	Preston *et al.*, 2007
LSS mortality solid tumors	1950–1997	86 572	3 062 046	Preston *et al.*, 2003
LSS incidence leukemia	1950–1987	93 696	2 778 000	Preston *et al.*, 1994
Workers solid tumors and leukemia	variable (1943–1997)	407 391	5 192 710	Cardis *et al.*, 2005

for a reliable RBE determination. This system is referred to as *DS*86. Recently another revised system has been established (DS 02) (Young and Kerr, 2005) which had, however, only minor influence on risk estimates (Table 23.5).

There are two ways to analyze existing data, namely, in terms of *absolute* and *relative* risk. In the first case it is assumed that radiation induces cancers on top of those occurring spontaneously; in the latter it is postulated that radiation increases the already prevailing risk by a dose-dependent factor, which means that the tumor types expected to have the highest numbers after radiation are those that already have a high prevalence in the population. Tumor rates (TR) may then be formally expressed as

$$TR = TR_{sp} + g_a(D) \quad \text{(absolute risk model)} \qquad (20)$$

or

$$TR = TR_{sp}[1 + g_r(D)] \quad \text{(relative risk model)} \qquad (21)$$

where TR_{sp} represents the spontaneous tumor rate, which depends, of course, on age, sex, tumor type, and other factors, and g_a and g_r are the absolute and relative risk factors, respectively. They are also functions of age, sex, and so on, but particularly of dose. The kind of relationship to be applied is still under debate, especially whether a linear or a linear-quadratic dose dependence is more appropriate. It is not possible to arrive at unambiguous decisions for the time being, so that linearity is commonly assumed as a prudent method of hazard estimation.

The time course of tumor appearance differs between leukemia and solid tumors. While leukemia has only comparatively short latency periods of 8–15 years, solid tumors manifest themselves only after much longer periods of time and tend to accumulate later in life. Figure 23.15 displays yearly rates of radiation-induced tumors for different periods of observation. The total number of deaths for the entire time 1950–1990 amounted to 334 caused by solid tumors and 87 due to leukemia (out of a population of 86 000).

Radiation-induced solid tumors seem to follow roughly the age behavior of spontaneous tumors so that the model of relative risk is applicable if allowance is made for the fact that there is some reduction in excess relative risk with

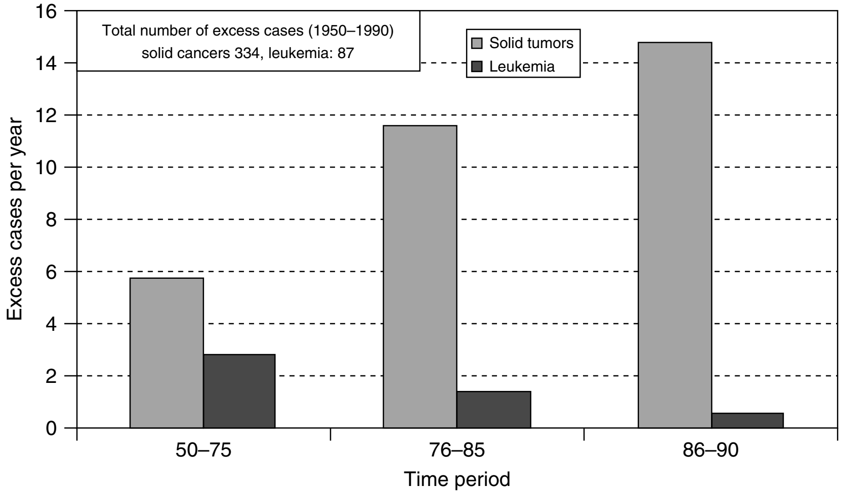

Fig. 23.15 Excess tumor cases per year for different time periods after exposure (after data from Pierce *et al.*, 1996).

increasing attained age. Leukemia, on the other hand, shows up comparatively early and does not depend very much on attained age. The rate of new cases decreases with time and it may be assumed that now, more than 50 years after exposure, no new cases are to be expected. "Excess relative risk" is thus not a really appropriate indicator for leukemia.

The long-term follow-up of the Japanese bomb survivors has seen not only revisions in dose determinations but also reappraisals of the medical findings. Because of the long latency periods, malignancies other than leukemia can only be properly assessed after many decades.

These data are now available, which led to a substantial increase in risk estimates. A matter of special concern is the finding that children exposed at young age are considerably more susceptible to radiation-induced tumors than previously assumed. This conclusion could not be reached before because most cancers develop only late in life. These stages are now seen in those people who were very young at the time of bombing.

Figure 23.16a gives incidence "excess relative risks" (relative risk – 1) for a number of cancer sites. Figure 23.16b shows the respective mortality estimates.

More recently, tumor mortality has also been studied in people occupationally exposed to radiation. In principle, it could be expected to obtain more reliable data as doses are continuously monitored and the health status is usually also regularly checked. The doses incurred, however, are rather small so that the statistical power is expected to be limited. This is borne out by a recent worldwide pooled study (Cardis *et al.*, 2005). Nevertheless, it was possible to obtain risk estimates for solid tumors and leukemia. They are slightly higher than those from the LSS in Hiroshima and Nagasaki but well within the error margins (Figure 23.17). It is noteworthy that the workers are exposed to radiation continuously at lower dose rates. There is no indication that the effect

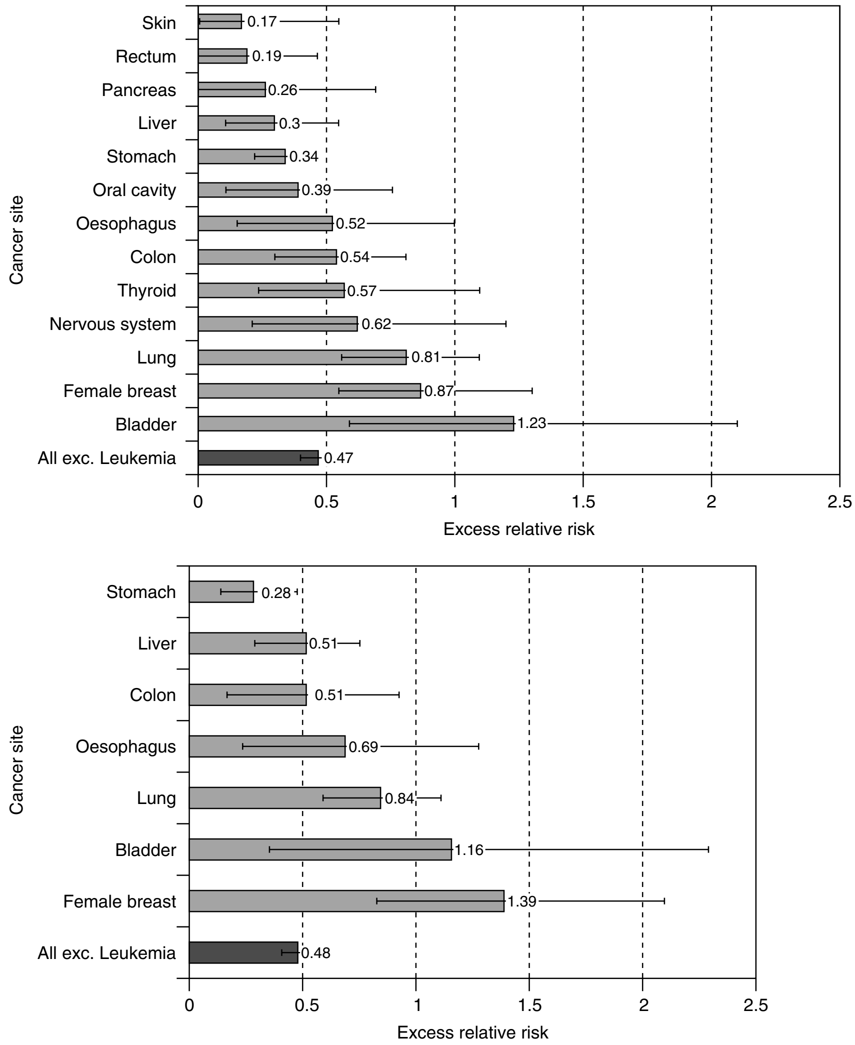

Fig. 23.16 (a) Excess relative incidence risks (RR) estimates for solid cancer at different sites (Preston *et al.*, 2007). The error bars indicate 95% confidence intervals (b) as in Figure 23.16a but for mortality (Preston *et al.*, 2003).

level is reduced because of this exposure condition.

The American BEIR Committee (BEIR, 2005) analyzed all available data to estimate the lifetime risk. Figure 23.18 summarizes some of their results. It gives the percentage risk for cancer incidence and mortality of solid cancers and leukemia after an exposure to 0.1 Gy. There is a marked difference between males and females, the latter being clearly more sensitive. The total risks for incidence after a dose of 0.1 Gy are 0.9% for men and 1.4% for women. The respective figures for fatal cancers are 0.5 and 0.7%.

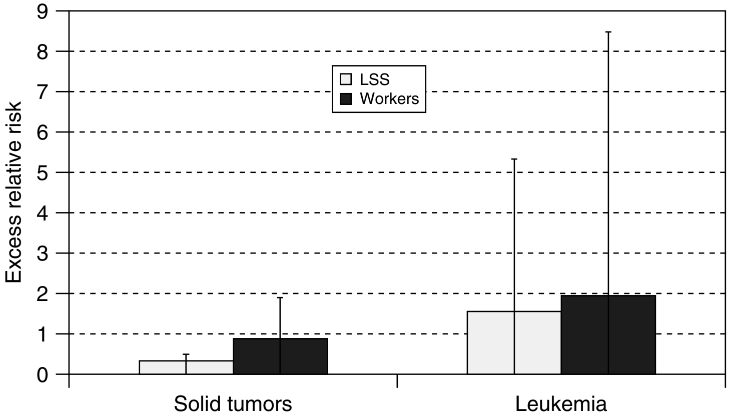

Fig. 23.17 Comparison of mortality excess relative risks from epidemiological studies in occupationally exposed people (‘‘workers’’) and the Life Span Study (LSS) of survivors in Hiroshima and Nagasaki (Cardis *et al.*, 2005). The Japanese data were reanalyzed by Cardis *et al.*, (2005).

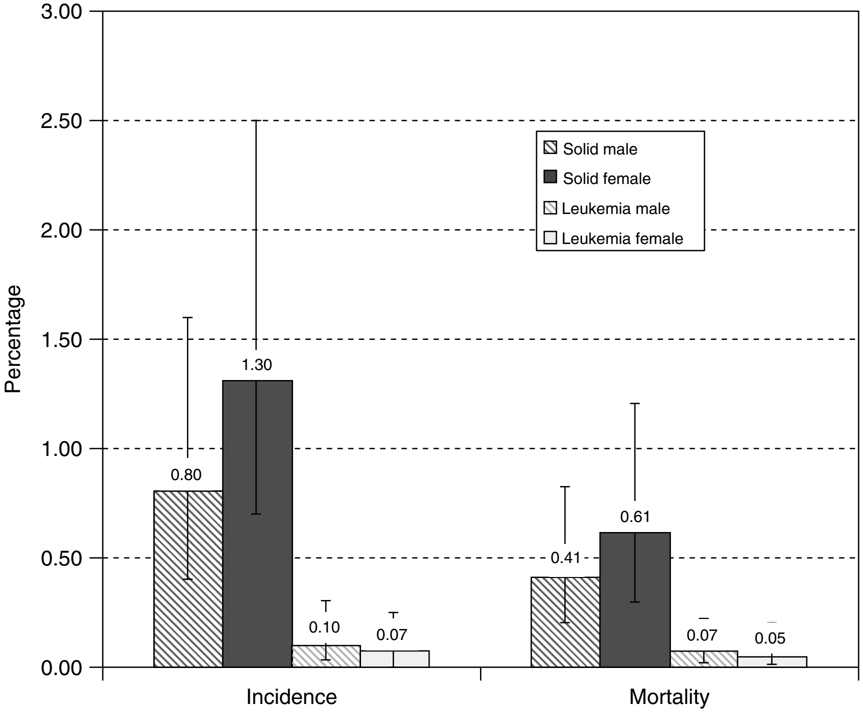

Fig. 23.18 Lifetime risks after an exposure to 0.1 Gy of ionizing radiation (after data from BEIR, 2005).

Another important source of radiation-induced tumor initiation in humans is the epidemiology of uranium mine workers. They are exposed to α particles of ^{222}Ra and its daughter products, which cause lung cancer. There is quite a number of studies on this topic, which were summarized and analyzed in the BEIR VI report (BEIR, 1999). Radon plays a significant role in the normal environment also (see Section 23.9.1.2, Environmental Radiation Impact).

23.7.4
Tissue and Whole-Body Effects of Infrared Radiation

Because of the weak penetration ability of IR, the organs most at risk are the eye and the skin. Penetration depth depends on wavelength: IR-A penetrates deeper (to several mm) than IR-B or IR-C.

The most important eye damage is cataract formation, which has often been reported as a result of long-term exposure to comparatively weak IR sources. With the widespread use of lasers this hazard has to receive special attention. The most effective wavelength region appears to be IR-A. Although there appears to be common agreement that a threshold exists for cataract formation, it has so far not yet been clearly defined. The exposure limits currently recommended (Section 23.9.2.2) are assumed to be on the "safe" side. With higher exposures retinal burns may also be found.

The effects on the skin are due to local heating and depend on the penetration depth, which is a function of wavelength. There may be considerable differences with skin type and pigmentation. With low exposures, erythema-like reddening is seen; higher levels may lead to edema, blisters, and burns.

As a delayed effect "erythema *ab igne*" may be seen. It appears at skin areas that were repeatedly exposed to higher temperatures not sufficient to cause burning (ICNIRP, 2006). In very rare cases, carcinomas may also be an aftermath of this condition.

23.7.5
Tissue and Whole-Body Effects of Radio Frequency and Microwaves

Possible or suspected carcinogenic actions of RF and MW radiation have recently gained considerable attention in public discussion because of the widespread use of mobile communication. Organ and whole-body effects may be due to two phenomena: heat production and electrical or magnetic interferences. Although there is a wealth of literature reports, no clear picture has yet emerged, much less a coherent theoretical interpretation. There is no sound evidence for carcinogenic, mutagenic, or teratogenic action. Impairment of fertility can be caused by temperature increase in the testis since this organ is known to be particularly heat sensitive. The same might apply to the embryo but there is no proof so far that, for example, diathermia may lead to malformations. Local overheating can also lead to cataracts in the eye but the SAR values necessary are far beyond present protection limits (Elder, 2003).

A large epidemiological study on cancer and mobile communication is presently under way in a number of European countries ("INTERPHONE study"). As a common design is used, it is planned to pool all results to provide a large database. Parts have already been published (Berg *et al.*, 2006). No associations between brain tumors and mobile phone use could be found. A negative finding was also reported for acoustic neurinoma in Japan (Takebayashi *et al.*, 2006).

Induced electrical currents can interfere with nerve action. Changes in electroencephalograms have been reported but the techniques employed are subject to criticism. Very high fields can cause respiratory tetanus, that is, the inability to breathe due to muscle contraction, and even to uncoordinated asynchronous heart contractions. It is conceivable that lower levels may change behavioral performance; this is indicated by some animal studies, but studies with human subjects are inconsistent.

A recent critical review may be found in Valberg, van Deventer, and Repacholi (2007).

It should be noted that special conditions prevail for electronic equipment on or in the body, like hearing aids or cardiac pacemakers.

23.8
Applied Radiation Biology

There are quite a number of radiation techniques in the life sciences; only a few can be briefly reviewed here. Diagnostic radiology and the use of radioisotopes as tracers are completely omitted because radiation *action* is not the essential determinant in these cases. The range of applications extends from molecular biology to medical therapy and food preservation; examples will be given. Only basic principles can be discussed; detailed prescriptions would be out of scope.

23.8.1
Molecular Techniques

23.8.1.1 Action Spectroscopy

UV and visible radiation can only exert a biological action if it is absorbed by a suitable chromophore. The dependence of a given biological effect on wavelength can, at least in principle, be used to identify the responsible component by means of its absorption spectrum. This is the basic idea of "action spectroscopy." Despite its impressive simplicity it is not free from pitfalls and requires careful consideration if erroneous conclusions are to be avoided. There are a number of necessary conditions which are not always easy to fulfill:

1. The fluence dependence of the effect should be similar for all wavelengths, that is, the response curves should be superimposable if the fluence is appropriately scaled by a constant factor for each wavelength. If this is not the case, the reaction is most likely caused by different mechanisms.
2. The quantum yield Q should be the same at all wavelengths.
3. The absorption spectrum of the chromophore in the system must be known, or it must be determined that it does not differ from that in its pure form.
4. Absorption and scattering of substances not taking part in the primary reaction must be known if they cannot be neglected.
5. The chromophore absorption should not be too high, to avoid saturation effects.
6. The effect should be independent of fluence rate since this often varies widely with different wavelengths ("reciprocity").

Response curves may have very different shapes, sometimes well defined in mathematical terms but mostly not. To exclude any possible bias, action spectroscopy should always be based on the *same* effect, and the isoeffect fluences should be compared.

If one is dealing with the same mechanism over the whole range (condition 1) and if the quantum yield Q is constant (condition 2), it can be safely assumed that the same effect is caused by the same number of primary alterations. Their number depends on the quantum yield and the number of quanta absorbed; thus, when comparing the same effect at two different wavelengths,

$$Q\sigma_{\text{abs}}(\lambda_1)\phi(\lambda_1) = Q\sigma_{\text{abs}}(\lambda_2)\phi(\lambda_2) \tag{22}$$

where σ_{abs} is the absorption cross-section and ϕ the quantum fluence. Since $Q =$ constant, one obtains

$$\phi(\lambda_1)/\phi(\lambda_2) = \sigma_{\text{abs}}(\lambda_2)/\sigma_{\text{abs}}(\lambda_1) \tag{23}$$

The actual task is to determine the quantum fluence necessary to produce a given effect as a function of wavelength. Since σ_{abs} is proportional to the extinction coefficient $\in$, one may also write

$$\phi(\lambda_1)/\phi(\lambda_2) = \varepsilon(\lambda_2)/\varepsilon(\lambda_1) \tag{24}$$

If the measured quantity is not the quantum fluence but rather the energy fluence F_E, the relation becomes

$$F_E(\lambda_1)\lambda_1/F_E(\lambda_2)\lambda_2 = \varepsilon(\lambda_2)/\varepsilon(\lambda_1) \tag{25}$$

In practical action spectroscopy, $1/F(\lambda_1)\lambda_1$ is usually normalized to a reference wavelength and plotted versus wavelength. If the above conditions are fulfilled, the resultant curve should be equal to the chromophore's extinction spectrum.

23.8.1.2 Molecular Weight Determination by "Radiation Inactivation"

Nearly all techniques for the determination of molecular weights of biological macromolecules require the separation of the particular component. Apart from the experimental effort involved they cannot be used in those cases where, for example, an enzyme loses its specific activity if it is removed from its supporting matrix. This is very often the case with membrane-bound proteins. Their molecular weight may be estimated from the inactivation doses upon γ- or X-ray exposure. In most cases an exponential relationship is found between enzyme activity and dose:

$$y = e^{-kD} \tag{26}$$

where y is the remaining activity, D the dose, and k the "inactivation coefficient." If one assumes that the indirect effect (see Section 23.5) can be neglected and that a fixed energy absorbed per molecule suffices for inactivation, one may also write

$$y = e^{-mD/\varepsilon} \tag{27}$$

which forms the basis for the application. Here m is the molecular mass and $\in$ the "critical energy," which has been found to be 66 eV for γ-rays with energies >1 MeV. Over about two orders of magnitude there is a good proportionality between analytical (obtained by conventional techniques) and radiological molecular weight. The upper limit of the applicability lies around 10^8 g/mol (Kempner, 1988; Beauregard *et al.*, 1987).

23.8.2
Radiation Disinfection and Sterilization

Microbial contaminations are a major source of concern in food and drinking water production and in other branches of industry. In many cases they are fought by the application of chemicals which, however, may also pose a health hazard. Although radiation could serve as a convenient and generally less hazardous alternative, its acceptance – at least as far as human consumption is concerned – meets with considerable reservations in public, which are very often based on misconceptions. Sterilization of technical products, on the other hand, is already standard practice.

The discussion in this section will be restricted to UV and ionizing radiation. IR and MWs can also be used under certain circumstances but their action is exclusively through heat production, and a treatment of the problems of heat sterilization is clearly out of scope of this chapter.

UV is in principle a very convenient and comparatively inexpensive tool to kill contaminating microorganisms. Its applicability is severely limited, however, by its low penetration power. It can therefore only be applied for surface decontamination and with fluids transparent to the wavelength range applied. Although pure water does not absorb in the region between 200 and 300 nm, in most cases dissolved or suspended constituents prohibit the use of UV for the processing of drinking water. By constructing appropriate exposure devices where the effective penetration depths can be kept short, this problem could eventually be circumvented. The cost factor has to be taken into account, but it must be weighed against the possible benefits, which lie in the avoidance of toxic and unpleasant chemicals like chlorine.

The most effective wavelengths as deduced from the action spectrum of cell inactivation are around 260 nm, making the low-pressure mercury lamp (which emits essentially only 254 nm) the source of choice. Its applicability is, however, limited by the comparatively low irradiances available so that high-pressure mercury lamps also have to be taken into consideration. Since they emit a much broader spectrum, photochemical reactions with chemical contaminants must be considered.

The use of ionizing radiation is currently heavily debated, particularly with regard to food irradiation. It is feared that it may cause unforeseen hazards to the general population, but the arguments are rarely based on solid scientific facts. Some of the points raised are as follows.

1. *Nutritive value may be lost.*
   It is true that certain vitamins like A, E, thiamin, pyridoxine, and ascorbic acid are to a certain extent destroyed by irradiation. Fatty acids undergo changes that may influence flavor and odor. Foods with high water content may change their texture after irradiation. These statements are certainly true, but they must be judged against the effects of other ways of food processing, such as heat sterilization or the addition of chemical preservatives.

2. *Radiation may produce toxic products.*
   Doses necessary for a sizable reduction of microbial contamination do cause radiation-chemical processes. Animal experiments on a

very large scale have shown, however, that harmful effects are not to be expected. The toxicity involved is certainly less than that of "acceptable" chemical preservatives.

3. *Irradiated food may become radioactive.* This is the argument that causes the most widespread fears, but it is nevertheless wrong. Since nuclear reactions that may lead to induced radioactivity have clear energy thresholds, they can be easily avoided by imposing upper limits, which are 5 MeV for photon and 10 MeV for electron irradiations. Under these conditions there is no induced radioactivity in foodstuff.

There are, however, a few real disadvantages that must not be overlooked:

- The doses normally applied are not sufficient to kill viruses.
- Bacterial toxins produced before sterilization are not destroyed, but this is true also for most other treatments.
- Irradiation may change the microflora in such a way that only the most resistant organisms survive. Their regrowth could lead to "atypical" spoilage, which is not readily recognized, and the food may erroneously be considered safe.

The last three points do not appear to be strong enough to ban food irradiation as an easy and comparatively cheap and safe way to reduce considerable losses by contamination and spoilage. As a consequence a special committee of the European Community recommended food irradiation as an allowed means of preservation (Urbain, 1986). The European Union (EU) publishes yearly reports about food irradiation in its member states, the last one available is for 2005 (European Union, 2007). In the United States, wheat and wheat flour may be irradiated with doses up to 0.5 kGy, pork up to 1 kGy, dry enzyme preparations up to 10 kGy, and dry vegetable seasonings up to 30 kGy. With these doses, reduction but never a complete eradication of the contaminants is achieved. Higher doses may, of course, be applied for the sterilization of technical products that are not for human consumption. Current information is provided by the FDA website (http://www.cfsan.fda.gov/~dms/opairrad.html).

For more detailed discussions, the reader is referred to (Molins 2001; Sommers and Fan 2006).

23.8.3
Therapeutic Applications

23.8.3.1 Nonmalignant Diseases

Ionizing radiations are nowadays mainly used for cancer treatment; but they are also applied to the treatment of nonmalignant diseases, for example, arthritis or macular degeneration (see Meyer, 2002; Seegenschmiedt, Micke, and Willich, 2004). There is, of course, always the risk of cancer induction to be taken into account but as the patients involved are usually of older age this is not considered to outweigh the expected benefits.

IR radiation serves as a convenient method for heating certain parts of the body, but the action is not specific for its radiative nature and hence will not be discussed. Radio waves and MWs are also used to increase the temperature at deeper sites in the body ("diathermy"), which has also found applications in cancer therapy. The beneficial action of electric and magnetic fields has sometimes been claimed, but it still waits for solid experimental evidence and is, therefore, not treated.

UV light is commonly believed to improve health, although there is no basis for such a general statement. The wide distribution of tanning studios reflects a psychological rather than a physiological impact. It is quite clear that their frequent use presents a considerable danger to acquire skin cancer. This is particularly the case for juveniles. ICNIRP has, therefore, published a strong warning against the indiscriminate use of tanning appliances (ICNIRP, 2004a).

There are, however, a few cases where UV treatment is indicated. Rickets, which is caused by vitamin D deficiency, does not play an important role nowadays and is mentioned only for historical reasons.

There are, however, a number of special cases where phototherapy can be successfully applied:

- Hyperbilirubinemia is a condition sometimes occurring in newborns. It is characterized by an increased blood bilirubin level, a decay product of hemoglobin. It may be treated by exposure to blue light, which is thought to stimulate the further decomposition of this metabolic product.
- The UV treatment of skin tuberculosis is today only of historical interest. More important is the treatment of two particular skin diseases: vitiligo and psoriasis. The first one expresses itself in the form of nonpigmented circumscribed areas, while the other is typified by sharply defined red-covered spots caused by a misregulation of epithelial cell divisions. It is estimated to be found in 1–5% of the population. The classical way to treat these diseases was to deliver series of UV-B exposures; nowadays photochemotherapy is preferred. A photosensitizer is given, either by local injection or orally, and the skin is exposed to UV having a wavelength coinciding with the maximum of the sensitizer's action spectrum. Tar preparations were formerly used, but today psoralens are exclusively applied. The best results appear to be obtained with 8-MOP. The most used wavelengths are around 360 nm, that is, in the UV-A region; hence the name PUVA (=psoralen + UV-A) was given to the method. Since PUVA has been shown to cause mutations in *in vitro* systems, a possible carcinogenic action must be taken into account. However, so far there has been no evidence of skin tumors from observations on a large number of patients. Nevertheless, further careful supervision is warranted, particularly in view of the very long latency periods involved.

23.8.3.2 **Cancer Therapy**

The "classical" radiation therapy of tumors uses quantum or electron radiation provided commonly by linear accelerators. The energy is adjusted in such a way that the dose maximum lies at the tumor site. By careful treatment planning using multiple beams and beam shaping by custom-made absorbers, the tumor volume can be delineated and the healthy tissue spared to a great extent. This technique has now reached a high degree of sophistication.

Intensity-modulated radiation therapy (IMRT) is a new approach, which has the potential to revolutionize classical radiation therapy (Cash, 2006). With the help of imaging techniques like computed tomography (CT), positron emission tomography (PET) and magnetic resonance tomography (MRT) a three-dimensional picture of the tumor and its surrounding tissue is constructed forming the basis for treatment planning. The images are coupled to the multileaf collimator at the head of the linear accelerator, which is moved around the patient in such a way that a true conformal dose delivery is possible. The X-ray beam is subdivided into numerous small "beamlets" whose intensities are adjusted in such a way that the tumor and more resistant parts receive higher doses than the surrounding healthy tissue. In this way one can achieve a high degree of sophistication in individual exposure schemes to reach local control of the tumor with (at least theoretically) maximum sparing of nearby critical structures. IMRT appears to be particularly applicable to prostate and head and neck cancers. It is assumed that in this way the advantages of particle therapy may be approached without the need for expensive particle accelerators that are not available in standard clinics.

IMRT requires a correct positioning of the patient during treatment and a close spatial agreement with the treatment plan. Movements of the patient or of internal organs, for example, by breathing, can lead to substantial shifts in the dose distribution so that parts of the tumor may be missed and healthy organs overdosed. This problem may be overcome by image guided radiotherapy (IGRT) (Dawson and Sharpe, 2006) where images of the tissue containing the tumor are recorded immediately before or during treatment and local dose distributions adjusted. IGRT is still in the experimental stage and requires considerable effort of physicians and medical physicists but it offers the potential of remarkable improvements.

More recently, particle therapy has also gained some importance. The most widely used is based on protons. Since they deliver most of their energy just before the end of their range, very good dose discrimination can be achieved. There is typically a dose factor of 5 between the so-called *plateau* and the *peak* regions. As the dose maximum is very sharp, small tumors can be very effectively treated with an optimal sparing of the surrounding areas. This technique has been applied especially to ocular melanomas; several thousand patients have so far been treated with excellent results. Not only could the tumor be locally cured, but also eyesight could be saved to a large extent in most cases. While in the beginning, treatments were performed with accelerators built for research in physics (the forerunner being Boston, Massachusetts, U.S.A.), more recently "dedicated" machines have been established in specialized hospitals.

Protons possess a very favorable dose distribution, but their biological effectiveness is not much different from that of γ- or X-rays as a consequence of their comparably low LET. To deliver an even higher "biological" dose and overcome complications like the "oxygen effect," heavier ions are required. Studies along this line started many years ago in Berkeley, California, USA, but had to be terminated because of the shutdown of the accelerator. Meanwhile two new studies were started, one in

Chiba, Japan, where a dedicated heavy-ion accelerator was built, and the other in Darmstadt, Germany, which made use of the existing heavy-ion accelerator and is still in the preclinical study phase. A new method for treatment planning has here been developed where the beam energy is modulated in such a way that the treatment volume matches the tumor as closely as possible ("raster scan"). The technology developed in Darmstadt has been transferred to a new specialized clinical center in Heidelberg (Germany), which will presumably open in summer 2009 (Schulz-Ertner, Jakel, and Schlegel, 2007).

A recent review lists a total of more than 56 000 patients who have been treated so far by particle therapy, with the majority being treated by protons 49 000. There are presently 26 medical proton facilities worldwide in operation and three using carbon ions. Quite a number is in the planning or building state. Reviews about clinical experiences are provided by Schultz-Erkner, Jakel, and Schlegel (2007), Schultz-Erkner and Tsujii (2007), and Greco and Wolden (2007). The Particle Therapy Co-Operative Group (PTCOG) operates a website where all current developments are listed (http://ptcog.web.psi.ch/).

23.8.4
Biodosimetry

23.8.4.1 Fluorescence *In situ* Hybridization (FISH) for Chromosomal Translocations

Chromosomal aberrations are discussed in Section 23.5.3. Apart from their fundamental relevance they are an important tool of biodosimetry. If lymphocytes taken from exposed individuals are cultivated *in vitro*, aberrations can be scored and used as an indicator of dose. Classically, dicentric chromosomes ("dics") are used for this purpose since they are comparatively easy to recognize. The lowest dose limit resolvable is about 0.1 Gy with X- or γ-rays. Dics interfere with further cellular proliferation; 50% of the cells carrying them will die at every division. This means that these "unstable" aberrations will rapidly fade out so that reliable dose estimates are impossible after months or years. Translocations, on the other hand, are stably transmitted to the progeny, allowing in principle biodosimetry at any time, even after decades. Technical problems of their scoring prevented their use until the so-called fluorescence *in situ* hybridization (FISH) for chromosomal translocations technique was introduced. Studies have shown that translocations persist indeed much longer than dics. Their dose dependence is similar to that of dics, and the detection limit lies in the same range (about 100 mGy for γ-rays). The issue of biodosimetry by chromosomal aberrations is discussed by Sevan'kaev *et al.* (2006) and by several authors in Obe and Vijayalaxmi (2007).

23.8.4.2 ESR Dosimetry

Ionizing radiation induces the formation of free radicals in the exposed tissue, but their lifetime is usually very short. This is not the case if they are created in a solid matrix where their mobility is severely restricted. In this case they may persist for very long periods and may thus be detected by ESR, for example, in teeth or bone. The method has practical applications both in radiation protections and in radiotherapy. It can also be applied to irradiated food (Sevan'kaev *et al.*, 2006; Regulla, 2005).

23.9
Radioecology, Radiation Protection, and Guidelines

Possible hazards by radiation constitute a matter of great public concern. Although it was originally concentrated on "radioactive radiation" (this misnomer is used here only as a quotation, obviously meaning "ionizing radiation") it has recently been extended even into the field of RF and MW radiation. Possible dangers have long been recognized and regulations established to protect those people professionally exposed to radiation. This is at least true for ionizing radiation for which the regulation system is most advanced. Because of this the discussion will concentrate mainly on "radiological protection" since the recommendations for nonionizing radiations are developed to a large extent on the basis of a similar philosophy. Before dealing with the matter, it is appropriate to discuss briefly the impact of radiation sources in the environment.

23.9.1
Radioecology

23.9.1.1 Nonionizing Radiations

Radioecological problems involving nonionizing radiation are restricted to photochemical processes in the atmosphere. Ozone (O_3) plays a central role here. It is photochemically formed by light absorption in the wavelength range around 240 nm. The maximum of its absorption spectrum coincides roughly with that of nucleic acids; compared to O_2 it is shifted toward longer wavelengths. This means that ozone formation is favored in the upper layers of the atmosphere, while its destruction prevails in lower regions since both reactions are part of a complete steady state. A reduction of the ozone belt would lead to a shift of the solar spectrum on the Earth's surface toward shorter wavelengths. It is estimated that a decrease by 10% would double the fraction of solar radiation at 290 nm (Caldwell *et al.*, 2007; Rowland, 2006).

Estimating the biological risk is not easy. There are a number of studies on the effect of increased short-wavelength UV in plant communities and marine ecosystems. The results are inconclusive so far; it appears that there is a high buffering capacity for varying amounts of UV light. The expected increase of skin tumors in humans appears to be the most important risk.

23.9.1.2 Ionizing Radiation

With regard to human radiation hazards, a distinction must be made between external and internal exposure. In the first case only electromagnetic radiations, neutrons, and a few energetic electron sources are of any practical concern. Internal exposure is brought about by the incorporation of radionuclides via ingestion with food or inhalation. Environmental radioactivity can enter the food chain in a number of ways. Most important is the uptake from water and soil by plants and animals or directly in the drinking water. Here all radionuclides have to be taken into account, and α emitters play a particular role since they deposit energy with high LET.

For the assessment of doses, one must consider all the transfer probabilities from the original source to the final deposition in the body. Additionally the dose distribution inside the organs affected, either directly by incorporation or indirectly by exposure from a distance, has to be computed. To facilitate the solution, the path of radioactivity in the environment is broken down into a number of transfer compartments. The whole web can be treated as a system of coupled linear differential equations. The most important parameters are the transfer coefficients, which give the fraction of a given compound transported from one compartment to another. Transfer coefficients depend only on the chemical nature and are, therefore, equal for different isotopes of the same element. They can be used to estimate the expected radioactivity in food or milk if the extent and kind of environmental contamination are quantitatively known.

To assess the impact on human populations, food consumption has to be taken into account. This cannot be done in an exact way since personal lifestyle and regional habits may lead to wide variations. The fate and radiological importance of incorporated radioactivity depends on the chemical nature of the compound as well as on the physical properties. The length of expected exposure is determined by the effective half-life $T_{(1/2)\mathrm{eff}}$, which is composed of the physical decay ($T_{(1/2)D}$) and the biological excretion probability ($T_{(1/2)B}$) according to

$$1/T_{(1/2)\mathrm{eff}} = 1/T_{(1/2)D} + 1/T_{(1/2/)B} \tag{28}$$

Most radionuclides are not distributed equally in the human body but show certain organ specificities. A well-known example is iodine, which is selectively enriched in the thyroid. Organ specificity must be taken into account for hazard evaluation. On the basis of physiological, chemical, and physical data, it is possible to calculate organ and whole-body doses that can be expected after the incorporation of a given amount of a certain radionuclide. A few examples are listed in Table 23.6.

Environmental Radiation Impact

Natural sources There are wide variations in doses received by the general public depending on occupation, terrestrial environment, and even housing. Natural sources are still most important. Cosmic space radiation contributes significantly even at sea level but the doses increase, of course, with altitude. It may be estimated that the dose rate at 11 km (typical cruising altitude of passenger aircraft) is about 6 μS per hour (see Section 23.9.2.1, Basic Principles, Quantities, and Units, for definition of Sv). Environmental radioactivity from long-lived radionuclides surviving from the formation of the earth ("primordial radionuclides") contributes both to exposure from the outside (only γ radiation) or to internal irradiation via ingestion or inhalation.

Table 23.7 lists average values as estimated in a recent UNSCEAR report (2000). Data are given as "effective doses" in mSv. The world average of the total is 2.4 mSv but there may be very wide variations because of different geological conditions. There are areas (e.g. in India or Brazil) where the natural background is one order of magnitude larger than the world mean.

Radon (^{222}Ra) and its immediate daughter products contribute obviously the largest share of environmental radiation hazards. They originate from the underground and building materials and may concentrate in housings. It is well known from uranium miners who are exposed to high concentrations that the

Tab. 23.6 Dose factors for conversion of radioactivity taken up by ingestion in effective whole-body or organ doses. Calculations for adults (>17 years of age) and for new born children (< 1 year of age). Data from ICRP (2002).

Nuclide	Whole body ($Sv\ Bq^{-1}$)		Organ ($Sv\ Bq^{-1}$)		Affected organ

Tab. 23.7 Estimated per capita annual effective dose equivalent from natural sources in areas of normal background (UNSCEAR, 2000).

Source	World average annual effective dose (mSv)	Typical range (mSv)
Cosmic radiation	0.4	0.3–1.0
Terrestrial external	0.5	0.3–0.6
Inhalation (mainly Radon)	1.2	0.2–10
Ingestion	0.3	0.2–0.8
Total	**2.4**	**1–10**

inhalation causes lung cancer (BEIR, 1999). Extensive new epidemiological studies in Europe (Darby, Hill, and European Collaborative Group on Residential Radon and Lung Cancer, 2003) and the United States (Field *et al.*, 2006) show that radon also plays an important role in residential dwellings and may contribute significantly to lung cancer morbidity and mortality in nonsmokers.

Man-made radiation sources Figure 23.19 surveys the contribution of nonnatural radiation sources to the

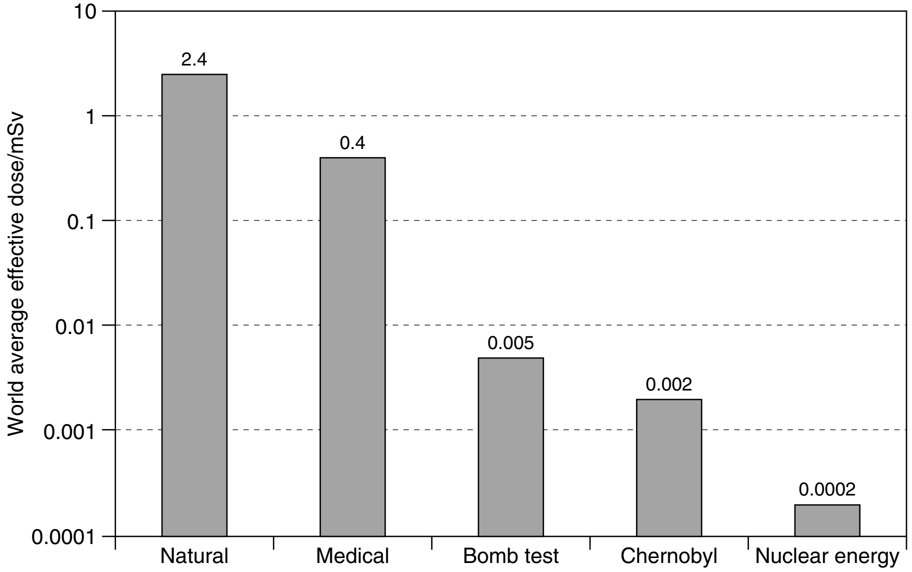

Fig. 23.19 The contribution of man-made radiation to the global radiation budget (data from UNSCEAR, 2000).

exposure of human populations at a global scale. Medical applications (essentially only radiodiagnostics) are most important although there are very wide variations between countries. Japan, Germany, and the United States give values of around 1–2 mSv per year, and there is a tendency for further increases.

Atmospheric testing of nuclear weapons was banned and stopped in 1963, but there are still remains of the radioactivity released at those times. The world average of the contamination by the Chernobyl accident in 1986 is now relatively low but the level depends very much on the distance and is still considerably larger in the countries originally affected (see next section). Nuclear energy production with presently about 450 plants in operation worldwide gives only a very small proportion, but this is, of course, only valid for normal undisturbed working conditions.

Medical exposures constitute an important branch of the health system in developed countries. There is no question of the justification but it must be acknowledged that medical exposures also constitute a certain risk. The doses depend on the particular examination and the technique employed. Computed X-ray tomography provides impressive images but the dose per examination is about 10 times higher than with conventional techniques. Table 23.8 lists a few examples. Doses are given as ''effective doses'' although this concept is not really appropriate but it may serve as a convenient means of comparison. World averages of frequencies of diagnostic procedures are also given, as well as their relative contribution to total population dose. Computed X-ray tomographies are still comparatively rare (0.6%) but they

Tab. 23.8 Effective doses of X-ray diagnostic examinations, their frequencies, and relative contribution to population dose

Examination type	Effect. dose (mSv)[a]	Frequency (world average) (%)[b]	Percentage of population dose[b]
Chest radiography	0.02–0.05	27	3
Chest fluoroscopy	~0.4	11	10

amount to 34% of the population dose due to medical diagnostic applications. It can already be foreseen that their frequency will rise in future, particularly in developed countries where they are often regarded as a convenient means for a general health check. They are, however, not without risk. With a mean effective dose of 8 mSv a single CT examination corresponds to the exposure on about 80 transatlantic flights.

Impact of the Chernobyl accident The accident in the Soviet reactor of Chernobyl on April 26, 1986, created a widespread radioactive contamination affecting more than 100 000 people in Belarus, Ukraine, and parts of the Russian Federation. Because of uncertain dose assessment, firm epidemiological data are not readily available, but a few conclusions can now be drawn:

1. Acute radiation syndrome was diagnosed in 134 recovery workers who were close to the reactor site. Twenty-eight of them died during the first four months. Eleven more deaths were confirmed in the years 1987–1998 but the causes were not always clearly radiation related (UNSCEAR, 2000).
2. Contrary to common perceptions, there is *no* increase in childhood leukemia, both in the Ukraine and in Belarus. There are indications of a slight increase of leukemia in the group of liquidators but the epidemiological evidence is not

compelling because of methodological problems. It cannot be excluded that cancer rates may rise in future years but this statement is based only on estimates of low-dose risks, which are not proven. In any case, the expected increase is presumably too low to be detectable by epidemiological surveys (Cardis *et al.*, 2006)

3. A dramatic increase in thyroid cancers was found in children and young adolescents caused by the uptake of ^{131}I. In the period 1986–2002 there were 2010 cases in Belarus, 2344 in Ukraine, and 483 in the Russian Federation, giving a total of 4837. As the background rate is rather low, one can assume that most of them are radiation related. Fifteen patients are known to have died; most of the others could be successfully treated. Based on previous experience, one must expect that the number of thyroid cases in those individuals exposed as children will continue to rise (Cardis *et al.*, 2006).
4. There is no evidence for radiation-related stillbirths, miscarriages, and malformations in newborns. It has to be acknowledged, however, that the sequelae of the disaster led to widespread psychological consequences in the whole population, which may have serious health impacts (UNSCEAR, 2000).

23.9.2
Principles of Radiation Protection Regulations

Radiation protection as a system of recommended measures has evolved essentially to protect people occupationally exposed to ionizing radiations from possible harmful effects. It was not the original intention to apply it for the general population, but it is now widely used in this context and constitutes an important issue in political discussion. Since radiation can be measured with high precision and sensitivity and because of the detailed knowledge of biological radiation effects, radiation protection may without exaggeration be considered to be the best-founded approach to the assessment of environmental hazards.

23.9.2.1 Ionizing Radiations

Basic Principles, Quantities, and Units For the purpose of radiation protection, a distinction is made between nonstochastic (formerly also named *deterministic*, more recently (ICRP, 2007) renamed as *tissue damage*) and stochastic damages. The first group comprises effects where the severity increases with dose and where a threshold dose exists (however small it may be). Examples are all acute effects but also radiation-induced developmental malformation as a result of *in utero* exposure. Stochastic damage is characterized by the fact that a degree of severity cannot be given and that only the *probability* of the occurrence is a function of dose. It is generally assumed that in this case there are *no* threshold doses although this is not necessarily inherent to the concept. For protection purposes, one assumes a linear dependence between the probability of the effect and dose (“linear-no-threshold (LNT) concept,” LNT hypothesis). Stochastic effects are germline mutations constituting the genetic risk and cancer.

The physical quantity "dose" is not sufficient for hazard evaluation since the extent of damage depends also on radiation quality, as discussed in Section 23.6.2.4. This was taken into account by introducing a new quantity named *equivalent dose* or more recently "radiation weighted dose" H, used exclusively for radiation protection measurement. It is related to dose D in the following manner:

$$H = w_R D \tag{29}$$

where w_R is the radiation weighting factor that is based on relative biological effectiveness for stochastic effects. Table 23.9 summarizes the recommended values. The International Commission of Radiological Protection (ICRP) in its most recent recommendations (ICRP, 2007) made few adjustments that are also given in the table. If D is measured in Gy, the unit of radiation weighted dose is "Sievert" (Sv). The old unit is "rem" (1 rem = 0.01 Sv).

To convert partial body exposures into whole-body equivalents, the quantity "effective dose" has been introduced. It applies only to stochastic effects and is not intended to be used for risk estimation in specific individual exposure conditions. The effective dose is obtained by multiplying the organ or tissue radiation weighted doses by "tissue weighting factors" w_T, which relate to the organ sensitivities with regard to genetic (in the case of gonads) or cancer risk. They are averaged over the whole population (i.e. all age groups); recommended values are listed in Table 23.10. Organs not specifically mentioned are summarized as "remainder tissues." According to the most recent recommendations (ICRP, 2007) they are composed of 14 tissues: adrenals, extrathoracic region, gall bladder, heart, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate (male), small intestine, spleen, thymus,

Tab. 23.10 Weighting factors w_T for tissues at risk (after ICRP, 1991, 2007).

Tissue or organ	ICRP 60 (1991)	ICRP 103 (2007)
Gonads	0.20	0.08
Bone marrow	0.12	0.12
Colon	0.12	0.12
Lung	0.12	0.12
Stomach	0.12	0.12
Urinary bladder	0.05	0.04
Breast	0.05	0.12
Liver	0.05	0.04
Oesophagus	0.05	0.04
Thyroid	0.05	0.04
Skin	0.01	0.01
Bone surfaces	0.01	0.01
Brain		0.01
Salivary glands		0.01
Remainder	0.05	0.12
Sum	**1.0**	**1.0**

Tab. 23.9 Radiation weighting factors. The most recent ICRP recommendations (ICRP, 2007) give a functional dependence for the neutron weighting factor versus neutron energy.

Radiation type	ICRP 26 (1977)	ICRP 60 (1991)	ICRP 103 (2007)
Photons, electrons	1	1	1
Protons	10	5	2
Neutrons	10	5–20	5–20
α particles, heavier ions	20	20	20

and uterus/cervix. The w_T is used for the average weighted dose of all the remainder organs or tissues. The sum of all weighting factors is unity; they thus give the relative sensitivity with respect to stochastic effects.

Limitation It cannot be overemphasized, particularly for stochastic damage, that there is no "safe" amount of radiation. Consequently, the former usage of the phrase "tolerance doses" has been abandoned. The ICRP states the overriding principle in radiation protection in a rather categorical way by saying that (ICRP, 1977).

1. no practice shall be adopted unless its introduction produces a positive net benefit;
2. all exposures should be kept as low as reasonably achievable, and economic and social factors taken into account; and
3. the dose equivalent to individuals shall not exceed the limits recommended for the appropriate circumstances by the Commission.

The second point is known commonly as the "ALARA principle," which implies that the limits mentioned in Table 23.11 have to be considered as *upper limits* and by no means as "tolerable."

Radiation protection thus rests on three fundamental principles: justification, optimization, and risk limitation.

Since with partial body irradiation, rather high values might result for organs with a low risk factor for stochastic damage, separate limits for nonstochastic damage have also been defined. They are intended to protect from acute damages where threshold doses exist.

Tab. 23.11 Yearly dose limits (ICRP, 1991).

Body, organ or tissue	General public (mSv)	Persons occupationally exposed to radiation (mSv)
Whole-body, effective dose	1	20
Lens of the eye	15	150
Skin, hands, or feet	50	500

Limits are not only given for irradiation from the outside but also for incorporated radioactivity. They are, of course, specific for each particular radionuclide. By use of the conversion factors given in Table 23.8, annual limits of intake (ALI) can be calculated that correspond to the stochastic limit under the assumption that the nuclide in question is the only radiation source. In the case of multiple exposures, the total impact can be calculated according to

$$\sum \frac{w_{Ti} H_{Ti}}{H_{Wb,l}} + \sum \frac{I_j}{ALI_j} \leq 1 \qquad (30)$$

Here H_{Ti} is the dose equivalent of the ith tissue, w_{Ti} is the corresponding weighting factor, $H_{Wb,l}$ is the limit dose equivalent for whole-body exposure, I_j is the yearly intake of the jth radionuclide, and ALI_j is the corresponding annual limit of intake.

The presently recommended limit values are listed in Table 23.11.

23.9.2.2 Nonionizing Radiations

As indicated earlier, the system for radiation protection is most advanced for ionizing radiations. The ICRP is the most influential body in this field in setting out general rules and recommendation for protection measures in this field. There is an analog organization for nonionizing radiations, namely, the ICNIRP that deals – among others – with guidelines for the protection against UV, IR, RF, and MW radiations.

Protection from UV radiation in the wavelength range from 180 to 400 nm (excluding coherent sources like lasers) was treated by ICNIRP in 2004 (ICNIRP, 2004b). Recommended exposure limits are given in terms of "weighted energy fluences" in J/m^2. The weighting function shown in Figure 23.20 follows essentially the action spectrum for erythema induction, normalized to a wavelength of 270 nm. As the unit (J/m^2) is the same as for unweighted radiation, one has to be careful when comparing values from different sources. The eyes and the skin constitute the organs at risk. For the first it is stated that the exposure should not exceed 30 J/m^2 spectrally weighted radiation and also the unweighted exposure should not be larger than 10^4 J/m^2 to avoid damage.

Skin sensitivity depends on the "skin type" with "type I" characterized by a light complexion and subject to sunburn even with little exposure, being the most sensitive. As a guideline it is recommended that the weighted exposure should not exceed 30 J/m^2 to minimize long-term risks such as skin cancer. These limits are intended to be used for the working population and do not apply for therapeutic treatments. It is also clear that extensive sunbathing and/or frequent use of sunbeds leads to overexposure, increasing the risk of skin cancer. The World Health Organization (WHO, 2003) as well as (ICNIRP, 2004a) address this question, which is of increasing concern for public health, in special publications. An extended foundation document on UV protection of workers has been recently published by ICNIRP in cooperation with WHO and

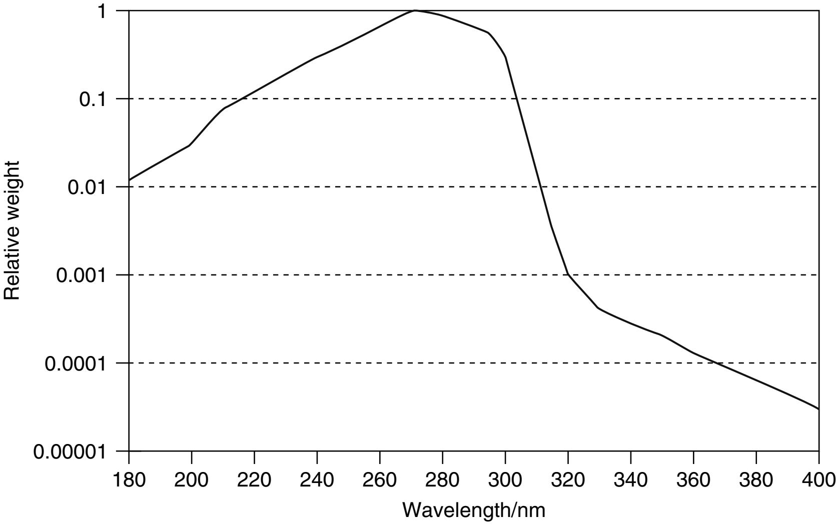

Fig. 23.20 UV weighting function (ICNIRP, 2004b)

the International Labour Organisation (ILO) (Vechia *et al.*, 2007).

The special properties of lasers, namely, the coherence and particularly the high intensities, warrant a more detailed consideration of protection measures, which is outside the scope of this article. The organs most at risk are again the eye and the skin. Protection measures and exposure limits are discussed in ICNIRP (2000).

ICNIRP has also issued a statement about protection from extended IR exposure (ICNIRP, 1997, 2006) that should be consulted for more details.

Exposure limits for RF and MW are based essentially on thermal effects as there is no convincing evidence for biological or health effects below the limits for thermal effects. ICNIRP (1998) proposed the values listed in Table 23.12

Glossary

Action spectroscopy: determination of the wavelength dependence of a biological effect. May be used to identify primary chromophores.

ALARA principle: principle of radiation protection to keep all exposures "as low as reasonably achievable".

Apoptosis: "Programmed cell death": disintegration of a dying cell characterized by a sequence of distinct metabolic processes.

Ataxia telangiectasia: Recessive hereditary disease in humans characterized by extreme sensitivity to ionizing radiations.

Bacteriophage: viruses of bacteria.

Cell cycle: Sequence of events between two subsequent cell divisions.

Chromophores: Light absorbing species responsible for a photobiological effect.

Chromosomal aberrations: change in the number of chromosomes (numerical aberration) or in their structure (structural aberrations). Radiation produces mainly the latter.

Chromosome: organizational unit of genetic material in eukaryotes, consists of deoxyribonucleic acid and protein, can be seen in the microscope in mitosis.

Colony-forming ability: the ability of a cell to divide indefinitely. In radiobiology usually equated with survival.

Deoxyribonucleic acid: molecular carrier of genetic information. Commonly abbreviated as DNA.

Dicentric chromosomes: chromosomal aberration where two chromosomes are joined in such a way that there are two

Tab. 23.12 Recommended exposure limits for RF and MW irradiations ("Specific absorption rates (SAR)") (ICNIRP, 1998).

	Frequency range	Whole-body limit (W/kg)	Localized limit head and trunk (W/kg)	Localized limit limbs (W/kg)
Occupational	100 kHz–10 MHz	0.4	10	20
	10 MHz–10 GHz	0.4	10	20
General public	100 kHz–10 MHz	0.08	2	4
	10 MHz–10 GHz	0.08	2	4

centromeres (attachment sites for the spindle during mitosis).

Dimer: UV photoproduct in DNA. Formed between two pyrimidine bases in the same strand.

DNA: abbreviation for *deoxyribonucleic acid,* the macromolecule that carries the genetic information in cells.

Dose equivalent: Formerly, the product of the (physical) dose and the quality factor for different radiation types. It is now replaced by "equivalent dose."

Dose: quantity of absorbed ionizing radiation. Defined as energy absorbed per unit mass. Units: Gray, rad.

Double-strand breaks (DSBs): rupture of the phosphate–sugar backbone of DNA in both strands opposite to each other. DSB are assumed to be the most important lesions caused by ionizing radiations.

Equivalent dose: see "dose equivalent".

Erythema: reddening of the skin ("sunburn").

Escherichia coli: bacterium mostly used in molecular biology.

Eukaryotes: cells possessing a nucleus and chromosomes.

Exposure: quantity defined as the total charge (of one sign) per unit mass liberated by ionizations. Measured in C/kg.

Genome: the total genetic material of a cell.

Gray: SI unit for dose of ionizing radiation. Equal to 1 J/kg. Abbreviation: Gy.

Hyperthermia: Increase of body temperature above normal levels. Used in cancer therapy.

ICNIRP: International Commission for Nonionizing Radiation Protection.

ICRP: International Commission on Radiological Protection, an international nongovernment organization that reviews the scientific literature and issues recommendations for radiation protection. Regularly publishes recommendations in the *Annals of the ICRP.*

Linear energy transfer (LET): energy locally imparted per unit distance. The term *locally* requires specification, for example, by "cutoff energies" for liberated electrons. Unrestricted LET is numerically equal to the stopping power.

Melanoma: malignant invasive skin tumor, starting from melanocytes as precursor cells.

Microdosimetry: Subdiscipline concerned with energy depositions in sites of microscopic dimensions.

Mitosis: The cell division process in eukaryotes.

Mutation: Stably inherited change of genetic information.

Necrosis: Disintegration of a dying cell.

Organogenesis: the phase during embryonic development when the organs are initiated. In humans from about day 8 to day 60 of pregnancy. Sensitive period for teratogenic effects by ionizing radiation.

Phage: bacteriophage.

Photochemotherapy: combination of light and specific photosensitizers for the treatment of diseases.

Photodynamic effect: photobiological effect caused by singlet oxygen formed in sensitizing molecules upon light absorption.

Photoreactivation: Monomerization of UV-induced pyrimidine dimers through light absorption.

Quality factor: Weighting factor to account for the relative biological effectiveness of different kinds of ionizing radiation. Used in radiation protection to determine the equivalent dose.

rad: old unit for the quantity "dose". 1 rad = 0.01 Gy.

Radicals: short-lived aggressive chemical species formed by radiation absorption, which have unpaired electrons in their outer orbitals.

Recombination: exchange of parts of genetic material between DNA molecules or chromosomes.

Relative biological effectiveness (RBE): a factor defined as the ratio of doses to give the same effect with different kinds of ionizing radiations compared to X- or γ-rays.

rem: old unit for the quantity "equivalent dose" and "effective dose." 1 rem = 0.01 Sv.

Roentgen: old unit for the quantity "exposure." Abbreviation R, $1\ \mathrm{R} = 2.58 \times 10^{-4}$ C/kg.

Sievert: SI unit for equivalent dose and effective dose. Abbreviation: Sv.

Stem cells: undifferentiated cells capable of division in organs.

Stopping power: energy lost by a partricle per unit distance.

Syndrome: complex combination of clinical symptoms.

Teratogenesis: formation of malformations during embryonic development.

Translocations: exchange of parts between different chromosomes without loss of genetic material.

Virus: noncellular entity consisting of nucleic acid and a protein coat. Cannot proliferate without the cell's machinery. Most viruses are specific for a given cell type.

24.1
Introduction

Although living systems, including humans, are exposed to sound (including ultrasound) in the natural environment, the main effects of the exposure (other than sensory) comes from human activities and man-made devices. With the advent of electronic technology in the early 1900s, it became possible to generate ultrasound conveniently and economically. It was soon found in laboratory experiments that ultrasound, in the frequency range 10 kHz to a few megahertz, was capable of producing a wide range of effects in physical, chemical, and biological systems. Reviews and selected papers from the early work are contained in publications by El’piner (1964), Dunn and O’Brien (1976), Wells (1977), and Nyborg (1991, 1999). (The present chapter is essentially a revision of the latter two references, which includes advances since 1999.)

Naturally, there was a great deal of curiosity as to how ultrasound produced these effects. Under some circumstances, temperature elevation was shown to be the cause. As ultrasound propagates through biological tissue, absorption occurs (NCRP, 1992); that is, acoustic energy is converted into heat. The temperature rises to an extent that depends on the nature of the sound field as well as on characteristics of the tissue. In some experimental situations with mammals, the temperature elevation is high enough to produce structural or functional change, either beneficial or adverse. Thermal mechanisms for biological effects of sound are taken up in Section 24.2.

In other applications, temperature elevation is negligible. Chief among nonthermal mechanisms is *cavitation*, an activity that involves bubbles or cavities containing gas or vapor. This topic has taken on greatly increased significance during the last decade because of the practice, now widespread in examinations with diagnostic ultrasound, of injecting gas-containing microspheres into the blood as contrast agents to improve the images. There are many facets to cavitation activity; gas bubbles exhibit a surprising variety of behavior in a sound field. This topic is discussed in Sections 24.3 and 24.5.

Other aspects of sound by which action occurs include steady (time-averaged) forces, torques, and steady circulations set up in various media. Radiation forces and torques occur also in electromagnetic fields, but the acoustic counterparts

ISBN: 978-3-527-40702-6

have features that are unique to sound fields. These are taken up in Section 24.4, along with some intriguing phenomena for which the mechanism has not been determined, though believed to be neither heat nor cavitation.

An understanding of the mechanisms for biological effects of sound are important in connection with such widely varying medical applications as stimulation of tissue repair and destruction of malignant tissue. Applications to cellular biotechnology include disintegration of cells, cell separation, cell fusion, and, most recently, mediation of gene therapy by making cells temporarily permeable. In addition, there is also considerable need for increased understanding of mechanisms in order to evaluate risks involved in medical applications. This is especially true for applications of diagnostic ultrasound to examinations of the fetus, since these are now employed very widely. Today, most children have been exposed to ultrasound before birth.

24.2
Biological Effects from Sonically Induced Temperature Elevation

24.2.1
Basic Theory

In a fluid-like medium, sound energy is converted irreversibly into heat by viscous dissipation and relaxation processes (Pierce, 1994). In a continuous-wave sound field of moderate pressure amplitude, where the pressure at a point varies above and below the ambient pressure by an amount that varies sinusoidally with time, the time-averaged rate (q_v) at which heat is generated per unit volume is often given adequately by the expression

$$q_v = \alpha {p_0}^2/\rho_0 c \tag{1}$$

Here, p_0 is the pressure amplitude, α is the absorption coefficient in nepers per unit length, ρ_0 is the density of the fluid, and c is the speed of sound in the fluid (Nyborg, 1981; Cavicchi and O'Brien, 1984). In a plane traveling wave, energy is transported along its direction of propagation at a rate I per unit area given by

$$I = 0.5p_0^2/\rho_0 c \tag{2}$$

Combining Eqs (1) and (2), one obtains, simply,

$$q_v = 2\alpha I \tag{3}$$

For a plane wave traveling along the x direction, the pressure amplitude (p_0) is proportional to $e^{-\alpha x}$ if scattering is negligible, as has been shown to be true for liver and other soft tissues (NCRP, 1986). From Eq. (2), the intensity is then given by

$$I = I_0 e^{-2\alpha x} \tag{4}$$

where I_0 is the intensity at $x = 0$. One never has perfect plane waves, but Eqs (2)–(4) are often good approximations if the sound field resembles a traveling wave and is not too nonuniform.

In mammalian tissues, heat is transported not only by conduction but also by convection in the flowing blood, that is, by *perfusion*. Knowing q_v for a given situation where ultrasound is propagating through perfused mammalian tissue, the temperature elevation can be approximated by means of appropriate solutions to a widely used *bioheat transfer equation* from Pennes (1948). This can be written (NCRP, 1992) as

$$\frac{\partial T}{\partial t} = \kappa \nabla^2 T - \frac{\Delta T}{\tau} + \frac{q_v}{c_v} \qquad (5)$$

where T is the temperature and ΔT its elevation above the base temperature; the tissue is characterized by a thermal diffusion constant κ, a perfusion time constant τ, and a heat capacity per unit volume c_v. Basic solutions have been obtained for a point source that begins generating heat at $t = 0$; also, for spherical, line, and discoid sources, as well as for ultrasound beams propagating through perfused absorbing media. These have proved useful in arriving at safety criteria for diagnostic ultrasound and, also, in planning therapeutic or surgical applications of ultrasound.

24.2.2
Safety Concerns for Diagnostic Ultrasound

At frequencies in the megahertz range used in most medical ultrasound, acoustic absorption coefficients for mammalian tissues are high enough to allow temperature elevations produced in medical applications to be significant, even in some applications of diagnostic ultrasound. In tissues where cells divide rapidly, as in the mammalian embryo or fetus, even a small temperature rise can produce damage if prolonged sufficiently. For a wide range of teratogenic effects, the time t in minutes required for exposure to temperature T (in degrees Celsius) to produce an effect has been equated, approximately, to

$$t = 4^{43-T} \qquad (6)$$

when T is not greater than 43 °C (Miller and Ziskin, 1989; NCRP, 1992). According to Eq. (6), damage may occur after 4 minutes of exposure to a temperature of 42 °C, and after 16 minutes of exposure to 41 °C. For more recent analysis of possibilities for thermal risk to the fetus, see Miller, Miller, and Church (2005). Among fetal tissues, the absorption coefficient is highest in bone, and the potential for heating increases with gestational age. Safety criteria derived from algorithms for calculating estimates of the maximum temperature rise that would be produced by ultrasonic exposure of bone and other tissues have been formulated during the past few years (AIUM/NEMA, 1992; NCRP, 1992). These criteria are expressed in terms of *thermal indices,* which are becoming familiar to users of diagnostic ultrasound equipment.

24.2.3
Thermal Therapy Using Ultrasound

First introduced in the 1940s and 1950s, ultrasound, focused or unfocused, has received increasing attention in recent years as a mean of modifying tissue in selected parts of the body; special emphasis has been given to its capability for elevating tissue temperature in a controlled manner. Applications of unfocused ultrasound to physical therapy are discussed in reviews by Lehmann and de Lateur (1990) and McDiarmid, Ziskin and Michlovitz (1996). As reported by these authors, heating produced by ultrasound may lead to increase in collagen extensibility, alterations in blood flow, and increases in enzymatic activity of skeletal muscle. By using frequencies ranging from 1.0 to 3.0 MHz and intensities in the range 1.0–3.0 W cm^{-2}, it is possible to increase significantly the temperature of tissue at depths of 5 cm or more. Possibilities can be seen for an example by using Eqs (1)–(4). At a frequency of 1 MHz the absorption coefficient α of muscle tissue is, roughly, 0.1 Np cm^{-1} (NCRP, 1986). From Eq. (4), the intensity of a 1 MHz beam entering muscle tissue with an initial value of 1.0 W cm^{-2} will be 0.37 W cm^{-2} at a distance of 5 cm and, according to Eq. (3), heat will be deposited there at the rate of 0.074 J cm^{-3} s^{-1}. Taking the heat capacity to be 4.2 J cm^{-3} for the tissue, one concludes, neglecting effects of heat conduction and perfusion, that the tissue temperature will be increased at the rate of 0.0176 °C s^{-1}, or 1.06 °C min^{-1}. (Neglecting effects of heat conduction is reasonable for exposures with a broad beam, e.g. with a cross-sectional area of the order of 10 cm^2, applied for only a few minutes).

When using focused ultrasound, a much higher intensity can be applied to a designated small region of tissue. In techniques developed for medical applications using high *intensity focused ultrasound* (HIFU), temperatures ranging from 60 to 90 °C are reached. In a general review of current practice, ter Haar (2004) described applications of FUS to thermal ablation of tissue in the prostate, liver, and other organs. It is reported by Wu (2006a) that HIFU is widely employed in China, where 3500 patients with solid tumors were treated with this modality in 20 hospitals during the period December 1997 to March 2001. A problem in treating internal tumors is to ensure that the entire malignant region is raised to the required temperature. It is shown by Hynynen and McDannold (2006) that the temperature can be monitored successfully by the use of magnetic resonance imaging (MRI) and exploiting the thermal sensitivity of the water proton resonance frequency shift. Many articles describing recent findings from research on biological effects produced by focused ultrasound are contained in a conference proceedings volume (Clement, McDannold, and Hynynen, 2006).

24.3
Biological Effects from Cavitation at Low and Intermediate Levels

24.3.1
Introduction

It was found during the 1920s and 1930s, in the earliest experiments on physical, chemical and biological effects of ultrasound in liquid media, that many of the effects were caused by ‘‘cavitation,’’ an activity occurring when small cavities (‘‘bubbles’’) filled with gas or vapor were present. Since then, this activity has been extensively studied. The physical response of a bubble to ultrasound can be, in one extreme, simple sinusoidal pulsation or, in the other, complex motion including violent collapse. The effect on a biological cell from exposure to ultrasound in the presence of bubbles can vary from mild perturbation to complete destruction. In mathematical analysis of mild bubble response to a sound field, linear equations are used, analogous to those employed in treating the classic ‘‘mass-on-a-spring’’ problem in introductory physics. For the more complex response, the equations required are nonlinear and are dealt with by use of computational techniques. The subject has been reviewed for various purposes by Flynn (1964), Coakley and Nyborg (1978), Neppiras (1980), Apfel (1981), Atchley and Crum (1988), Young (1989, 2005), and Leighton (1994, 1996).

24.3.2
Activity at Low Sound Levels

24.3.2.1 Linear Theory of Bubble Vibration

Theory for cavitation is based primarily on a model in which a small spherical body of gas, the bubble, exists in a homogeneous liquid, away from disturbing boundaries. It is set into volume (breathing) oscillation by the time-varying acoustic pressure (p) associated with a sound field that is set up in the liquid. (The acoustic pressure is defined as the difference between the instantaneous pressure at a point in the field and the static ambient pressure.) If p varies sinusoidally in time with frequency f, and if the pressure amplitude (p_0) is not too high, the radial displacement (ξ) of the bubble (increase in bubble radius) will also vary sinusoidally in time with frequency f and with ξ proportional to p. Under these conditions the equation of motion is a linear differential equation:

$$m\frac{\partial^2 \xi}{\partial t^2} + b\frac{\partial \xi}{\partial t} + k\xi = F(t) \qquad (7)$$

By analogy to the mass-on-a-spring problem, the parameters m and k are the effective mass and spring constant, respectively, while b is proportional to the damping constant. If there is a film, shell, or collection of impurities at the surface of the gaseous body, these constants may be affected; in the preparation of *contrast agents,* discussed in Section 24.3.2.2, they are altered deliberately. In this section, the bubble is considered to be a "free bubble," consisting simply of homogeneous gas surrounded by homogeneous liquid. For a bubble whose equilibrium radius is R_0, in a liquid of density ρ_0, the effective mass is given by

$$m = 4\pi \rho_0 {R_0}^3 \qquad (8)$$

this is three times the mass of liquid that would be contained in a sphere equal in volume to the bubble. When effects of surface tension are ignored, the effective stiffness constant, k, for the bubble is proportional to the polytropic index, γ, being given by

$$k = 12\pi \gamma R_0 P_a \qquad (9)$$

where P_a is the ambient hydrostatic pressure. For a free air bubble, γ is 1.4 if the changes in volume occur adiabatically. The effective driving force function $F(t)$ is proportional to the local acoustic pressure in the fluid (specifically, the pressure that would exist in the absence of the bubble); taking this pressure to be $p_0 \cos(\omega t)$, where ω is the angular frequency $2\pi f$, the driving function is found to be

$$F(t) = -4\pi {R_0}^2 p_0 \cos(\omega t) \qquad (10)$$

Like its mass-on-a-spring analog, the oscillating bubble responds with increased displacement amplitude when the angular frequency is in the vicinity of the resonance value:

$$\omega = \omega_0 = (k/m)^{1/2} \qquad (11)$$

Corresponding to ω_0 is the resonance frequency $f_0 = \omega_0/2\pi$. Choosing convenient units, one obtains from Eqs (7), (8), and (11) a simple formula for f_0, applicable in the lower ultrasonic frequency range to an air bubble in water at 20 °C and standard atmospheric pressure, namely,

$$f_0 = 3.3/R_0 \qquad (12)$$

Here f_0 is in kilohertz when R_0 is in millimeters. For example, f_0 is about 33 kHz for a bubble of radius 0.1 mm. However, this simple formula fails at megahertz frequencies and must be modified to take into account surface tension. For a free bubble of 1 μm radius, the computed f_0 in water, assuming adiabatic conditions, is 3.3 MHz if surface tension is neglected and 4.7 MHz if air–water surface tension for 20 °C is assumed.

When the frequency of a driving ultrasound field is equal to the resonance frequency of the bubble, the ratio (ξ_0/R_0) of the radial displacement to the bubble radius is given by the expression $p_0/\delta P_a$, where δ (equal to $b/m\omega_0$) is a damping constant that depends on properties of the liquid. For an air bubble in water, resonant at a frequency of 1 MHz, δ has been calculated to be 0.14; hence, for these conditions, a relative pressure amplitude (p_0/P_a) will produce a relative change in radius (ξ_0/R_0) equal to $7p_0/P_a$. For example, if the ratio of p_0 to atmospheric pressure is 0.1%, the ratio of the oscillatory amplitude of the bubble to its radius will be 0.7%. This is, of course, a much greater change in radius than would be produced in a solid or liquid sphere.

24.3.2.2 **Scattering: Ultrasound Contrast Agents**

In the situation discussed above, a gas-filled bubble in a liquid where there is an ultrasound field of given frequency f, will pulsate at the same frequency and will then itself become a source of ultrasound, which radiates outward from the bubble. The latter is thus an agent that is capable of *scattering* acoustic energy from the original field. The usefulness of this capability in medicine was discovered in the late 1960s and early 1970s by investigators using diagnostic ultrasound to study blood flow in the circulatory system. In their studies, the blood had been made visible mostly by ultrasound scattered from erythrocytes and other cells. However, they found that when suitable bubbles were present in the blood they scattered far more energy than the cells and greatly increased the contrast between blood and the background tissue (Gramiak, Shah, and Kramer, 1969; Ziskin *et al.*, 1972). These findings created considerable interest, and led to much use of small bubbles as contrast agents. It was necessary to find means of stabilizing the bubbles by adding suitable material to their surfaces to avoid rapid dissolution by surface tension. By 1990, commercial products had become available and detailed investigations of their acoustical properties were being carried out (Bleeker, Shung, and Barnhart, 1990). Since then, many more types of bubble-based ultrasound contrast agents (UCAs) have been commercially produced; 16 are described by Bouakaz and de Jong (2007). The UCAs must be small, a few micrometers in diameter, in order to pass through narrow capillaries. The majority are encapsulated with flexible shells or films, 10–250 nm in thickness, which prevent the gas from dissolving too rapidly, and, also, affect the dynamics. Fluorocarbons of high molecular weight are often used as the gas, since these dissolve relatively slowly.

24.3.3
Activity at Intermediate Sound Levels

When UCAs of uniform size and specified characteristics became available commercially, it became possible to carry out ultrasound exposures under a degree of control over bubble population, which was much greater than with free bubbles. Both *in vitro* and *in vivo* studies have shown that the presence of either free (uncoated) bubbles or UCAs increases the likelihood of biological effects, unless the pressure amplitude is fairly low. In obtaining the experimental results discussed in the following sections, the sound levels were such that the concepts of linear acoustics are useful, although the assumptions are not fully applicable.

In dealing with phenomena of acoustics, which occur at sound levels that are somewhat higher than those at which linear acoustics applies, it is common to use a method of successive approximations in which quantities such as the displacement, velocity, and pressure are each represented as a series of terms of decreasing order of magnitude. For example, the acoustic pressure might be written as

$$p = P_a + p_1 + p_2 + \cdots \tag{13}$$

Here, the zero-order term P_a is the pressure, which exists in the absence of sound, while the first-order term p_1 is the pressure in the "linear acoustics" approximation, and varies periodically in time with frequency f. The second-order term is found to be a constant times the product of two first-order quantities and consists of two parts: one is "second-harmonic," being periodic with frequency $2f$, and the other is time-independent. It is the latter, time-independent second-order quantities that are particularly relevant in discussing biological effects of ultrasound at intermediate sound levels. The quantities q_v and I, for which expressions are given in Eqs (1) and (2), are time-averaged second-order quantities, each being proportional to the square of p_0, the amplitude of the first-order pressure. Later sections deal with radiation pressure, radiation force, and acoustic streaming, all of which are treated as time-independent quantities of second order.

24.3.3.1 Heating

Gas bubbles of appropriate size can be very effective in converting acoustical energy into heat. The energy per unit volume extracted from a plane ultrasound wave of intensity I traveling through a suspension of n bubbles per unit volume is given by the product $n\sigma I$, where σ is the total single-bubble cross-section for absorption and scattering. For a free resonant air bubble in water, σ is given approximately (Coakley and Nyborg, 1978) by

$$\sigma = 2900\,\pi R_0{}^2 \tag{14}$$

thus, the area σ is 2900 times the cross-sectional area (πR_0^2) of the bubble. Equating the expression for q_v in Eq. (3), to the expression $n\sigma I$, one finds that the attenuation coefficient is equal to $n\sigma/2$. Taking the radius R_0 at 1 MHz to be 3 μm and considering about 90% of the attenuation to be caused by absorption, one obtains $3.7 \times 10^{-4} n$ as the absorption coefficient α in Np/cm for the bubble suspension. Choosing n as 1000 cm^{-3}, corresponding to an average of one resonant bubble per cubic millimeter and a volume fraction of air equal to 1.1×10^{-7}, one obtains 0.37 Np cm^{-1} for α, a value larger than the measured absorption coefficient for most mammalian soft tissues at 1 MHz.

For UCAs, the vibrations induced by ultrasound are restrained by the films or shells at their surfaces, but they nevertheless cause high absorption. Marsh *et al.* (1997) measured the attenuation (most of which was absorption) of ultrasound in highly concentrated solutions of a commercial contrast agent, using frequencies in the range 1.0–10 MHz and obtained values up to about 9 Np cm^{-1}. Such values are higher than reported absorption coefficients for any soft tissues (NCRP, 1986; Duck, 1990). The presence of UCAs in tissue being exposed to ultrasound will increase the temperature rise produced; this can be helpful in therapeutic applications and, on the other hand, needs to be recognized in safety considerations.

24.3.3.2 Rectified Diffusion

It was observed in early experience with ultrasound that small free gas bubbles in water may become larger after exposure to ultrasound. For single bubbles, this phenomenon is now understood as resulting from the process of gas diffusing into and out from a pulsating bubble. As a bubble expands and contracts in response to the time-varying pressure in a sound field, gas diffuses inward and outward. The net inward flow during a cycle is, in general, nonzero; this is partly because the area of the gas–liquid interface varies and partly because the gas-concentration gradient on the liquid side of the interface varies during the cycle (Hsieh and Plesset, 1961). The net inward flow is often positive, causing the bubble to grow in a process called *rectified diffusion*. Theories have been developed for the process, and experiments have been done to test them, especially in water and other aqueous media. Crum (1984) has reviewed the state of knowledge on conditions for growth and on the rate of growth.

24.3.3.3 Acoustic Radiation Forces on Free Gas Bubbles and UCAs

Here the term "bubble" is used to represent either a free bubble or a UCA, unless noted otherwise. In a standing-wave field, any gas bubbles that are smaller than the resonance size tend to collect at maxima of the pressure amplitude, while larger ones move to the minima. This behavior, attributed to acoustic radiation forces (ARFs), is readily explained by considering the force exerted by surface stresses on a highly compressible body in a field over which the acoustic pressure varies sinusoidally in time, with spatially varying amplitude but with constant phase in the vicinity of the body. The instantaneous force is given by $-V\nabla p$, where V is the instantaneous volume of the body, ∇ is the gradient operator, and p is the instantaneous acoustic pressure near the bubble. The acoustic pressure varies in time with frequency f, while V is assumed to be the sum of a constant part V_0 and a part v that varies in time with the same frequency f.

The time-averaged force over a cycle, that is, the ARF, is then equal to $\langle -v\nabla p\rangle$, where $\langle\rangle$ indicates the temporal average. Since v and p are taken to be first-order quantities, the radiation force is of second order (as indicated earlier). This time-averaged product (of two sinusoidally varying quantities) is equal to the product of the two amplitudes times the cosine of the phase difference between them. From these considerations, it is found that for a small bubble the radiation force is in the direction of increasing pressure amplitude, for a large one it is in the opposite direction, and for a resonant bubble it is zero. These aspects of radiation force on bubbles are important in designing arrangements for exposing cell suspensions to ultrasound when free bubbles are involved. If the arrangement is such that standing waves are established with periodically spaced maxima and minima of the pressure amplitude, bubbles smaller than resonance size will move toward the pressure maxima and become active there, perhaps growing to resonance size, while the larger bubbles will go to the pressure minima and become less active there. (Some of these may then shrink and be returned to a pressure maximum.) Hence, the effects on cells will occur mostly at the pressure maxima unless means are employed to rotate the vessel or stir the suspension.

In a traveling wave, the situation is unlike that for a standing wave; here, the ARF on a gas bubble is always in the direction of sound propagation and is maximum for bubbles of resonance size (Coakley and Nyborg, 1978; NCRP, 2002, Chapter 4).

Since UCAs have become available, much has been learned about their acoustical characteristics, as well as their potential for biomedical applications. When UCAs are present in a liquid through which an ultrasound beam is passing, they move in the direction of the beam, as expected from theory for radiation force in a traveling wave (Dayton, Allen, and Ferrara, 2002). This force has implications for applications in which UCAs are present in the blood of a patient who is being examined with diagnostic ultrasound. Experiments with small animals have shown that when an ultrasound beam passes across a blood vessel, any UCAs in the blood will be forced toward the distal side of the vessel. This capability may be useful in drug delivery or other applications where it is desired to bring a UCA in contact with a binding site on the epithelium.

If two or more free bubbles are near one another in a sound field, they will often move toward each other and coalesce to form a single larger bubble. It is this process and that of rectified diffusion (Section 24.3.3.2) that are believed to account for the growth of free gas bubbles in a sound field. The attraction that leads to coalescence can be explained in terms of radiation forces (Coakley and Nyborg, 1978). For UCAs, the forces between bubbles are of the same nature as for free bubbles. The attractive forces bring resonant UCAs together and aggregates form. Dayton *et al.* (1997) have studied the behavior of UCA aggregates in flow fields while exposed to ultrasound, finding conditions under which deaggregation occurs temporarily, followed by reaggregation.

24.3.3.4 **Attraction of Particles to a Vibrating Bubble or UCA**

It is shown in Section 24.4.2 that any small vibrating object in a suspension of particles will create highly localized fields of radiation force that act on neighboring particles. In the vicinity of a vibrating bubble, any particle nearby is acted on by a radiation force that is directed toward the bubble if the particle is more dense than the surrounding fluid. Hence, particles in solution tend to collect at the surfaces of vibrating bubbles. This conclusion can be reached by considering the situation of a small particle of volume v near a vibrating spherical bubble of rest radius R_0 as a special application of Eqs (21a and b) in Section 24.4.2 (Nyborg and Miller, 1982; NCRP, 2002). The following equation is obtained:

$$F_{\mathrm{rad}} = vD\frac{\partial}{\partial r}\langle \mathrm{KE}\rangle \tag{15}$$

where D is defined in Eq. (21b) and $\langle \mathrm{KE}\rangle$ is the time-averaged kinetic energy density in the liquid immediately outside the bubble. (The term in Eq. (21a) involving $\langle \mathrm{PE}\rangle$, the time-averaged potential energy, is negligible in this region.) The alternating flow here is essentially that of an incompressible fluid at points whose distance from the bubble center is small compared to the acoustic wavelength. The bubble surface is considered to be vibrating sinusoidally at frequency f with displacement amplitude ξ_0, and velocity amplitude U_0, equal to $2\pi f\xi_0$. The corresponding oscillatory velocity of the liquid at a distance r from the bubble center is radially directed, with amplitude u_0, given by $U_0R_0^2r^{-2}$. The time-averaged kinetic energy density $\langle \mathrm{KE}\rangle$ in the fluid is $0.25\rho_0u_0^2$, where ρ_0 is the density of the liquid. If $(\rho - \rho_0)$ is much less than ρ_0, where ρ is the density of the particle, the combination $D\rho_0$ can be replaced by $(\rho - \rho_0)$ and one obtains from Eq. (15)

$$F_{\mathrm{rad}} = -v(\rho - \rho_0)U_0{}^2R_0{}^4r^{-5} \tag{16}$$

the minus sign indicating that the force is directed toward the bubble. Considering the liquid to be Newtonian with viscosity coefficient η, and that the Stokes law applies, the particle will move toward the bubble, acquiring the limiting velocity U_{lim}, equal to $F_{\mathrm{rad}}/6\pi\eta a$. Taking the particle to be spherical with radius a and the volume v thus equal to $4\pi a^3/3$, one obtains

$$U_{\mathrm{lim}} = (2/9\eta)a^2(\rho - \rho_0)U_0{}^2R_0{}^4r^{-5} \tag{17}$$

When considering the particles to be biomolecules, such as protein molecules, it is convenient to characterize them in terms of the *sedimentation coefficient* s, a quantity used in centrifugation measurements and other applications. For a particle driven through a viscous fluid, the quantity s, in units of seconds, is the ratio of its terminal speed to the acceleration associated with the driving field (IUPAC, 1997). In the present application, the acceleration is acoustical in origin. In a liquid of Newtonian viscosity η where Stokes Law applies, it is found for a spherical particle of radius a that s is given by

$$s = 2a^2(\rho - \rho_0)/9\eta. \tag{18}$$

Combining Eqs (17) and (18), one obtains, simply,

$$U_{\mathrm{lim}} = sU_0{}^2R_0{}^4r^{-5} \tag{19}$$

As an example, suppose a UCA with a radius R_0 of 5.0 μm vibrates at a frequency of 1 MHz with a displacement amplitude of 0.50 μm. The velocity amplitude U_0 is then 3.14 m s^{-1}. A protein molecule for which s is 4×10^{-13}, s is suspended in the fluid outside the bubble at a distance of 0.5 μm from its surface so that the distance r from the bubble center is 5.5 μm. According to Eq. (19), the radiation force will cause the molecule to move toward the surface with velocity U_{lim} equal to 0.62 μm s^{-1}. It thus appears that all such molecules contained in a shell of thickness 0.5 μm outside the bubble can be drawn toward it and reach its surface in less than a second. The bubble acts as a miniature centrifuge!

There are no known experiments with particle suspensions to which the above theory has been applied, in which the particles are of the size of proteins. However, the phenomenon of particle collection near vibrating bubbles has been observed and investigated with larger particles, such as platelets and erythrocytes (Nyborg and Miller, 1982; Miller, 1988). Although not yet been explicitly demonstrated, it is probable that the attraction of suspended substances to vibrating UCAs is involved in the gene transfer techniques described recently by Miller (2006), Tachibana and Tachibana (2006), and Wu (2006b).

24.3.3.5 Microstreaming Associated with Vibrating Bubbles and UCAs

It is pointed out in Section 24.4.3 that most sound fields set up in fluids give rise to acoustic streaming, that is, to time-independent circulation of the fluid. When bubbles are present in a cell suspension exposed to ultrasound, small-scale acoustic streaming (often called *microstreaming*) takes place in the immediate vicinity of each bubble and causes viscous stress to be exerted on nearby cells. Elder (1959) made detailed studies of the motion near vibrating bubbles of near-resonant size at 10 kHz. In his experiments, the bubble was situated near a solid surface. He found that the streaming pattern might take on any of four different forms, depending on the purity of the liquid and other factors. He also made determinations of the streaming speeds and, under some conditions, found order-of-magnitude agreement with approximate theory of the kind described in Section 24.4.3.

Following these findings, many studies were made on the biological implications of microstreaming associated with small gas bodies; a thorough review of available information on this topic was published by Miller (1987). To obtain this information, investigators had employed a variety of arrangements: (i) a single bubble of near-resonance size, (ii) an array of gas bodies formed by trapping air in small holes drilled in a solid surface, (iii) an array of gas bodies trapped in holes of Nuclepore membranes, and (iv) intracellular gas-filled channels in plant tissues. With these arrangements, cellular and molecular alterations were observed at relatively low values of the pressure amplitude; the effects included hemolysis, release of protein from bacteria, degradation of (high molecular weight) DNA in solution; aggregation of human platelets; release of adenosine triphosphate (ATP) from erythrocytes; and mechanical disruption of plant cells. Theory and experiment showed that the magnitude of the velocity gradient required to break a rodlike molecule, such as DNA, decreases as the length increases.

The bubble-associated streaming field is highly localized; a cell in suspension must be brought into near-contact with an active bubble in order for the stress to be effective. The attractive force discussed in Section 24.3.3.4 tends to bring about cell–bubble contacts, as does the outer part of the microstreaming flow itself. Calculations for cells in suspension indicate that in a cell–bubble ‘‘contact’’ the time interval during which the cell is subjected to high stress is short, of the order of milliseconds or less. Usually, a cell must undergo several contacts before breaks occur in the membrane, which allow cell contents to be released. However, for a vibrating gas-filled channel contained within plant tissue, the situation is very different. Here, the stresses produced by continuous vibration are applied steadily to membranes adjoining the channel, and membrane failure occurs at relatively low values of the stress.

In nearly all *in vitro* ultrasound experiments and applications involving activity of small gas bodies prior to about 1995, the gas bodies were "free" bubbles. Uncertainties arose because investigators were usually not able to specify the numbers, sizes, or positions of free bubbles present during experiments. When UCAs became commercially available, investigators were presented with new possibilities, by having bubbles of controlled size and characteristics for use in experiments and applications. As part of a recent symposium, Bouakaz and de Jong (2007) describe UCAs, listing characteristics of over a dozen types now available commercially, Blomley, Claudon, and Cosgrove (2007) discuss their applications to ultrasound imaging, Miller (2007) and Dalecki (2007) describe, respectively, information on biological effects obtained from *in vitro* and *in vivo* exposures to ultrasound in the presence of UCAs, and Nyborg (2007) discusses mechanisms for effects. There is much interest in findings that cell membranes can be altered reversibly, thus facilitating transfection, during exposure to ultrasound of low or moderate acoustic amplitude when UCAs are present. The mechanism probably includes aspects of microstreaming and radiation pressure. It is concluded by Wu (2002) from theoretical considerations that these are likely under some conditions and that under others, higher amplitudes are required, for which the mechanisms are discussed in Section 24.5. Miller (2007) reaches similar conclusions from experiments of a special kind, made possible by availability of UCAs. Here, cells to be exposed are arranged as a monolayer on Mylar film that is positioned in a suitable liquid so that the film is horizontal and the cells are below the film. UCAs are then introduced below the monolayer and allowed to rise until they are in contact with the cells, after which ultrasound is applied from below. Effects are observed later by examining the monolayer with microscopy.

24.4
Biological Effects from Nonthermal Noncavitational Mechanisms

24.4.1
Introduction

There have been numerous investigations in which changes were produced by sound in biological systems, where there was no significant temperature elevation and no indication of cavitation. Instead, the mechanism was identified as a manifestation of ARF or torque, or as acoustic streaming.

24.4.2
Acoustic Radiation Force

When sound interacts with an object, the temporal average of the force exerted on it is usually not zero and is called the *acoustic radiation force*. In Sections 24.3.3.3 and 24.3.3.4, the forces acting on a gas bubble and on a suspended particle near a vibrating gas bubble were discussed. Here, the topic is taken up somewhat more generally.

One application of ARF is to the calibration of acoustic equipment used for generating sound beams of defined characteristics. When a beam of ultrasound travels through water and impinges on an immersed object that absorbs all of the incoming energy, the radiation force F_{rad} exerted on the object is given simply by

$$F_{\text{rad}} = W/c \tag{20}$$

where W is the total acoustic power in the beam and c is the speed of sound in water. Taking c to be 1500 m s^{-1} and the power to be 1 W, one obtains 7×10^{-4} N (equivalent to the weight of 68 mg) for F_{rad}. Equation (20) is the working equation for radiation balances that are used to measure the total power in a beam (NCRP, 1986).

Equation (20) can be used to calculate the steady force F_{rad} on any object, or any portion of tissue that absorbs (and does not reflect or scatter) ultrasound, if W is equated to the power absorbed. Using this relationship, Mihran, Barnes, and Wachtel (1990) explained changes in the action potential of myelinated frog sciatic nerve generated by electric stimuli, which occurred when 500 μs pulses of 2 MHz ultrasound were focused on a small area of the nerve trunk; the threshold value of F_{rad} was determined to be 0.2μN.

In other studies, Dalecki *et al.* (1997a) applied 5 ms pulses of focused 1.2 MHz ultrasound to frog heart and found that if these were applied during the systole (contraction) phase the blood pressure in the aorta might decrease. Tests indicated that radiation force was the cause; a threshold value of about 1 mN was obtained for F_{rad}.

Many studies have been made of effects produced by exposing cell suspensions to ultrasound in which ARF is found to be involved. In the analysis of results, use is sometimes made of an equation developed by Gor'kov (1962), which applies rather generally to small particles, such as biological cells. According to this equation, the radiation force on a sphere of volume v and density ρ in a liquid of density ρ_0 is

$$F_{\text{rad}} = vD\nabla\langle KE\rangle - v(1-\theta)\nabla\langle PE\rangle \tag{21a}$$

$$D = 3(\rho_s - \rho_0)/(2\rho_s + \rho_0) \tag{21b}$$

where θ is the ratio of the compressibility of the particle to that of the surrounding medium. Here, $\langle \text{KE}\rangle$ and $\langle PE\rangle$ are the time-averaged densities of the kinetic energy and potential energy, respectively, in the ultrasound field. One important application of Eqs (21a and b) is to the force on small particles in a stationary wave. There $\nabla\langle PE\rangle$ is equal and opposite to $\nabla\langle KE\rangle$ so that F_{rad} can be written as $C\nabla\langle KE\rangle$, where C is a constant equal to $v(D+1-\theta)$. If the cell is more dense and less compressible than the surrounding fluid, as is usually true for cells in saline or in body fluids, then C is positive and the radiation force is in the direction of $\nabla\langle KE\rangle$. Since the kinetic energy density KE is proportional to the square of the velocity amplitude, this means that cells move toward velocity "antinodes," that is, to maxima of the velocity amplitude. Experiments with cell suspensions exposed to standing waves support this conclusion; cells collect in bands one-half wavelength apart, as expected.

Similar banding has been observed *in vivo*. Observations of blood vessels during application of ultrasound, under special conditions where standing waves were established, have shown that a series of evenly spaced clear regions may appear in the otherwise opaque interior of the vessel. The red cells are packed into periodically spaced bands, the distance between centers of the bands being about one-half of a wavelength. When the ultrasound is turned off, the cells typically disperse and the blood flow continues normally (Dyson, Woodward, and Pond, 1971).

An acoustic intensity of about 1 W cm^{-2} has been found to be sufficient to produce the banding in vessels where the blood is moving slowly. Such intensities are commonly produced in therapy devices and are sometimes encountered in the focal regions of beams used in Doppler techniques. The possibility of adverse effects from the banding can be avoided or reduced by minimizing the time during which the beam is held in a single location.

An application of Eqs (21a and b) to the attraction of particles by a vibrating bubble has already been discussed in Section 24.3.3.4.

A somewhat related application of Eqs (21a and b) is to the force between two particles, such as two biological cells, in a sound field. This situation is somewhat more complex than the bubble–particle interaction since the scattered field of a particle such as a biological cell (whose compressibility is much less than that of a bubble) is a combination of mono- and dipolar fields. It is found that the force between particles is a function of the angle between the particle–particle axis and the direction of the local acoustic particle velocity. If the angle is zero or π radians, the particles repel each other; if it is $\pi/2$ they attract. Because of this, particle doublets tend to form whose axes are perpendicular to the local acoustic particle velocity. Further, these doublets may combine with other doublets or singlets to form larger groups, all with the same alignment. So far this aggregation process has been observed only *in vitro* (Nyborg, 1989).

Acoustical methods have proven useful for moving or manipulating cells. Bardsley *et al.* (1990) have found that techniques involving the use of ARF are advantageous for concentrating cells in bringing about cell fusion. Wu (1991) developed theory for “acoustic tweezers” involving the radiation force field created by superposing two 3.5 MHz focused beams projected in opposite directions; he showed experimentally that, with this arrangement, latex particles of 270 μm diameter in water could be trapped at the focus. Spengler and Coakley (2003) showed that with 3.17 MHz standing waves in a chamber only a single half-wavelength in depth, latex particles 25 μm in diameter were trapped at a central plane. Although confined to a small region by the ARF, the particles were found free to combine with each other in patterns determined by van der Waals force and electrostatic interactions. Hence, it was concluded that the ultrasound trap technique was a promising one for facilitating studies of aggregation patterns. Coakley *et al.* (2004) followed up on these findings. They employed a 3.17 MHz half-wavelength standing-wave trap together with video recording to study aggregation processes involving (i) erythrocytes, with and without lectin, (ii) chondrocytes, and (iii) neural cells. Haake *et al.* (2005) report further development of methods for use of ultrasound in manipulation of cells, and provide references showing that this is an active area.

Quite a different kind of application for ARF is found in techniques now employed or proposed for determining elastic properties of tissues. An example is described by Nightingale *et al.* (2001) in which breast lesions are detected by a method ("remote palpation") analogous to manual palpation. Here, diagnostic ultrasound is used to measure displacements of tissue components produced by pulses of focused ultrasound projected into breast tissue. Other methods for determining tissue properties by use of ARF are described in a review by Parker *et al.* (2005). These techniques, included under the rubric of *elastography*, have already become an important part of medical imaging procedures.

24.4.3
Acoustic Streaming and Microstreaming

Small-scale acoustic streaming associated with vibrating gas bubbles is discussed in Section 24.3.3.5. Here, we take up the subject of streaming more generally, although only briefly. Relevant aspects of the topic have been reviewed by Nyborg (1965, 1978, 1998), Rooney (1981), and Miller (1987). When a sound field exists in a fluid, acoustic boundary layers are set up near surfaces of walls or immersed objects. Near these surfaces the tangential component $u_{\tan}$ of the acoustic particle velocity changes rapidly. At a solid wall where a nonslip condition applies, $u_{\tan}$ drops abruptly to zero in a short distance (δ) called the *acoustic boundary thickness*. At the surface of a "semisolid" object, such as a biological cell, $u_{\tan}$ is not zero, but differs considerably from its value in the fluid; again, an acoustic boundary layer of thickness δ exists near the surface in which there is a high gradient of $u_{\tan}$. The quantity δ depends on the viscosity coefficient η and density ρ_0 of the fluid, as well as the frequency f, as follows:

$$\delta = (\eta/\pi\rho_0 f)^{1/2} \tag{22}$$

For water at room temperature at a frequency of 1 MHz, the boundary-layer thickness is 0.56 μm and is thus comparable to a wavelength of visible light. It is the existence of boundary layers that is responsible for the generation of acoustic streaming near surfaces of cells or other objects when there is relative motion between the fluid and the object. In the boundary layer, the acoustic particle velocity varies rapidly with distance from the boundary and also varies, though usually more slowly, in directions parallel to the boundary. It has been shown that in the boundary layers established by a continuous sound field, the elements of fluid are subjected to steady torque; it is the action of this torque that produces the steady circulatory motion known as acoustic streaming in the outer fluid.

Theory for the acoustic streaming has been developed for a number of basic situations. We shall not attempt to summarize the theoretical findings here, but instead refer the reader to the reviews cited above. In the much-investigated topic of streaming near a fixed cylinder in an oscillating fluid (which presents essentially the same streaming situation as an oscillating cylinder in a quiescent fluid), it is found that the streaming flow is characterized by high velocity gradients in a thin boundary layer near the cylinder surface. If the cylinder diameter is not too small and the oscillatory amplitude is not too great, the acoustic streaming ("dc") boundary-layer thickness is approximately equal to δ, the "ac" boundary-layer thickness, given in Eq. (22). An approximate expression for the viscous stress S at the cylinder surface is

$$S = 2\pi \eta f \xi_0{}^2 / R_0 \delta \qquad (23)$$

where ξ_0 is the amplitude of the fluid oscillation relative to the cylinder and R_0 is the cylinder radius. Experiments have been done with vibrating tungsten wires for which it is found that time-averaged stresses of the order of 10^2 Pa or more are easily produced in the small-scale streaming (often called *microstreaming*) near the vibrator. Exposing cells and large biomolecules to the action of a vibrating wire has brought about a variety of effects, including lysis of erythrocytes, altered phagocytic index for leucocytes, clumping of platelets, and deactivation of enzymes (Rooney, 1981; Williams, 1983). More recently, Wu (2006b, 2007) found that exposing suspensions of Jurkat lymphocytes to microstreaming of this kind can cause them to become temporarily permeable to 500 kDa molecules.

Analysis of conditions in the half-wavelength traps discussed in Section 24.4.2, and related arrangements, shows that small-scale acoustic streaming plays an important role, in addition to the radiation force. Kuznetsova and Coakley (2004) describe detailed findings for a 1.5 MHz chamber and include an extensive list of references to other studies where microstreaming was involved.

Eddying motions of this kind can also be produced by ultrasound within blood vessels or in the interior of cells if the contents are sufficiently fluid. In general, microstreaming is generated in fluids adjacent to vibrating surfaces if the vibration pattern is sufficiently nonuniform. In their reviews, Williams (1983) and Miller (1987) describe experiments involving acoustic microstreaming produced in marine eggs, muscle fibers, plant cells, and blood vessels, leading to disturbances of various kinds. In the exposures of blood vessels (which were done *in vivo*), vigorous microstreaming led to thrombogenesis, apparently because of shearing action on platelets.

In a series of publications by Stavros and Dennis (1993), Nightingale *et al.* (1995), and Nightingale, Kornguth, and Trahey (1999), it is demonstrated that radiation force and acoustic streaming can be employed clinically for determining the nature of breast lesions. If the lesion under investigation is simply a fluid-filled cyst, focused ultrasound will produce flow, which can be detected with Doppler ultrasound. If no flow occurs, the lesion must be recognized as solid.

24.4.4
Other Nonthermal Noncavitational Effects

A challenge for investigators of mechanisms comes from findings that some therapeutic effects of ultrasound occur under conditions where the temperature rise is minimal, there is no evidence of cavitation activity, and the mechanism has not yet been determined. Insight into possibilities comes from earlier studies. For example, Schnitzler (1969) and Ravitz and Schnitzler (1970) did experiments in which highly localized ultrasound was applied to frog muscle fibers. A metal cone tapered to a small rounded tip with radius of curvature 20 μm acting as a point source was set into vibration at a frequency of 85 kHz with the tip in contact with a muscle fiber. Vibrating the tip with displacement amplitude of 2 μm for 1 minute produced disruption within mitochondria on the interior of an adjacent fibril, as determined by electron microscopy. (A wedge-shaped tip acting as a line source was also used.) Increasing the amplitude and time to 5 μm for 10 minutes led to severe damage. The effect was less for fibrils at a greater distance from the vibrator. In other experiments, the permeability of cells to sodium ions was reversibly increased by exposure to the localized vibration at an amplitude of 1 μm for an hour. The above results were obtained under conditions where there was little temperature rise and no indication of cavitation. It was reasonably concluded that the localized mitochondrial damage and the reversible increase in membrane permeability resulted from fields of time-averaged stress produced by the ultrasound. These stresses may have led to strain or microstreaming in the muscle fiber.

Related experiments were subsequently done by Frost (1974) and by Frost and Nyborg (1973) in which a localized ultrasound field was set up in a similar manner in a soft viscoelastic solid material, with an arrangement permitting determination of stress/strain fields. The latter was accomplished by choosing birefringent epoxy for a solid sample and using a polarizing microscope. A localized 85 kHz ultrasound field was established in the epoxy by the vibrating wedge-shaped tip of a tapered horn; this small tip, acting as a line source, was pressed against one edge of the sample by a static force F^*, which was superposed on the oscillatory force that produced the vibration. By observing the isochromatics as the vibration continued, for various values of the source amplitude, it was found that strain was generated for which the orientation was outward from the tip; that is, it was in the radial direction, like that produced by the static force F^*. Also, the magnitude of the vibration-produced strain (averaged over a cycle), like the strain produced by the static force F^*, was found to vary inversely with distance from the source. For both the F^*-produced and the vibration-produced strain, it was found that as the vibration continued the strain magnitude varied with time approximately according to a parallel spring-dashpot (Kelvin-Voigt) model for a viscoelastic medium. At low amplitudes, the cycle-averaged strain magnitude at a given point after a given time was found to be approximately proportional to the square of the vibration amplitude, but at higher amplitudes the relationship became linear, then nonlinear again.

Since it became known that localized ultrasound of low or moderate level can produce significant changes in viscoelastic media, including biological tissue, it was natural to explore possibilities for the broader beams of ultrasound that were commonly available. Pilla *et al.* (1990) directed a 1.5 MHz ultrasound beam, about 4 cm^2 in cross-sectional area, at the hind limbs of rabbits in each of which the tibular shaft had been cut. The ultrasound was applied in pulses, each of 200 μs duration, delivered at the rate of 1000 s^{-1}; the duty factor was thus 0.2. The intensity during each pulse, averaged over the 4 cm^2 area, was 150 mW cm^{-2}; the time-averaged (and spatially averaged) intensity was therefore 30 mW cm^{-2}. Tests made at various times after the treatment showed that, although the ultrasound did not affect appreciably the final mechanical strength, the healing process occurred more quickly in the treated fibula than in the sham-treated controls.

Since the 1990 study many others have been done, with similar findings; some of these studies were with laboratory animals and some were done as clinical trials (NCRP, 2002, Chapter 3). Here the conditions used were the same *low intensity pulsed ultrasound* (LIPUS) conditions as were employed by Pilla *et al.* (1990). In a clinical trial, Heckman *et al.* (1994) treated fractures of 33 patients and found that the time for (clinical and radiographic) healing was 86 ± 6 days for patients treated with ultrasound, and was 114 ± 10 days for controls. In an animal study, Cook *et al.* (2001) evaluated the repair of osteochondral defects (3.2 mm diameter and 5.0 mm deep) in the patellar groove of 106 rabbits; histological tests showed that daily 20-minute applications of ultrasound caused continuous improvement with most of the benefit occurring in the first 12 weeks.

Parvizi *et al.* (2002) considered mechanisms for the healing action of LIPUS, noting, for analogy, that clinicians commonly apply mechanical force to the skeleton in various ways when treating skeletal disorders. Also, chondrocytes, known to be critical in the response to fractures, have been shown to respond to mechanical forces. These authors carried out *in vitro* experiments in which cultured rat chondrocytes were exposed to LIPUS, finding that the internal concentration of calcium was significantly increased by the exposure. They concluded that it was signaling from this increase in calcium concentration that led to the increased synthesis of proteoglycan (critical for fracture repair) by chondrocytes, which had been observed in previous experiments.

Zhou *et al.* (2004) found that exposures to LIPUS, from 6 to 11 minutes in duration, of cultured fibroblasts from human foreskin, resulted in an increased number of the cells. They also obtained evidence that the ultrasound promotes the cell proliferation via activation of integrin; in this they support findings of Schmidt *et al.* (1988) that integrin receptors at the cell surface mediate the response of a cell to mechanical stress.

Much has now been learned about the effects exposure to LIPUS produces on cells that are important to the healing process. It is expected that these effects come about because of mechanical stress applied by the ultrasound. However, the specific nature of the stress is still unknown. The nonthermal noncavitational mechanisms discussed in Sections 24.4.2 and 24.4.3 are obvious candidates. For any of these, it must be recalled that under LIPUS conditions, the ultrasound is delivered in pulses about 200 μs in duration delivered periodically at a frequency of about 1 kHz.

Acoustic streaming, probably of small scale, would be a possible source of stress if there is fluid present in the tissue region exposed.

For any medium, radiation force might be involved in any of various ways. Radiation force might be delivered by a beam passing through an absorbing medium; the force per unit volume (cf. Eqs (3) and (20)) would be $2\alpha I/c$, where α is the absorption coefficient for the medium, I is the intensity and c the speed of sound. In another situation, the force given by Eqs (21a and b), might be exerted on a single particle in any sound field for which the potential and kinetic energy densities are known. In still another situation (for which the equations are given elsewhere (NCRP, 2002, Section 3; Nyborg, 1989), the force is between two small particles in a sound beam, as discussed briefly in

Section 24.4.2; here, the force is attractive if the line connecting the particles is perpendicular to the beam direction, and is repulsive if the two directions are parallel.

24.5
Nonlinear Cavitation Activity

24.5.1
Introduction

In Sections 24.3.2 and 24.3.3, the gas bubble is considered to vibrate in a volume mode, maintaining a spherical or quasispherical shape during its oscillation. Much valuable information is obtained from theory for a spherical bubble. However, in aqueous media exposed to ultrasound in the lower-frequency range (e.g. below 1 MHz) at pressure amplitudes in common use, free bubbles seldom remain spherical. Even at modest amplitudes, surface waves develop on the bubbles and the associated microstreaming (see Section 24.3.3.5) is altered. At higher amplitudes, the waves become highly distorted and microbubbles are entrapped, as when “white caps” appear on a lake or ocean during a windy day. As a result of these processes, the original free bubble may fragment and disappear. Surface waves may also develop on UCAs when in an ultrasound field of high amplitude; these may lead to fragmentation of the UCA shell, and release of the enclosed gas as free bubbles. Although the activity of a free gas bubble may not continue long in an ultrasound field of high amplitude, it may be of a violent nature which is destructive or, if controlled, is useful in various applications. Much attention has been given to the analysis of bubble dynamics under high amplitude conditions. In the following section, some relevant theories are briefly discussed.

24.5.2
Bubble Dynamics Under High Amplitude Conditions

In Section 24.3.2.1, an equation of motion, Eq. (7), is given for a gas bubble that applies when the oscillation amplitude is small. Small-amplitude theory, based on solutions of this equation, is very useful in that it leads to convenient analytical expressions. For most of the phenomena discussed in Section 24.3.3, such expressions have been developed and have proven sufficient for many purposes. However, the basic equations that govern bubble motion are nonlinear, and at high amplitudes the consequences of this nonlinearity cannot be avoided. Reviews dealing with nonlinear equations for cavitation and their solutions have been published by Flynn (1964), Neppiras (1980), Apfel (1981), Young (1989, 2005) and Leighton (1994, 1996). As given by Neppiras (1980), one form of the governing equation is (using the dot to represent differentiation with respect to time)

$$R\ddot{R} + (3/2)\dot{R}^2 = (1/\rho_0)\{P_{\text{eff}}(R_0/R)^{3\gamma} - 2\sigma/R - [P_a - p_0\sin(\omega t)]\} \tag{24}$$

where R is the instantaneous bubble radius, P_{eff} is equal to $P_a + 2\sigma/R_0$, and σ is the surface tension at the gas–liquid interface; γ, R_0, P_a, and p_0 have the same meanings as in Section 24.3.2. Equation (24) applies to a sphere containing a perfect gas surrounded by inviscid liquid in which the acoustic pressure is p_0

$\sin(\omega t)$. Equation (24) reduces to Eq. (7) (neglecting damping and surface tension) when linearizing approximations are made, namely, neglecting the term $(3/2)\dot{R}^2$, replacing R with $R_0 + \xi$, and assuming the radial displacement ξ is much less than R_0.

Except at small values of the pressure amplitude p_0, solutions of Eq. (24) have quite a different character from the sinusoidal functions of time that satisfy Eq. (7). As the applied pressure amplitude p_0 is increased, the bubble response may dramatically change. If p_0 becomes great enough to cause enough bubble growth during an expansion phase so that the maximum value of R exceeds R_0 by a critical factor of about 2 or more, the conditions for *inertial* (formerly called *transient*) *cavitation* will be met. Holland and Apfel (1990) arrived at a practical criterion for diagnostic ultrasound. Under these conditions, the inward momentum of the liquid, acquired during the contraction phase, causes the bubble to collapse. During a collapse event, the inward speed of the bubble surface can become supersonic and give rise to shock waves, both within the bubble and in the surrounding liquid. After a collapse, the bubble may rebound and undergo further cycles of expansion and contraction, or it may fragment because of the surface phenomena referred to earlier (Section 24.5.1). During a very short time interval, when the radius is near its minimum, the pressure in the bubble can reach hundreds of megapascals and the temperature thousands of kelvins. Experimental evidence for the existence of high temperatures and their implications for biological effects of ultrasound are discussed in Sections 24.5.3 and 24.5.4.

Curves of radius versus time can be complex and critically dependent on parameters of the bubble and the sound field. In a sound field of frequency f, the curves can exhibit harmonics of frequency $2f$, $3f$, and so on, even for modest values of the pressure amplitude. At somewhat higher levels, the motion becomes aperiodic; subharmonics of frequency $f/2$, $f/3$, and so on, occur as do ultraharmonics at frequencies $3f/2$, and so on. Under some conditions, the solution becomes indeterminate, allowing multiple values for the radius. Such indeterminacy is an aspect of *deterministic chaos*, a development in theory that is generally relevant to nonlinear systems; the investigations by Lauterborn and associates on the implications of chaos theory for bubble behavior have been reviewed by Young (1989).

24.5.3
Effects of Cavitation in Biological Suspensions

Many experiments have been done in which ultrasound is applied to suspensions of cells or macromolecules and evidence is found for a change of some kind. The subject has been reviewed by El'piner (1964), the NCRP (2002), Miller (1987), Williams (1983), ter Haar (2004), and Miller (2007). In these *in vitro* experiments the mechanism for observed effects is almost always some form of cavitation, involving either free bubbles or UCAs. Ultrasound is employed widely for sterilization and for applications where it is desired to release cell contents. Following the advent of UCAs, which allow much better control of the cavitation process, there has been increasing interest in *sonoporation*, a technique that makes cells temporarily permeable, thus facilitating transfection (Wu, 2006b).

In special situations, when controlled bubble populations and low pressure amplitudes are used, the effects of bubble activity can be ascribed to microstreaming and related phenomena, which are discussed in Sections 24.3.3.4 and 24.3.3.5. At the higher amplitudes, which are commonly used, the action is much more complex, as described in Section 24.5.2.

24.5.4
Effects of Cavitation in Tissues

Organized tissues present contrasts to typical *in vitro* systems in the nature and extent of cavitation activity that occurs in them during exposure to ultrasound. Cell culture media are usually well supplied with freely mobile cavitation nuclei, whereas the same is not true in tissues. Evidence for cavitation nuclei in normal body fluids has not been reported, and the gaseous bodies that exist in some nonfluid tissues are restricted in their translational motion.

Much information on the response to ultrasound of tissue containing gas-filled spaces has been obtained by experiments with plants and insects. The subject of cavitation in organized tissues has been reviewed by Carstensen (1987), Miller (1987), and Frizzell (1988). Certain plant tissues make convenient materials for study because they are relatively transparent, contain gas-filled intracellular channels, and can be viewed with an optical microscope while they are being exposed to ultrasound. Some insects have proved to be attractive animal models, since gas-filled tracheae and branching tubes permeate the tissue.

When a leaf of the water plant *Elodea* is viewed during application of ultrasound, a great deal of motion is seen within cells (in the large vacuoles that these cells possess), especially cells near the larger gas-filled channels. This motion is evidently acoustic microstreaming, brought about by the vibration of cell walls that accompanies volume oscillation of the gas in the intracellular channels. At low values of the pressure amplitude the motion is slow, but at large amplitudes it becomes vigorous enough to cause cell death, probably by rupture of the plasma membrane. Miller (1987) presents evidence that the rupture is caused by shearing stress associated with the microstreaming. From experiments at different frequencies, resonances are observed, approximately as expected from calculations of resonance frequencies for the gas-filled channels.

In experiments with larvae of the fruit fly *Drosophila,* it was found by Carstensen (1987) that larvae are killed by exposure to pulsed ultrasound if the incident intensity during the pulse exceeds about 10 W cm^{-2}, corresponding (for a plane traveling wave in water) to a pressure amplitude of about 0.6 MPa. This was found true even with pulse repetition rates and pulse durations approaching those used in diagnostic ultrasound. From studies with fertilized *Drosophila* eggs, it was found that the sensitivity of the organism increased greatly at the stage of development when the trachea and tubules filled with air. These results have implications for safety of pulsed diagnostic ultrasound when it is applied to tissues containing small air spaces.

In mammalian tissues the lung alveoli provide an abundant source of small gas-filled spaces; effects of acoustic waves on the lung are discussed later. In other tissues, there is little evidence for cavitation activity produced by ultrasound, unless the amplitude is high *or unless bubbles have been inserted into the tissue*. Since UCAs became available, the latter possibility has become feasible as part of common practice; this changes the potential significantly for cavitation activity. Dalecki (2007) has reviewed existing information on bioeffects produced by ultrasound in tissues containing blood into which UCAs have been injected. These bioeffects include hemolysis (Dalecki *et al.*, 1997b), effects on the vasculature (Miller and Gies, 2000) and effects on the heart (Dalecki, *et al.*, 1997a). Besides deleterious effects, UCAs show promise for enhancing the dissolution of clots *in vivo* (Birnbaum *et al.*, 1998).

An intriguing finding, with recognized implications, is that phagocytic cells will engulf UCAs and that the latter will respond actively to ultrasound even after being phagocytosed (Dayton *et al.*, 2001). This phenomenon has added new capabilities to medical imaging (Forsberg *et al.*, 1999), and also provides excellent capabilities for research on UCA–cell interactions (Miller and Quddus, 2002).

Some of the effects obtained in tissues when UCAs are present occur at modest ultrasound levels under which noninertial forms of cavitation are involved, while others occur at higher levels and require the more violent activity characteristic of inertial cavitation. In their review, Hynynen and McDannold (2006) describe medical procedures currently used or considered, involving HIFU, in which cavitation sometimes plays an important part. Particularly noteworthy was the demonstration that, if UCAs are present, the blood–brain barrier can be opened by the use of HIFU, so that drugs can be administered as needed. Also, when UCAs are used, it is found that the desired temperature can be reached with the use of lower intensities; rationale for this was developed by Holt and Roy (2001). In another application, Vaezy *et al.* (1999) found that HIFU can be used to stop active bleeding from vascular injuries; while heating is the primary mechanism, useful roles are also played by acoustic streaming and cavitation.

If medical applications of ultrasound were ranked in order of the amplitudes employed, acoustic lithotripsy would be at the top of the list. An acoustic lithotripter is a device for destroying stones in the kidney or gallbladder by focused ultrasound of very high amplitude.

Coleman and Saunders (1989) showed that extracorporeal shock lithotripters generate short pulses (“shocks”) in water in which peak positive pressures extend up about 100 MPa and peak negative pressures to 10 MPa. These pulses are less than a microsecond in duration and, in clinical practice, are delivered at pulse repetition frequencies up to 40 Hz. In a surgical procedure, it is typical to apply 1000 shocks, or more. Cavitation appears to be one of the principal means of action for lithotripter pulses, but there are many questions to be answered about when and where the action will occur. Recalling results discussed above for plant and insect tissue, it would seem reasonable that the mammalian lung, whose function requires air-filled spaces, would respond to ultrasound in a special way, as has been proven to be true. Delius *et al.* (1987) carried out experiments in which lithotripter pulses were applied *in vivo* to canine gallbladder, in which human gallstones had been implanted. Besides obtaining 90% success in destruction of the gallstones, they found lung hemorrhages in 80% of the animals.

Electron microscopy of hemorrhaged tissue revealed small breaks in the walls of blood vessels. Further information on lung damage was obtained by Hartman *et al.* (1990) in experiments where adult and fetal mouse lung were exposed *in vivo* to pulses from a lithotriptor. In adult, lung hemorrhage was produced when the acoustic pressure in the pulse was 2 MPa or more; however, in fetal lung, which evidently contains little or no air, there was no observable damage, even for acoustic pressures as high as 20 MPa. Further biophysical information on applications of acoustic lithotripsy may be found in NCRP (2002).

24.6
Discussion

Since the first experiments with ultrasound (and intense audible sound), much has been learned about its potential for altering biological structures and processes, and about its mechanisms for producing effects. Thus, useful information has been obtained and made available to users of ultrasound in diagnostic medicine so that harmful thermal effects can be minimized. At the same time, advances have been made in techniques for delivering heat in a prescribed manner to sites where it is needed. New methods, including the use of MRI, enable the determination and control of temperatures in therapeutic procedures much more accurately than before.

The role of small gas bodies in biomedical applications of ultrasound has undergone a transformation since UCAs became commercially available. Investigators are now able to have microbubbles of controlled size and characteristics at their disposal. Among the promising applications that these make possible (besides their intended use in improving ultrasound image contrast) is in sonoporation, that is, controlled modification of cell membrane permeability, in order to facilitate drug transfer.

In another advance, LIPUS procedures have become well established and are increasingly used for the treatment of bone fractures. Since the intensity levels used are modest, LIPUS is a form of ‘‘soft’’ ultrasound therapy for which the mechanisms are yet to be learned. Neither heat nor cavitation appears to be important. Serious consideration is being given to the interaction of ARFs, modulated at an audible frequency, with chondrocytes and other structures that are important to the healing process and are known to be stimulated by mechanical stress.

From these examples, it is seen that much has been learned about biological effects that ultrasound can produce; however, important questions remain. Continued research into the mechanisms, and further development of applications, show promise of being very rewarding.

Glossary

Acoustic radiation force: time-averaged force exerted by a sound field.

Acoustic streaming: time-averaged flow produced by a sound field.

Bubble: a small body of gas surrounded by liquid.

Cavitation: the mechanical response of one or more bubbles in a sound field.

Free bubble: a bubble with no film or shell at its surface.

LIPUS: acronym for low-intensity ultrasound.

UCA: acronym for ultrasound contrast agent.

Ultrasound contrast agent: a bubble designed for use with diagnostic ultrasound; it has a thin film or shell at its surface.

INTRODUCTION

Life on Earth has, since its inception some 3.5 billion years ago, been constantly bathed in geomagnetic information of a reasonably steady and uniform nature. Speculations have existed since the mid-1800s that organisms might use geomagnetism in orientation or navigation. Thus, it is surprising that scientific investigation of a possible geomagnetic basis for the long-recognized, but inexplicable, migratory and homing feats by some animals (e.g., a "magnetic sense") did not occur until the 1940s (Yeagley, 1951). By the late 1960s, however, students of animal behavior had accumulated data consistent with this possibility (see Yeagley, 1951; Barnothy, 1964; Brown, 1962; Brown *et al.*, 1960; Brown *et al.*, 1964; Merkel and Wiltschko, 1965).

Many early investigations addressing geomagnetic responsiveness of organisms were suggestive and not universally accepted. Some were conducted with very strong (10× earth strength, or more) inhomogeneous fields produced with bar magnets and super imposed on the local magnetic environment (Brown, 1962; Yeagley, 1947, 1951; Keeton, 1971; Southern, 1972a). Others were correlative studies (Southern, 1972b) or involved attempts to reduce or null the geomagnetic field such as with metal cages (Merkel and Wiltschko, 1965). Although their reports comprise much of the seminal literature describing magnetic influences on animal behavior, the effects noted by these and other early workers either had little relevance to the strength or configuration of the geomagnetic field or were not reliably reproduced—in some cases even by the same experimenters.

That animals perceive and respond to geomagnetism was probably first universally accepted around 1970, largely as a result of the studies of Lindauer and Martin (1972) with honeybees and those of Keeton (1974) (see Larkin and Keeton, 1976) with homing pigeons. Certainly by 1975 the biology-geomagnetism connection had been convincingly made even though a mechanistic basis for animal orientation or navigation using the "weak" geomagnetic field remained a com-

plete mystery. One possibility, *that organisms might respond to or sense the geomagnetic field by virtue of being permanently magnetized or through magnetic tissues* (biomagnetism), although obvious in retrospect, was not seriously considered until after 1975. Keeton (1972), for instance, in reviewing pigeon homing, summarized several hypothetical models of bird orientation. Included were mechanisms based upon magnetically induced electrical fields (Faraday effect), accumulation of Coulombic electrostatic charges by flying birds, piezoelectric properties of feathers, nuclear magnetic resonance, and mechanical displacement as with accelerometers (otoliths or hair cells) but with no mention of permanently magnetic materials *per se.*

It was into this setting that the magnetotactic bacteria (Blakemore, 1975) made an unexpected entry. As a microbiology graduate student at the University of Massachusetts, Amherst, the author was microscopically examining muds which had been collected and brought from Woods Hole, MA, by his major advisor, Professor E. Canale-Parola. He observed swimming bacteria constantly moving with a bias toward one side of the mud drops being examined (Fig. 1). These bacteria reoriented, making arcs or U-turns, all swimming in the same (magnetically oriented) direction when a small magnet was brought near. Upon examining these "north-swimming organisms" by electron microscopy (Fig. 2), the author was again surprised to find that each bacterial cell possessed intracellular, iron-rich crystals which he speculated might be a magnetic material such as magnetite. [Pioneering studies of H. Lowenstam (1962a) describing biogenic magnetite comprising a hardened surface coating of mollusc radular denticles were unknown to him.] Shortly after the magnetotactic bacteria were reported (Blakemore, 1975), honeybees (Gould *et al.*, 1978) and birds (Walcott *et al.*, 1979), previously shown by ethologists to have geomagnetic sensibilities, were examined with sensitive cryogenic rock magnetometers to determine if they, too, might contain permanently magnetized material. These searches must have produced some heady moments!

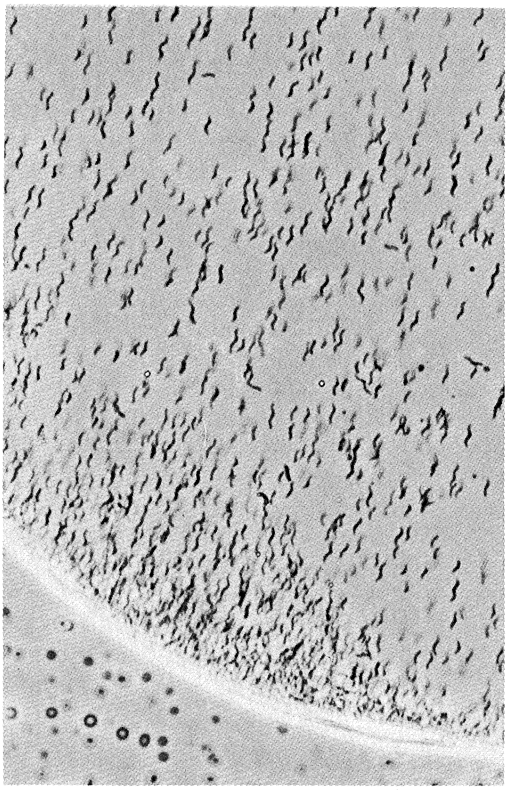

FIG. 1. Swimming dipping needles. Cells of the bacterium *Aquaspirillum magnetotacticum* each possess an intrinsic magnetic dipole moment [μ approximately $(1-3)\times10^{-12}$ erg G^{-1}; $(1-3)\times10^{-3}$ pA m^2] and consequently align in magnetic fields. Their swimming direction is thereby magnetism-biased (i.e., they are magnetotactic). Shown here are cells from a laboratory culture photographed with electronic flash to arrest their motion as they swim and preferentially accumulate at the edge of a water drop in response to an applied magnetic field of μT intensity. Each cell measures approximately 0.32×4.0 μm.

In the ensuing decade and a half, the list of magnetic organisms steadily increased (Table 1). Thus, magnetotactic bacteria appear to have influenced the entire field of biomagnetism by providing a novel, and simple but credible, paradigm for the basis of geomagnetic sensitivity in organisms. In 1975 it became possible to refer in biology to permanently magnetized cells—biomagnetism had acquired factual status.

For magnetotactic microbes, the connection between cell magnetism and cell alignment in the Earth's field has been conclusively established (see below). However, the fact that large, multicellular organisms such as bees or pigeons may have tissues as much as 10 or 20 times more magnetic than background does not necessarily equate their biomagnetism with a geomagnetic responsive-

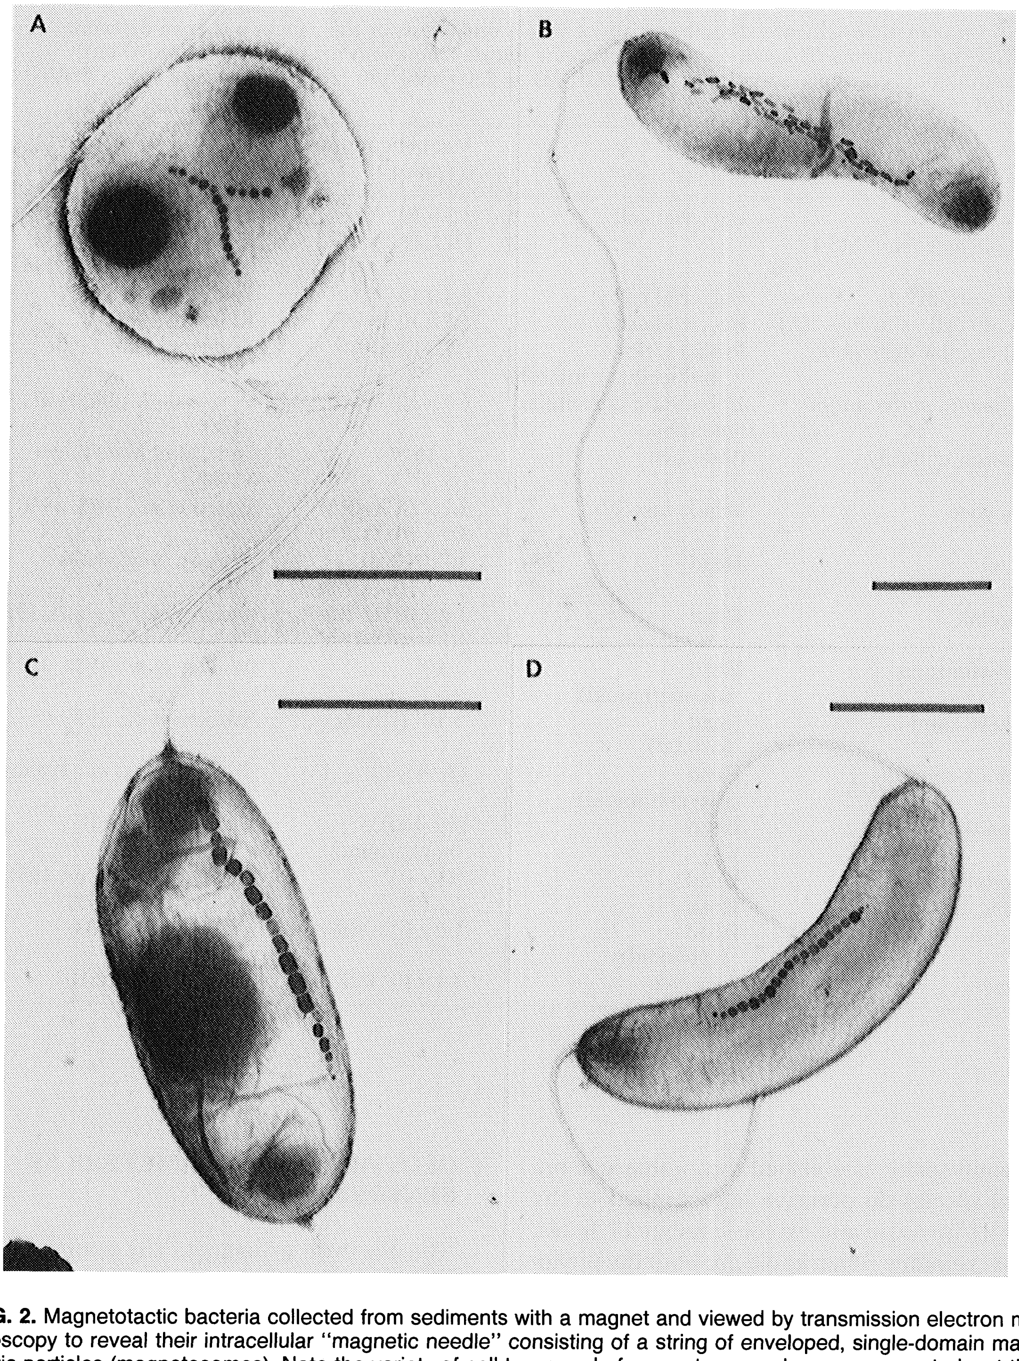

FIG. 2. Magnetotactic bacteria collected from sediments with a magnet and viewed by transmission electron microscopy to reveal their intracellular "magnetic needle" consisting of a string of enveloped, single-domain magnetic particles (magnetosomes). Note the variety of cell types and of magnetosome shapes represented, yet the consistency of magnetosome size and shape within each cell. Cells align in ambient magnetic fields by means of their intrinsic dipole moment imparted by the magnetosome string and swim in the field by means of their flagella. Bars = 1 μm.

ness. The greatest remaining challenge of biomagnetism research in higher organisms, in fact, may be separating out what appears to be an abundance of magnetized material in animals from that seemingly minute fraction which may be involved in magnetic sensing (Kirschvink, 1989). However, studies of conditioned and unconditioned behavior have

Table 1. Magnetic organisms. Biomagnetism of whole organisms or their parts has been determined for a variety of life forms. The values cited refer to the natural remanent magnetization (NRM) or saturation-induced remanent magnetization (sIRM) as determined in almost every case with a SQUID. See text (Sec. 2.3) for details.

unequivocally established that numerous animal species do perceive and respond to the earth's intrinsic and extrinsic magnetic fields. What remains remarkable are both the phylogenetic diversity of organisms with geomagnetic responsiveness, and their degree of magnetic sensitivity. Remaining enigmatic are *how* animals sense the different field parameters and, in most instances, exactly *what*, in their normal lives, they use magnetic sensing for. The remainder of this chapter addresses these questions, and provides selected examples illustrating geomagnetic-biomagnetic interactions among phylogenetically diverse life forms.

1. GEOMAGNETIC PARAMETERS AS SENSORY CUES

The Earth is a magnet. The geomagnetic field does, in fact, have a major, although not perfect, dipolar character. This *intrinsic* predominant, dipolar field (*H*) has a dipole moment value (μ) of 8×10^{22} A m^2 (=J T^{-1}) at its center. Earth's dipolar field has an intensity of roughly 50 μT at its surface and is directed northward globally (the field direction is, by convention, the direction in which the north-seeking end of a compass needle points). Except at the magnetic equator, the field has a vertical component and is inclined from the horizontal. It is directed outward (upward) in the southern hemisphere and increasingly inward (downward) as one moves north of the magnetic equator (Fig. 3). At any particular locale, however, the geomagnetic field is neither as uniform nor constant as one might expect (given the dimensions of the magnet!). The field has a gradient of intensity increasing by several nT/km as one moves poleward such that the totally horizontal field at the magnetic equator is 29 μT and the totally vertical field at the North magnetic pole is >80 μT. Iron deposits and other crustal features contribute to permanent 100–1000-nT (1 nT is 1 γ of the older literature) local spatial anomalies, usually of somewhat greater intensity occurring as "peaks" against the generally more even "magnetic topography" of the background field.

The Earth also has *extrinsic* field components. Diurnal heating and cooling of the globe cause north-south shifts of the ionosphere (magnetosphere) producing daily 30–50-nT variations against the 50-μT background geomagnetic field. Magnetic storms caused by influx of ions from solar flares impose additional, but unpredictable, 10–10 000-nT fluctuations in the field. The minute temporal and spatial variations in the intensity or direction of the geomagnetic field, although insufficient to deflect a magnetic compass needle visibly, appear to be important factors in animal orientation behavior and navigation. As discussed below, they influence honeybee dancing, pigeon homing, and bird migration, and appear to correlate with locations of live whale strandings, for instance.

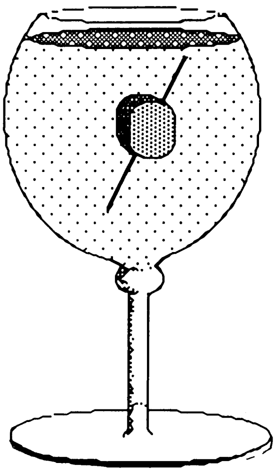

FIG. 3. An iron wire thrust through cork which is subsequently pared away to make the whole neutrally buoyant will, after being stroked with lodestone to magnetize it, always incline in the direction of magnetic dip (after W. Gilbert, 1600).

Potentially, organisms might detect the geomagnetic field direction, its intensity, intensity gradient in space or time, inclination, declination, or combinations of these parameters. Magnetism-based biological *compasses* respond to the overall dipolar field direction (although not all biological compasses are magnetic and at least two types exist among those which are). Small spatial anomalies in the Earth's field provide "magnetic topography" appropriate for a *navigational map,* and small diurnal or lunar fluctuations may enable temporal sensing thereby driving or entraining *biological clocks.*

2. BIOLOGICAL ADAPTATIONS AND GEOMAGNETISM

The sensory repertoire of birds, bees, and aquatic animals includes geomagnetic cues. Behavioral evidence suggests that in some animals, magnetic and other (visual, olfactory, vestibular, pineal) sensory systems or organs may be integrated. Except for the magnetotactic microbes, however, the magnetic information used and mechanism(s) by which organisms extract it from their surroundings remain unknown or equivocal. Larger, eukaryotic organisms, unlike microbes, cannot be passively oriented by earth-strength fields and therefore require neuronal processing of primary magnetic stimuli. They also respond to multiple and hierarchically arranged cues (physiographic, wind/air, light, celestial, odor, magnetic) in homing, migration, or communication (Southern, 1988; Gould, 1980a, 1982; Wiltschko *et al.,* 1981; Wiltschko and Wiltschko, 1989; Moore, 1980), of which geomagnetism may be of relatively low priority or preference.

In the early days of biomagnetic effects research the overall dipolar geomagnetic field was considered a "weak" field—perhaps too weak for biological sensing, critics argued. It is now more commonly considered to be "strong." This begs the question of just what a weak field may be. Birds (Southern, 1972b, 1988; Keeton *et al.,* 1974; Walcott, 1978, 1980) and especially honeybees (Lindauer, 1977; Walker and Bitterman, 1989a, 1989c) respond to nT fluctuations of the background field and may use normal 30–50-nT diurnal geomagnetic variations as *Zeitgebers*—environmental stimuli that serve to "set" a biological clock—or to calibrate solar or stellar compasses or other sensory systems. Magnetic storms, which produce 10–1000-nT fluctuations against the background field intensity of 50 μT, have resulted in disastrous bird losses when they have occurred during long-distance pigeon races (Keeton, 1974). Thus, the criterion for weak field has been set to a very low value by living organisms themselves. Ironically, animals possess sensitivity to these very small spatial and temporal perturbations of the geomagnetic field, yet when getting down to the actual business of moving around outdoors, they may select preferred cues over magnetic information. This has provided interest and challenge to the task of unraveling magnetic from other sensory capacities in eukaryotes.

Several mechanisms by which organisms might obtain and utilize geomagnetic information in their life's activities have been suggested. Of these, two presently have experimental support, one having been proven in the bacteria. The first involves electro-orientation (Faraday effect) in which an organism moving with respect to the geomagnetic field induces an electric field to which it is sensitive (Kalmijn, 1981). This is a "*dH/dt*" type of system in which the organism detects changes in the field with respect to its changing position or with time. The other (an "*H*" system in which absolute or relative field parameters are detected) recognizes that organisms or their components may be permanently magnetic ("biomagnetism") and thereby may couple magnetically to the geomagnetic field. Geomagnetic orientation via biomagnetism has been proven in the case of magnetotactic bacteria and is highly likely in at least some other organisms.

It has recently become surprisingly evident that there is a common basis for biomagnetism among diverse life forms, this property being conferred by an ability to produce and retain ultrafine magnetic biominerals of a particle size, particle number, interparticle configuration, and particle orientation or placement optimal for geomagnetic sensing.

2.1 Biogenic Magnetic Substances

Magnetic biominerals are known to be produced by unicellular bacteria, a multicellular prokaryote, and unicellular and multicellular (animal) eukaryotes. Table 2 summarizes currently known magnetogenic microbes, i.e., those which form magnetic biominerals (Blakemore and Frankel, 1989). Some magnetogenic microbes such as GS-15, *Shewanella*, and possibly *Desulfovibrio* produce magnetic minerals extracellularly in the culture medium. They are of little relevance to the subject of this chapter. Magnetogens which retain the magnetic biomineral phase intracellularly are magnetic. All magnetic magnetogens which have been described are motile, and they are *magnetotactic*; their motility is directed by magnetism. In addition to those which synthesize the iron oxide magnetite, magnetotactic bacteria have recently been discovered which produce intracellular

Table 2. The magnetogens. Diverse microbes produce magnetic iron biominerals, presumably as a result of dissimilatory iron reduction. Those (1–6) with intracellular particles of oxide or sulfide are magnetotactic and respond to geomagnetism. References to particular examples cited are (1) Maratea and Blakemore, 1981; (2) Moench, 1988; (3) Bazylinski *et al.*, 1988; (4) Torres de Araujo *et al.*, 1986; (5) Farina *et al.*, 1990; Rodgers *et al.*, 1990; (6) Heywood *et al.*, 1990; (7) Lovley *et al.*, 1987; (8) Myers and Nealson, 1988; (9) Bell *et al.*, 1987; (10) Freke and Tate, 1961.

magnetic iron sulfides (Farina *et al.*, 1990; Mann *et al.*, 1990; Heywood *et al.*, 1990) including greigite (Fe_3S_4) and the nonmagnetic mineral pyrite (FeS_2) or, perhaps, pyrrhotite (Fe_7S_8). Diverse magnetogens appear to produce iron biominerals by means of a common biochemical process which may involve cell respiration with iron reduction (dissimilatory iron reduction). A relationship between iron biomineralization and cell respiratory metabolism in magnetogenic microbes, if indeed it exists, is not expected to be true of animals because the latter are obligated to use O_2 in mitochondrial respiration.

Magnetite is one of the most prevalent biogenic minerals (Lowenstam, 1981). It has a characteristic ^{57}Fe Mössbauer resonance spectrum (Fig. 4) consisting of two overlapping six-line spectra and reflecting its mixed-valence state (Frankel *et al.* 1979, 1983). Magnetite can exist as bulk crystalline material such as in rocks, or as ultrafine particles. The tiniest grains, <40 nm, are superparamagnetic (SPM). Although they are permanently magnetized, their direction of magnetization is constantly buffeted by thermal forces, kT (commonly associated with Brownian motion), into one of the several crystallographically preferred or "easy" axes of magnetization. Thus, SPM particles maintain a constant direction of magnetization only when under the influence of an external, aligning magnetic field. Within large volumes of magnetite, magnetic domains (crystallographic regions in which unpaired spins are directed similarly) form which are separated by domain walls. This multidomain (MD) character is typical of magnetite particles larger than approximately 100 nm along a major axis (shape is important; somewhat longer but anisotropic particles may not take on MD character). Excluding anisotropy, for reasons having to do with the width of domain walls relative to the entire crystal dimension (see Frankel, 1982, 1984), particles larger than SPM (40 nm) and smaller than MD (<100 nm) exist as single domains (SD) of magnetite. SD grains have the saturating magnetization value, J_s, characteristic of the mineral ($480\ \mathrm{G\,cm^{-3}} = 4.8\times10^{5}\ \mathrm{A\,m^{-1}} = 4.8\times10^{5}\ \mathrm{J/T\,m^{3}}$ for magnetite); that is, they are each stably, spontaneously, and fully magnetized to the limit for the mineral and are, consequently, most efficient magnets.

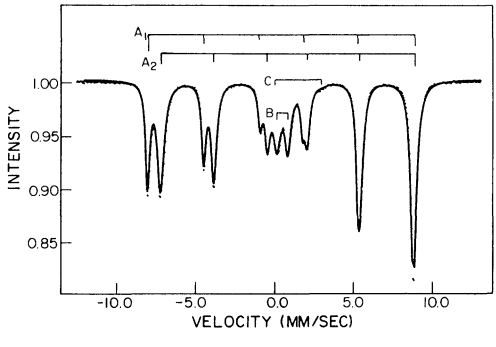

FIG. 4. The ^{57}Fe Mössbauer resonance spectrum of cells of the magnetic bacterium *Aquaspirillum magnetotacticum* indicates the presence of several iron species. Fe_3O_4 has a distinctive spectrum consisting of two overlapping six-line spectra denoted by lines A_1 and A_2. Spectral lines A_1 correspond to ^{60}Co gamma-ray absorption by Fe^{3+} in tetrahedral lattice sites of the mineral, whereas A_2 absorption lines are due to Fe^{2+} and Fe^{3+} in octahedral lattice sites. Spectral lines B are from a high-density hydrous iron oxide (ferrihydrite) and those marked C indicate the presence of some ferrous iron in the cells [from Frankel *et al.* (1983) and Frankel *et al.* (1985)].

2.2 The Bacterial Paradigm; A Biomagnetic Needle

The magnetic moment μ of a 50-nm SD magnetite particle, which is the product of its volume V and J_s, is 5.9×10^{-14} erg G^{-1} cm^{-3} (or electromagnetic unit, emu; see Glossary for equivalent SI unit). The particle magnetic energy tending to align it in the earth's field (i.e., the product of its magnetic moment μ and the geomagnetic field H) is roughly 3×10^{-14} erg. This is equivalent to the thermal energy ($kT=4.1\times10^{-14}$ erg) tending to randomize its orientation in water. Thus, despite having a permanent direction of magnetization, a single SD magnetite crystal will not align well in the geomagnetic field at room temperature. However, as predicted by the "chain of spheres" model of Jacobs and Bean (1955), SD grains constrained to lie in linear strings magnetically orient north-to-south and their moments are therefore additive. When connected in long strings within cells as in Fig. 2, SD grains comprising magnetosomes make superb magnetic needles. They align in the field (dragging their surrounding biomass with them) according to the Langevin function as in Fig. 5 (see Blakemore and Frankel, 1981; Frankel, 1982, 1984; Kalmijn, 1981); and when the ratio of their magnetic

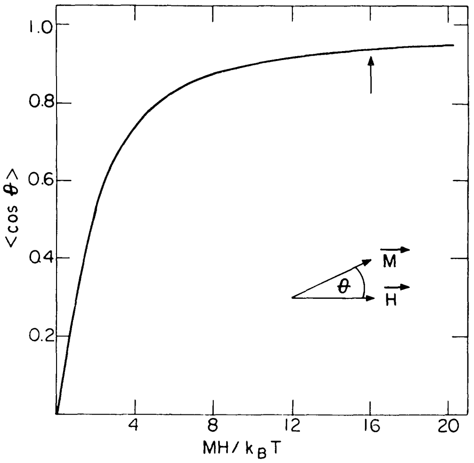

FIG. 5. The Langevin function: $\langle \cos\theta \rangle = L(MH/kT)$, plotted as a function of the ratio of magnetic (μ·**H** or **M**·**H**) to thermal (kT) energy. The arrow indicates the orientation of magnetotactic bacteria having a calculated cell dipole moment of 1.3×10^{-12} emu (1.3×10^{-3} pA m^2) in the geomagnetic field at ambient temperature (Frankel and Blakemore, 1980).

(μH) to thermal (kT) energies has a value of approximately 10 (as is the case for bacterial cells, which commonly have some 20 stringed particles), 80%–90% of the cells in a population are aligned in an earth-strength field of 50 μT (see Figs. 5 and 6 and Kalmijn, 1981). Neither more magnetite grains per cell nor a stronger ambient geomagnetic field would bring about significantly greater cell alignment in the field direction.

Consequently, magnetotactic bacteria in nature appear to be optimized for geomagnetic orientation in terms of

1. the value of their cell magnetic moment, i.e., number of magnetosomes;
2. the SD nature of their magnetosomes;
3. the arrangement of their magnetosomes in a string within the cell; and
4. the orientation of the string with respect to the axis of cell motility.

As stated by Professor E. Purcell, "This is a case of the compass steering the ship." Because their particles are SD and are arranged in a string, magnetic bacteria can be remagnetized (Kalmijn and Blakemore, 1978; Blakemore *et al.*, 1980; Mizota and Maeda, 1983), but not demagnetized. Magnetic moments of microorganisms have been evaluated in a variety of ways (see Sec. 3.1 and Table 1), yielding quite consistent values in the range $(0.1–1)\times10^{-12}$ emu $[(0.1–1)\times10^{-3}$ pA m$^2]$.

2.3 The Quest for Biomagnetic Needles

Animals containing magnetic biominerals frequently have small quantities per unit biomass. Moreover, in the case of magnetite, for which the SD dimension limits are known, the crystal size is limited (by unknown biological means) to the SD size range. SD magnetite grains are from 10 to 100 nm, and therefore are near the resolution limit (20 nm) of light microscopy. Light microscopy is not a reliable means of detecting even the largest magnetosomes. The Perl reaction involving ferricyanide can be used to stain bulk material for iron deposits but no histochemical stain specific for magnetite exists. How, then, may one determine the presence and form of minute quantities of minute magnetic biomineral crystals in biological samples? Electron- and x-ray-diffraction spectra, as well as the ^{57}Fe Mössbauer spectrum (Fig. 4), of magnetite are distinctive. However, when confronted with limited amounts (in some cases only several crystals) of material *in situ*

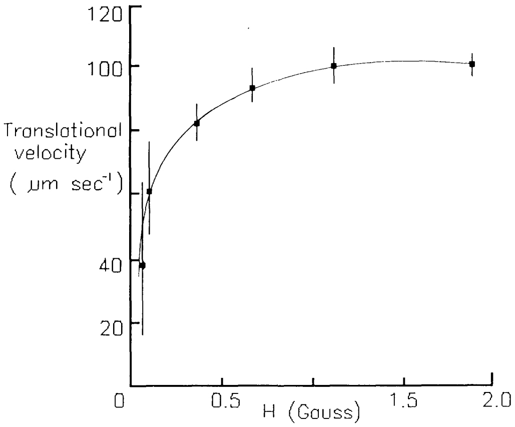

FIG. 6. The magnetic moment of magnetotactic bacteria from natural mud samples can be evaluated by a Langevin analysis. Cells directed by an ambient field of varying intensity up to 2.0 G (2×10^{-4} T) will orient progressively well as the field is increased, such that their forward speed (i.e., their translational velocity as opposed to absolute cell velocity) increases to the maximum cell swimming speed. As shown, cells in populations in natural habitats are 80%–90% aligned at the Earth's field intensity of 0.5 G (50 μT): they are optimized for geomagnetic interaction (see also Kalmijn, 1981).

or after tissue extraction, investigators of animal magnetism have too little material for techniques such as Mössbauer spectroscopy. This leaves as useful tools cryogenic magnetometry by means of superconducting quantum interference devices (SQUIDs), and the electron microscopical techniques of energy-dispersive x-ray analysis (EDXA), high-resolution transmission electron microscopy (HRTEM), and electron diffraction. The usefulness of magnetometry is related directly to the degree of care exercised in the skill of tissue dissection aimed at localizing biological magnetic material. Electron microscopy provides necessary confirmation of the nature of biomagnetic materials but at an extremely different degree of scale, the successful transition between these two scales requiring both skill and fortune.

Obviously, the most useful property in a search for biogenic magnetite is its magnetism. For instance, magnetite has a characteristic Curie temperature (858 K) at which it loses magnetism. Josephson-junction-based cryogenic rock magnetometers (Goree and Fuller, 1976; Fuller, *et al.*, 1985) provide sufficient sensitivity to determine the intensity of weak, natural remanent magnetization (NRM) of relatively large (100 cm^3) biological samples such as entire insects, bird heads, or portions of organs. The techniques are noninvasive and essentially nondestructive (of tissues). The presence of magnetite can raise the sample NRM above background by a factor of tens. Application of a strong ($>$ 300 mT) magnetizing field to a sample containing ferromagnetic material saturates its magnetic moment to the maximum value (i.e., that of its saturation isothermal remanent magnetization, or sIRM value). When magnetized in small incremental steps, resulting sIRM values for small, strongly magnetic, and homogeneously sized SD particles plot in a narrow range of magnetizing field values (see, for instance, Kirschvink *et al.*, 1985b; Walker *et al.*, 1985; Moskowitz *et al.*, 1988). The value at which a magnetizable substance maximally saturates provides information concerning its form and composition; MD magnetite saturates at about 90 mT, whereas SD magnetite continues to gain remanence to about 300 mT, while magnetizing fields greater than 1000 mT are required to saturate hematite and magnetic alloys containing nickel or cobalt. Additional information can be obtained by measuring remanence during progressive alternating current (ac) or alternating field demagnetization of the sample. Resulting coercivity spectra (plots of sample acquisition and loss of remanence) can indicate magnetic domain size and the particle-size distribution (see Cisowski, 1981; Walker *et al.*, 1985, 1988; Moskowitz *et al.*, 1988). It is possible to demagnetize MD but not SD particles or even assemblages of SD particles if they occur in certain distributional arrangements. Linear strings of SD particles, as in the arrangement of bacterial magnetosomes (Fig. 2), allow for strong particle-particle magnetic interactions. The resulting anisotropic character of the ensemble resists demagnetization. By carrying out ac demagnetization in the presence of a constant dc biasing field, one can determine the sample anhysteretic remanent magnetization (ARM). The resistance of (weak field) ARM to ac demagnetization is greater than that of (strong field) sIRM if the particles are SD or very small MD. Conversely, large MD particles have the opposite behavior. This different resistance to demagnetization of MD and SD particles is the basis of the Lowrie-Fuller test (Lowrie and Fuller, 1971; Fig. 7). Thus, merely determining that the median

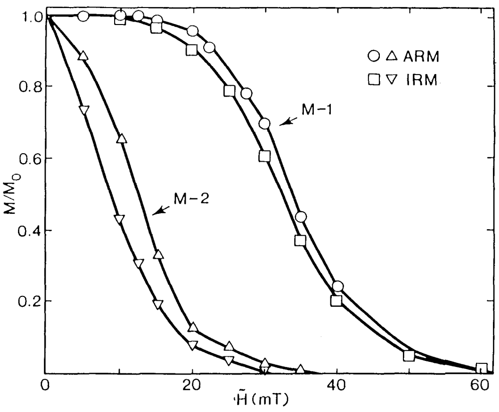

FIG. 7. The Lowrie-Fuller test applied to intact cells (M-1) and to extracted strings of magnetosomes (M-2) of *Aquaspirillum magnetotacticum*. The data are consistent with the presence of SD magnetite grains in a string arrangement as discussed in the text. (From Moskowitz *et al.*, 1988.)

destructive demagnetizing field of ARM is greater than that of sIRM is sufficient to establish the presence of SD particles in biological tissue. The manner in which ARM varies with variation in the dc biasing field also provides information regarding possible grain-grain interactions (i.e., reflecting the degree of separation between magnetic particles). As discussed by others (Kirschvink *et al.*, 1985b; Walker *et al.*, 1984, 1988; Moskowitz *et al.*, 1988), Cisowski (1981) showed that the shape of the ac demagnetization curve when compared to that of gain in sIRM should be symmetrical about the 50% magnetization point for uniformly dispersed magnetic particles. Particle-particle magnetic interactions, on the other hand, cause the intersection of these curves to fall below the 50% magnetization point. This technique has been useful in deducing that SD particles detected in fish (see Sec. 3.8) are arranged in strings as they are in the magnetotactic bacterium *Aquaspirillum magnetotacticum*.

Properly shielded and in clean environments, cryogenic magnetometers can provide sensitivity sufficient to detect several ng of magnetite. An instrument at Caltech, situated in a background noise of 5×10^{-12} A m^2, is sensitive to 0.1-ng magnetite in a sample volume of roughly 3000 cells (Kirschvink, 1982; Walker *et al.*, 1985).

The successful hunt for geomagnetically meaningful biological magnetism, then, should involve preliminary behavioral verification that an animal senses geomagnetism (preferably through conditioning but not merely through correlative studies), followed by magnetometry to localize magnetic tissues (carried out in concert with histological examination for iron deposits). Subsequently, conventional dissection (in unconventionally "clean" surroundings), chemical fixation, and electron microscopy allow fine-scale searches at the ultrastructural level. Most investigators hunting "biomagnetic needles" have concentrated on innervated tissues. Ultimately, influences of geomagnetism on nerve impulse transmission or other electrophysiological evidence of neuronal involvement will be necessary to elucidate completely the nature of the magnetic sense in higher organisms.

3. SOME EXAMPLES OF BIOLOGICAL INTERACTIONS WITH THE GEOMAGNETIC FIELD

Sufficient information has been gleaned from a number of living systems such that a "comparative biology" of geomagnetic responsiveness is emerging (Blakemore *et al.*, 1988). The variation typical of biology is also evident from consideration of biomagnetic-geomagnetic interactions exhibited by the phylogenetically diverse organisms described in the remainder of this section. A common theme throughout, however, appears to be the presence in geomagnetically responsive organisms of cell, tissue, or organ magnetic susceptibility—a property conferred upon widely different organisms by ultrafine magnetic particles similar to those within magnetotactic bacteria.

3.1 Prokaryotes

Except for the eukaryotic euglenoid discussed below, known magnetotactic microbes are prokaryotic. Great morphological diversity exists among these bacteria, and they are rather cosmopolitan in their environmental distribution. However, only several of the dozens of easily discernible types have been isolated and grown in axenic culture (Blakemore, 1982). Magnetotactic bacteria which have been phylogenetically analyzed belong to the α-subgroup of the proteobacteria; they are Gram-negative eubacteria (Eden *et al.*, 1991). No magnetotactic (or magnetogenic) archaebacteria have been described. None have been shown to exist autotrophically. All magnetotactic bacteria examined to date have been Gram-negative and facultatively or obligately anaerobic or facultatively or obligately microaerophilic. No strictly aerobic magnetotactic (or magnetogenic, for that matter) bacteria have been described.

Magnetotactic bacteria containing intracellular, membrane enveloped, iron-rich, structured particles (Blakemore, 1975) were shown by means of pulse remagnetization (Kalmijn and Blakemore, 1978) to be permanently magnetized cells. Axenically cultured cells (Blakemore *et al.*, 1979) of a microaerophilic, freshwater spirillum, *Aquaspirillum magnetotacticum* strain MS-1 (Maratea and Blakemore, 1981), were examined by Mössbauer spectroscopy which revealed that their particles, missing from nonmagnetotactic cells of the same species, were magnetite (Frankel *et al.*, 1979). Balkwill *et al.* (1980) referred to the *A. magnetotacticum* cell magnetic apparatus as the "magnetosome." More recent ultrastructural evidence indicated that each element of the magnetic apparatus of this organism consists of a crystalline mineral core enveloped within a lipid bilayer membrane (Gorby *et al.*, 1987) and the term "magnetosome" should now more appropriately be used to denote *each* membrane-bound crystalline particle (Fig. 8). Magnetic properties including NRM, sIRM, and ARM values and results of the Lowrie-Fuller test applied to *A. magnetotacticum* cells and their purified magnetosomes (Fig. 7) have been reported (Denham *et al.*, 1980; Moskowitz *et al.*, 1988).

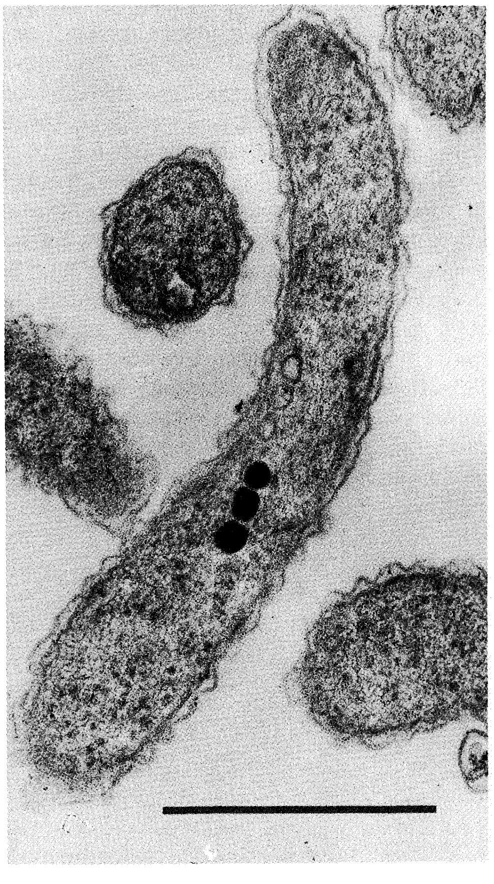

FIG. 8. Thin section through a portion of the magnetotactic bacterium *Aquaspirillum magnetotacticum* and viewed by transmission electron microscopy. Intracellular magnetosomes are evident as are triple-track (lipid bilayer) intracytoplasmic membranous magnetosome envelopes occurring as vesicles devoid of magnetite cores. Bar = 0.5 μm. (From Gorby *et al.*, 1987.)

The magnetic moments of magnetic microbes have been evaluated in a variety of interesting ways. These have included

1. electron microscopical determination of the volume of magnetite present, having a known value of J_s (Frankel *et al.*, 1979; Frankel and Blakemore, 1980; Kalmijn, 1981);
2. determination of the radius of U-turns and circular motions made by swimming cells in response to reversal of the ambient magnetic field and as a function of the applied field strength (Bean, 1979, 1989);
3. evaluation of cell translational velocity as function of aligning field intensity (e.g., a "biological Langevin analysis"; Kalmijn, 1981; Rodgers *et al.*, 1990);
4. pulse remagnetization (see Fig. 9; Kalmijn and Blakemore, 1978, and unpublished data);
5. evaluation of magnetic-field-dependent cell alignment as determined from elastic light scattering and magnetic-field-dependent cell birefringence (see Fig. 10; Rosenblatt *et al.*, 1982a, 1982b); and
6. use of cryogenic magnetometers (Moskowitz *et al.*, 1988, 1989).

Values of cell magnetic moments obtained by these diverse means are consistent among bacteria (Table 1), roughly $(0.1\text{–}1)\times 10^{-3}$ pA m^2.

The quantity, SD particle size, and arrangement of magnetosomes within the bacterial cell are ideal for geomagnetic sensing through biomagnetism and passive cell orientation in the geomagnetic field (Frankel and Blakemore, 1980, 1989; Blakemore, 1982; Blakemore and Frankel, 1981; Frankel, 1982, 1984). Studies of natural populations from around the world have revealed global selection for cell types with appropriate magnetic polarity for directing them away from surface waters (Blakemore *et al.*, 1980; Frankel *et al.*, 1981). The fact that no aerobic magnetotactic bacteria have been observed is consistent with an ecological role for magnetotaxis in directing cells downward toward less-oxygenated zones where they thrive. Two other strains of freshwater magnetic spirilla, MS-2 (isolated by N. Blakemore from the Durham,

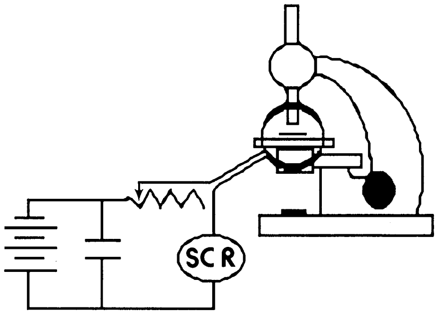

FIG. 9. Pulse remagnetization of bacterial cells (Kalmijn and Blakemore, 1978) was carried out while viewing them by means of a light microscope from which all ferrous metal components near the sample had been removed or replaced with nonferrous metal components. A 4-cm-diam single-turn Helmholtz pair of copper coils was fitted to surround the sample of bacteria on the microscope stage. A 4-μF capacitor connected to the coil in series with a variable resistor (critically damped RCL circuit) was discharged (triggered by a fast-switching silicon-controlled rectifier, SCR) to obtain a monophasic single-current pulse (up to 1350 A) having a time constant of 1.2 μs. The pulsing apparatus was placed within two room-sized Helmholtz pairs by means of which the local geomagnetic field was compensated or controlled. Magnetic pulses delivered antiparallel to the swimming bacteria were intense enough (200–600 G) and brief enough to effect their repolarization. Remagnetized cells in a constant ambient field immediately made U-turns and swam thereafter in the opposite direction. No cells became demagnetized.

NH, water-treatment plant) and a freshwater spirillum similar to MS-1 and MS-2 (T. Matsunaga, personal communication), have been isolated and cultured axenically, as has a magnetotactic, marine, helical to vibrioid strain, MV-1, which, unlike strains MS-1 (Blakemore *et al.*, 1984) and MS-2, produces magnetosomes anaerobically (Bazylinski *et al.*, 1988). These organisms are all microaerobic, tolerating O$_2$ to various low degrees, but none produce magnetite under aerobic conditions.

Magnetosomes of the marine strain MV-1, which appear as rectangular parallelepipeds in horizontal projection, are elongated hexagonal prisms (Sparks *et al.*, 1990) and crystallographically similar to particles from certain, as yet uncultured, magnetotactic bacteria [Fig. 11(A), 11(B)] found in sediments (Mann *et al.*, 1984b; Matsuda *et al.*, 1983; von Dobeneck *et al.*, 1987; Vali *et al.*, 1987; Petersen *et al.*, 1986; Towe and Moench, 1981). Magnetosomes of other species (Fig. 2), including those of *A. magnetotacticum*, which appear equant, with slightly rounded corners in horizontal projection, are cubo-octahedral [Fig. 11(C); Mann *et al.*, 1984a]. Still other magnetic bacteria collected directly from sediments possess anisotropic magnetosomes having a tear-drop or bullet shape (Fig. 2), often slightly arched (Blakemore *et al.* 1989) but based upon a hexagonally prismatic morphology (Mann *et al.*, 1987a, 1987b). Lattice imaging with HRTEM has revealed that SD particles, regardless of their morphology, when arranged in strings, have preferred crystallographic orientation such that the {111} faces of adjacent crystals are perpendicular to the string axis. This arrangement places the crystallographic easy axis of particle magnetization along the axis of the string, resulting in particle magnetic moments being

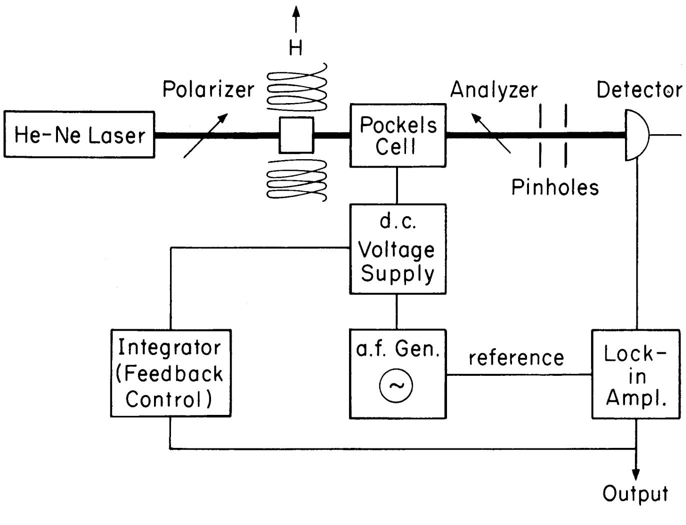

FIG. 10. Apparatus used by Rosenblatt *et al.* (1982a, 1982b) to measure the magnetic moment of *Aquaspirillum magnetotacticum* cells based upon their field-dependent optical birefringence. The bacterial cell suspension in a cuvette was placed within an electromagnetic coil all within a Mumetal enclosure to control bacterial magnetic alignment.

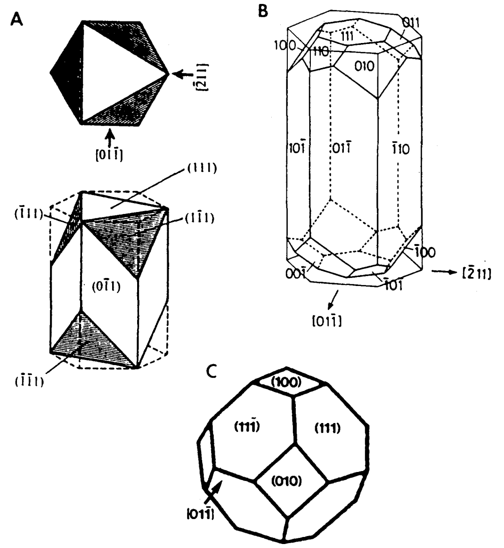

FIG. 11. Bacterial magnetosomes contain single-crystal mineral cores which are single magnetic domains. Magnetite grains which have been examined occur as truncated hexagonal prisms as in (A) (from Matsuda *et al.*, 1983) and (B) (from Mann *et al.*, 1984b), or as truncated octahedrons as in (C) (from Mann *et al.*, 1984a). Other types of crystal morphologies and mineral cores exist (see text). The crystal dimensions are roughly 40–100 nm along a major axis.

additive and in confirmation of the Jacobs and Bean "chain of spheres" model of magnetic SD interaction.

The crystal morphology of bacterial magnetite (but not that of sulfidic types of) magnetosomes varies in what is apparently a species-specific manner. This implies genetic control over magnetosome crystal morphology as well as biocontrol of their general arrangement within the cell (e.g., "stringed" vs clustered in arrays). Some biogenic forms of magnetite have not been synthetically produced. Biogenesis of fine-grain magnetite by *Aquaspirillum magnetotacticum* proceeds via partial reduction of a ferrihydrite precursor (Frankel *et al.*, 1983). Intracellular bacterial magnetite is formed, therefore, in a controlled process. It is tempting to speculate that the magnetosome membrane (Fig. 8), which is a true biological membrane consisting of a lipid bilayer in *A. magnetotacticum* (Gorby *et al.*, 1987), may control aspects of biomineralization including the maximum (SD) particle-size limit, arrangement in the cell, and crystal morphology. Consistent with this is the observation that extracellular magnetite produced in the absence of membranous structures by organism GS-15 (Lovley *et al.*, 1987) lacks the uniformity of crystal size and morphology exhibited by the biologically controlled forms of this mineral in magnetotactic bacteria and is not uniformly SD (Moskowitz *et al.*, 1989). Magnetite present within several higher organisms has been shown to exist within membranous vesicles (see Secs. 3.6 and 3.8). The fact that the somewhat elusive (Balkwill *et al.*, 1980) magnetosome membrane has not been detected in some magnetic bacteria (Bazylinski *et al.*, 1988) suggests caution in assuming that it has an important role in mineral biogenesis, however. More research is needed.

A northern hemisphere downward-swimming multicellular magnetotactic prokaryote from sulfidic, brackish water has been described (Rodgers *et al.*, 1990). A similar organism in Brazil (Esquivel *et al.*, 1983), also swam downward in that hemisphere. How individual flagellated cells comprising this organism are coordinated to bring about its translational motility in the magnetic field direction remains a mystery. Individual cells each contained magnetosomes consisting of the iron sulfide pyrrhotite (Farina *et al.*, 1990) or a mixture of pyrite (a nonmagnetic biomineral) and greigite (Mann *et al.*, 1990). The sulfides were detected using EDXA and their mineral structure was confirmed by electron diffraction and lattice imaging with HRTEM. The magnetic moment of an entire multicellular organism as determined by the method of Kalmijn (1981) was estimated to be 10^{-3} pA m^2 (Table 1). Magnetic iron sulfides have also been detected within unicellular prokaryotes found as cohabitants with this multicellular form (Heywood *et al.*, 1990; R. Blakemore, N. Blakemore, and R. Frankel, unpublished data). The process of magnetic iron sulfide biomineralization by these magnetogens is completely unknown.

There is strong selection pressure on natural populations of magnetotactic bacteria for downward swimming: virtually all cells swim downward. That this is a consequence of the interaction between cell magnetism and geomagnetism is evident both from study of natural populations and laboratory observations (Blakemore, 1982; Blakemore *et al.*, 1980; Kirschvink, 1980; Spormann and Wolfe, 1984; Torres de Araujo *et al.*, 1990). Wendy O'Brien in the author's laboratory incubated six small, natural enrichment cultures within solenoids capable of inverting only the vertical component of the local (northern hemisphere) geomagnetic field. The numbers of cells in each culture (as determined by direct microscopic counts) which migrated in the field direction were compared with those directed opposite to it before and after energizing three of the six coils (Fig. 12, vertical arrow). Within several weeks, south-and-down-seeking cells dominated the total population of magnetotactic bacteria in sediment samples within coils energized to reverse the vertical component (FR) but not in control samples in normal fields (FN). The population density of all magnetotactic bacteria decreased by several orders of magnitude (most likely as a result of the disruptive effect of O_2 introduced during the sampling process) but with strongest selection against upward directed cells. Obviously, the bacterial population responded within a few generations to magnetic-field inversion by acquiring reversed magnetic polarity, thereby preserving the downward directed trait. This new population of cells having reversed polarity probably derived from

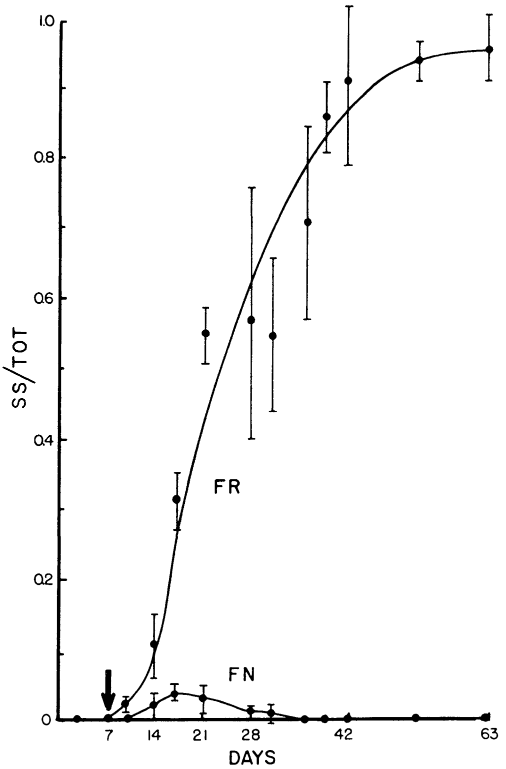

FIG. 12. Cell remagnetization without repolarization. Entire populations of magnetotactic bacteria as found in muds in the Northern Hemisphere, when incubated within solenoids to invert the vertical component of the local geomagnetic field, within several weeks acquired reversed magnetic polarity. Data shown indicate the mean values and ranges determined from direct cell counts in triplicate of north- and south-swimming bacterial cells in samples from triplicate cultures incubated in inverted (FR) and normal (FN) geomagnetic fields. The ratio of south-swimming to total magnetotactic cells is plotted against time. The vertical arrow indicates the point at which three of the six solenoids were energized (three were left as unperturbed controls) to invert the local field (FR). Populations of magnetotactic bacteria responded to a field inversion and preserved their downward swimming behavior.

1. death of upward-directed cells, and
2. favorable selection of the rare "improperly" magnetized cells present in any population resulting in their proliferation.

Magnetic repolarization requires either strong field gradients (Blakemore *et al.*, 1980) or magnetic pulses (Kalmijn and Blakemore, 1978; Mizota and Maeda, 1983) and was not a possible factor in these experiments. Thus, natural selection accomplished what could be managed by physicists only with a fair amount of energy: cell remagnetization in the absence of magnetic repolarization.

Despite this fascinating natural selection for downward swimming, magnetotaxis is not an essential trait. Nonmagnetotactic, nonmagnetogenic mutants of *Aquaspirillum magnetotacticum* grow at rates and to final cell yields of the magnetic parent strain in laboratory culture (laboratory cultures typically lack O_2 gradients, sediments, and other features which, in nature, maintain selection pressure for magnetotaxis). Moreover, magnetotactic bacteria in natural habitats can override their magnetic orientation with other taxes such as aerotaxis (Blakemore, 1982; Spormann and Wolfe, 1984). However, magnetic orientation will provide a constant bias to cell motion should other directional influences wane sufficiently to allow its expression (e.g., if chemical gradients are disrupted or move, or if cells or sediments containing them are physically dispersed as by scientists' wading feet, or wave or current action). In this regard, bacteria respond to multiple sensory inputs and are not so unlike pigeons (Sec. 3.6).

3.2 Eukaryotic Microbes

Torres de Araujo *et al.* (1986) reported magnetotaxis at geomagnetic field strengths in a heterotrophic, unicellular euglenoid, *Anisonema platysomum* Skuja from a Brazilian mangrove swamp. Each cell possessed numerous iron-rich crystalline particles having electron-diffraction patterns with d spacings characteristic of magnetite. Each $(80\text{–}180)\times(40\text{–}50)\text{-nm}^2$ particle was similar in size to the previously reported SD particles within magnetotactic bacteria. Each appeared to be of the anisotropic, hexagonally prismatic type of particle morphology peculiar to certain magnetotactic bacteria [see Fig. 2(B)]. On the basis of cell motion analysis in a reversing magnetic field, each "algal" cell was estimated to have a magnetic moment (Table 1) of 6.7×10^{-10} emu (6.7×10^{-1} pA m^2), or 600–700 times that of a representative magnetotactic bacterium. Assuming the particles were magnetite, each particle magnetic moment was estimated from its volume to be approximately 1.5×10^{-13} emu. From consideration of its total magnetic moment, each *Anisonema* cell was estimated to possess approximately 3000 such particles. Electron microscopy revealed cells densely endowed with strings of anisotropic, tooth-shaped magnetosomes. Thus, by maintaining the magnetite particle size in the magnetically efficient SD size range while increasing the number of strings of particles per cell, these eukaryotic unicellular organisms, although much larger than magnetotactic prokaryotes, and consequently having much greater coefficients of viscous drag, had roughly similar efficiency of (passive) orientation in the geomagnetic field due to their enhanced magnetism.

3.3 Mollusks

Some of the earliest reported biomagnetic effects were those of Frank Brown, Jr., who, working in Woods Hole, Massachusetts, in the 1960s, investigated responses to magnetism of a variety of invertebrates. Among these were studies indicating that mud snails, *Nassarius* (*Illyanassa*) *obsoleta*, were magnetically sensitive, showing responses correlating with lunar periodicities (Brown, Webb, and Brett, 1960) with maximal responses in mean daily snail orientation occurring near new moon and minimal responses at full moon. Despite these workers' efforts to address effects of geomagnetic strength fields (Brown, Webb, and Barnwell, 1964), it is unfortunate that their exhaustive studies were conducted by imposing very strong (10× Earth strength) inhomogeneous magnetic fields obtained with bar magnets upon the uniform geomagnetic field. This makes interpretation of these pioneering studies, although probably correct in their most important conclusions, difficult at best. Additional behavior studies with electromagnetic coil systems to provide uniform fields and analysis by magnetometry and electron microscopy of the invertebrates they studied might prove very interesting. Similarly, additional studies of a very interesting magnetic response in the sea slug *Tritonia*, more recently described by Lohmann and Willows (1987), are called for by their behavioral data.

Permanently magnetized biological material was first found in chitons. These primitive marine mollusks possess radular teeth capped with the iron biominerals magnetite, goethite, and lepidocrocite (Lowenstam, 1962a, 1962b, 1967; Towe and Lowenstam, 1967). The role of magnetite relates to its density and abrasion-resistance because these animals graze algae from rocks. However, strongly magnetized chiton teeth (in addition to other sources of biogenic magnetite) have been implicated in magnetization of marine sediments (Kirschvink and Lowenstam, 1979). Lowenstam (1962a) proposed that magnetite might serve to orient chitons with respect to the geomagnetic field. Tomlinson *et al.* (1980) noted seasonal alignment of chitons in captivity and in the sea in artificial and geomagnetic fields, but this has not been meaningfully related to the creature's biology.

3.4 Honeybees

Honeybee (*Apis mellifera*) scouts communicate directional information regarding a distant feeding site to forager bees in a hive by means of their waggle dance which they perform in the dark on normally vertical combs. This ritualized dance includes a straight run along the comb during which the bee waggles its abdomen (von Frisch, 1967). The run direction is related to the vertical (gravity vector) by an angle essentially equal to that between the sun's azimuth and the direction to the food source (e.g., up the comb if the food site is on an axis between the hive and sun, down if it is directly opposite the sun from the hive, and at appropriate intermediate angles with respect to vertical for sites at corresponding angles between these extremes). Martin and Lindauer (1977; see also, Lindauer and Martin, 1972) demonstrated that scouts consistently incorporated into their waggle dance a 15°–20° angle of misdirection (*"Mißweisung"*) between the vertical gravity vector and the inclined geomagnetic vector. Forager bees thus (mis)informed accurately compensated for this error when interpreting dance information relating the angle between solar azimuth and the line to the feeding site. Geomagnetism appeared to influence this important social communication behavior. *Mißweisung* disappeared over a period of several weeks if bees were made to dance in the dark on horizontal rather than vertical comb surfaces (in which case the bees danced along the cardinal points of the compass) and it disappeared entirely in a nulled geomagnetic field (Martin and Lindauer, 1977; see also, Kirschvink, 1981a).

Martin *et al.* (1989) showed that compensation of the geomagnetic field to within 2% of its natural intensity significantly reduced the normal tempo of scout bee waggle dances. This effect was even more pronounced if an oscillating (5 Hz) 90–125-μT sinusoidal magnetic field was imposed in an east-west direction after the initial compensation. The slowed dance tempo resulted in communication of misinformation regarding the distance to the feeding location, an error corresponding to more than 250 m in the particular experiments reported. Thus, alterations of earth-strength magnetic fields misdirected bees (through altered *Mißweisung*) and also (through altered dance tempo) caused them to communicate errors in distance information regarding location of a food source. These and other results clearly indicated that bees sensed the overall geomagnetic field.

Bees also sense temporal fluctuations in the geomagnetic field. Lindauer and Martin (1972) obtained evidence that normal diurnal fluctuations in the geomagnetic field influenced *Mißweisung*, and Walker and Bitterman (1989a, 1989c) have trained bees to respond to such fluctuations (discussed below). Martin (discussed in Neumann, 1988) has suggested that natural rhythms in geomagnetic and astrophysical magnetic fields are so regular, and detected so well by bees, that they use these directly in time-keeping functions, thereby obviating a role for an endogenous circadian clock. While this has been contested (Neumann, 1988), bee sensitivity to temporal magnetic fluctuations has not. Honeybees do, in fact, possess a time-averaged sun compensation system; e.g., after being deprived of sunlight for several hours, they can extrapolate the sun's rate of movement from when it was last observed (Gould 1980b). But unlike birds (see below), bees do not appear to use geomagnetic information as a backup orientation system on cloudy days. Rather, if on a cloudy day their hive is moved to a new location but of similar appearance with respect to a bait and major local landmarks such as a line of trees, they then refer in their waggle dance to (an informationally incorrect) solar azimuth which would be as predicted if they somehow remembered the sun's course as it would have been at the original site (Dyer and Gould, 1981).

Other effects of altered geomagnetic field on bee physiology and flying behavior have been noted. For instance, worker bees showed 40% reduced foraging activity (and, consequently, increased lifespan) in the presence of a static, inhomogeneous 80–145 μT field (Martin *et al.*, 1989), and comb-building by bees (de Jong, 1982) has been shown to have a geomagnetic field-dependent orientation. Free-flying (but not stationary) honeybees have been conditioned to discriminate the presence and absence of local magnetic anomalies (time-varying 0.01–10 Hz; 1–100 μT) superimposed on the background geomagnetic field (Walker and Bitterman, 1989c). As predicted if the basis of their geomagnetic sensitivity were through a mechanism involving permanent ferromagnetic material, flying bees with stainless-steel magnetized wires glued to their anterodorsal abdomens (Walker and Bitterman, 1989b) were significantly less able to be trained to discriminate between food targets (one having an associated anomalous magnetic field) as compared to controls with, or without, copper wires.

The mechanism of bee geomagnetic sensitivity and response is unknown. However, bees have single magnetic domain (SD) and superparamagnetic (SPM) materials of high coercivity (or else showing anisotropic character) located mostly in their abdomens (Gould *et al.*, 1978). Natural remanent magnetization (NRM) values of $(0.34\text{–}1.2)\times10^{-6}$ emu $[(0.3\text{–}1.2)\times10^{3}$ pA m$^2]$ and sIRM of $(1.7\text{–}2.7)\times10^{-6}$ emu per bee have been measured (Gould *et al.*, 1978; Gould *et al.*, 1980). This would correspond to roughly 2×10^{-8} g of Fe_3O_4. Apropos of this, a band of iron-rich oenocyte cells containing abundant particles consisting of (nonmagnetic) hydrous iron hydroxides was located in the abdomens of worker bees (Kuterbach *et al.*, 1982). These would not contribute to the magnetic remanence values measured by Gould *et al.* (1978). However, only 1/3 of the total hydrous iron oxide estimated to be present would need to be reduced to produce the quantity of Fe_3O_4 needed to account for the observed magnetic moment. Kuterbach *et al.* (1982) noted that this quantity of Fe_3O_4 would not have been detected by their methods.

Pulse remagnetization of foraging bees has reportedly been carried out and the results considered "positive" (Kirschvink, 1989). However, bees having sIRM values of 2×10^{-6} emu, when subjected to a very strong (210 mT) 60-Hz alternating demagnetizing field (Gould *et al.*, 1980), lost remanence to background levels $(0.01\times10^{-6}$ emu). This result suggests that most, if not all of the permanently magnetized material within bees is in the form of noninteracting SD or MD particles [i.e., it does not exist as strings of SD particles as found in bacteria, tuna, or salmon (see below) which resist demagnetization due to anisotropy]. Demagnetized bees showed no reduced ability to orient in the geomagnetic field as evidenced from analysis of their waggle dance (Gould *et al.*, 1980). Because bees may use different magnetic information as a compass from that which might be used as a map or in assessing time, it would be interesting to determine whether after attempts to demagnetize them, they subsequently danced on horizontal comb in the cardinal points of the compass or showed evidence of altered diurnal rhythmicity in behavior.

Natural magnetic remanences significantly above background values have been measured in other insect species (Table 1 and references therein). Whether this indicates the presence of biogenic magnetic material has not been adequately addressed. The wings of butterflies were magnetically very "dirty" due presumably to adventitious magnetic material (Jones and MacFadden, 1982), although head/thorax magnetism developed during pupation when nothing could enter the insect. No link between the presence of magnetite and ability to orient in the earth's field has been firmly established for any insect, although the results of Walker and Bitterman (1989a, 1989b) are consistent with this possibility.

3.5 Amphibians

Results obtained with male Eastern Red Spotted Salamander newts (*Notophthalmus viridescens*) provide fascinating evidence that these animals have more than one type of geomagnetic response. The data (Phillips, 1986) are consistent with two magnetic compass responses, one axial, one polar, depending upon whether the newts are appropriately induced by water temperature history to display either shoreward positional alignment or homing behavior.

3.6 Birds

The literature addressing magnetic influences on bird behavior is older and more voluminous than that for any other animal group, perhaps as a consequence of longstanding human interest in bird migration and pigeon homing (Keeton, 1974). The fact that the scientific literature extends back more than 40 years (Yeagley, 1951) attests to the relative ease with which bird magnetic responsiveness can be demonstrated (e.g., by attaching magnets to them); the fact that it is voluminous attests to the fact that simple statements have rarely been made (or uncontested). Birds (and bees) are behaviorally sophisticated animals which respond to a variety of hierarchically arranged sensory inputs including those of a solar, celestial, visual, olfactory, and magnetic nature (Southern, 1988; Moore, 1980; Gould, 1980a, 1982; Wiltschko *et al.*, 1981; Kiepenheuer, 1984). Different field parameters, including the overall dipolar geomagnetic field direction, the dip angle, change in dip angle, and anomalies in field uniformity in space or time are used by birds of various species or ontogenetic stages and at seasonally different times. Finally, whether individual birds exhibit behavior which can be correlated with geomagnetic sensory input can depend upon their previous experience (Lednor and Walcott, 1988), i.e., birds learn.

Convincing early experiments with bar magnets (Keeton, 1971, 1972) or paired, energized coils (Walcott and Green, 1974; Visalberghi and Alleva, 1979) attached to pigeon heads revealed that homing is disrupted (e.g., pigeon vanishing bearings are altered, although they may subsequently home correctly) by the resulting anomalous field which deprives the released bird of access to normal dipolar geomagnetic information. But these disturbances can be demonstrated best in young birds and on overcast days (Keeton, 1974) when reference to solar cues is abandoned [although even under sun, young birds cannot orient properly if fitted with disruptive magnets on their first flight (Keeton, 1971)]. Restrained pigeons cannot be trained by otherwise suitable conditioning methods to use magnetic information of geomagnetic intensity (Kriethen and Keeton, 1974), suggesting that bird motion is important for magnetic sensing. The first migratory excursions made by young birds may depend for success upon magnetic stimuli (Southern, 1972b, 1988; Alerstam and Högstedt, 1983; see also Bingman, 1984) whereas birds appear to learn subsequently to use other cues. For instance, although pigeons under sun show preference for using their solar compass, and nocturnal migrants a stellar compass, to be able to do so naive birds first calibrate it with their magnetic compass (Wiltschko *et al.* 1981; Wiltschko *et al.*, 1983). These and other results indicate that the bird magnetic sense is innate and may be a primary reference from which celestial (solar, stellar) compasses are calibrated in the manner of imprinting at an early age.

Analysis of premigrational restlessness (*Zugunruhe*) of caged European robins (Wiltschko and Wiltschko, 1972; Wiltschko, 1972) indicated that these birds do not respond to the absolute compass bearing but, instead, detect and use as "north" the angle of magnetic dip (e.g., the minimum angle between the gravity vector and the vertical component of the geomagnetic field). Similar findings were obtained in field studies with homing pigeons (Walcott and Green, 1974) who showed that birds with head coils energized to produce upward-directed fields (e.g. "north up" or "Nup") had, on cloudy days, vanishing bearings directed opposite to home and also to those of "Sup" pigeons with coils directing the field downward. This use of axial rather than polar north is identical to the manner in which Eastern Red Spotted Salamander newts use geomagnetic information (Phillips, 1986). Outdoors, however, European robins use (as yet unidentified) cues integrated with magnetic information in migration (Sandberg *et al.*, 1988). During nocturnal migration, they use their magnetic compass as a primary reference to select the seasonally appropriate migration direction and then switch to a stellar compass for maintaining accurate orientation (Wiltschko and Wiltschko, 1975, 1978). The fact that their axial compass does not discriminate magnetic north from south appears not to be relevant because they are not transequatorial migrants (for them, axial north always coincides with polar north).

Pigeons have magnetic tissues (Walcott *et al.*, 1979). Walcott *et al.* detected significant remanence in the dura and Presti and Pettigrew (1980) reported high sIRM values [$(10^{-6}-1.5)\times10^{-5}$ emu] in heads and necks of birds. However, these results have not been consistently reproduced (Walcott and Walcott, 1982). Presti and Pettigrew reported orange and black tissue deposits (magnetite is the only black iron oxide) which were not localized but diffuse throughout the head and neck muscles. Tissues provided a magnetometry signal consistent with the presence of about 10 ng of 70-nm SD magnetically interacting (stringed) magnetite cubes. The authors speculated on the presence of an axial magnetic detector based upon a muscle spindle (stretch or compression) type receptor. Attempts by others to detect significant remanences in diverse migratory birds (Ueda *et al.*, 1982) were unsuccessful, undoubtedly because of the high background associated with the SQUID employed.

The bobolink (*Dolichonyx oryzivorus*) migrates over the longest transequatorial route of any bird species. Behavioral responses of wild bobolinks and those reared in captivity correlated with reversal of the geomagnetic field (Beason and Nichols, 1984). The birds' preferred headings were analyzed in a planetarium equipped for reversal of the geomagnetic field enabling magnetic north to be dissociated from celestial north. In contrast to the behavior exhibited by European robins, (Wiltschko, 1972) these transequatorial migrants responded to polar rather than axial north. NRM and sIRM values of frozen or chemically fixed bird heads were 1.9×10^{-5} emu (1.9×10^{4} pA m^2) and 4.17×10^{-5} emu, respectively. Similar sIRM values (5×10^{-5} emu) as for entire heads were obtained with tissue from the post-nasal cavity. Heads continued to gain remanent magnetization with exposure to strong inducing fields of greater than 100 mT, up to a maximum at 300 mT. These results are consistent with the interpretation that the heads contained SD or small multidomains (pseudosingle domains) of magnetite. The Curie temperature was not determined nor was the Lowrie-Fuller test applied, nor has Mössbauer characterization been carried out because of the limited amount of material per bird. However, dissection and histochemical staining and x-ray spectra obtained with a scanning-tranmission electron microscope (STEM) revealed iron-rich deposits situated in sheaths around the olfactory nerve and in bristles projecting into the nasal cavity and intimately associated with nerve tissue. If the olfactory-associated iron is indeed biogenic as opposed to adventitious, and if it is associated with magnetic sensing, this finding may have important implications for studies by others implicating olfactory cues in bird orientation (see discussion by Beason and Nichols, 1984). The amount detected is theoretically (Yorke, 1979, 1981) within the range required to detect changes of less than 1% in the geomagnetic field. Thus, bobolinks may have enough sensitivity for a magnetic map sense and much more than that needed for their polar compass.

3.7 Primitive Fishes

Electroreception is known in chondrichthian (cartilaginous) fishes including the agnathans such as the anadromous lamprey *Lampetra tridentata* (Bodznick and Northcutt, 1981) but especially in elasmobranchs (sharks, skates, and stingrays), which use this sense in prey detection (Kalmijn, 1977, 1978, 1982). Chondrostean (primitive bony) fishes also possess electroreceptive capabilities (Fields and Lange, 1980). Cardiac decelerations and other electrophysiological evidence of sensitivity evoked by voltage gradients as low as 0.01 μV/cm (dc up to 8 Hz) were obtained in skates (Kalmijn, 1971) and fields estimated to be 0.2 μV/cm elicited a conditioned escape response in the ratfish, *Hydrolagus colliei* (Fields and Lange, 1980). These latter holocephalan creatures from the deep benthos possess ampullar organs presumably similar in function to the ampullae of Lorenzini, the highly sensitive electroreceptors of elasmobranchs. The electroreceptive ability of fish in seawater provides a theoretical basis for considering that they might also be geomagnetically responsive through the Faraday effect (Rommel and McCleave, 1972, 1973; Akoev *et al.*, 1976; Kalmijn, 1971, 1981, and references therein). This possibility was pursued by A. Kalmijn with V. Kalmijn, who conditioned captive stingrays (*Urolophus halleri*) to respond to reversal of the horizontal geomagnetic component. These animals, and perhaps other electroreceptive marine species, may thus detect the geomagnetic field by detecting induced voltage gradients in either active (swimming) or passive (drifting in currents) situations (Kalmijn, 1984). Field studies addressing the remaining question of whether induction or other means of geomagnetic orientation (sharks also contain magnetite) operate in free-roaming sharks have not been carried out.

3.8 Bony Fishes

The migratory feats of anadromous teleost fishes have made them especially good targets for inquiries of geomagnetic responsiveness (Quinn, 1982). Juvenile sockeye salmon (*Oncorynchus nerka*) without conditioning showed directional preferences in tank experiments which (in the absence of visual cues) were geomagnetically biased (Quinn *et al.* 1981; Quinn and Brannon, 1982). Similarly, evidence for geomagnetic-based orientation or navigation has been obtained for Atlantic salmon, *Salmo salar* (Rommel and McCleave, 1973), and chum salmon, *O. keta* (Quinn and Groot, 1983). Eels, *Anguilla rostrata* (Rommel and McCleave, 1972, 1973) and *A. anguilla* (Tesch, 1974), and the nonanadromous salmonid, the rainbow trout, *Salmo gairdneri* (Chew and Brown, 1989), also showed unconditioned orientational biases correlating with the Earth's magnetic-field direction.

Walker (1984) observed unconditioned avoidance responses to unanticipated magnetic fields presented to actively swimming, captive, juvenile yellowfin tuna (*Thunnus albacares*). He subsequently succeeded in training these fish to discriminate changes in Earth-strength magnetic fields reproducibly. The training methods used indicated neural processing of magnetic information, most likely by a magnetite-based transduction mechanism (Walker, 1984). Walker *et al.* (1984) inventoried tuna tissue and organ samples for magnetic remanence using a SQUID situated in facilities yielding a background moment of merely 5 pA m^2. Greatest values of remanence (>1000 pA m^2) were detected in eye tissue and sinuses within dermethmoid bones of the fish head. Alternating field demagnetization and sIRM data were consistent with the presence of approximately 8.5×10^7 single-domain magnetite particles in the dermethmoid tissue. The isolated crystals had characteristics of 45×38 nm^2 (SD) magnetite grains as determined by microscopic, electron microprobe, and x-ray-diffraction methods. The particles could provide sufficient torque for geomagnetic alignment only if they aggregated appropriately (e.g., preferably in strings) such that the product of M (the summed moments of stringed particles) with H (the geomagnetic field) exceeded kT by about a factor of 2–10 (see Frankel and Blakemore, 1980; Frankel, 1984) *and* if, in these large organisms, they were components of a sensory device equipped for neuronal amplification (Kirschvink and Gould, 1981). Walker *et al.* (1984) suggested that strings of 20–60 such particles would be sufficient for the fish to resolve magnetic-field intensity differences of 1–100 nT.

Walker *et al.* (1988), using magnetometry, obtained evidence consistent with the presence in sockeye salmon of interacting SD Fe_3O_4 grains, particularly in the eye and ethmoid tissue. Eye tissue was found to lack SD particles through its reaction in a modified Lowrie-Fuller test. Mann *et al.* (1988) confirmed the presence in sockeye ethmoid tissue of organically enveloped SD cubo-octahedral single crystals of Fe_3O_4 arranged in strings (median number per string of 21–25 particles) and arranged with their $\{111\}$ faces adjacent and lying perpendicular to the string axis. In each of these respects the magnetic material from salmon was identical to that described previously within cells of the bacterium *A. magnetotacticum*! Values of the ratio of magnetic (MH) to thermal (kT) energies for strings clustered bimodally: one at 2.7–5.3 and another at 6.6–9.5. The authors suggested that this might be indicative of a dual role for stringed magnetite: both as a compass and as a magnetic intensity detector. A rationale for magnetite-based orientation as developed by others (Yorke, 1979, 1981; Bean, 1979; Frankel and Blakemore, 1980; Frankel, 1982, 1984) is in support of their conclusions as to the suitability of this material in its quantity, size, and arrangement for geomagnetic sensing.

Single-domain magnetic particles have also been detected in chinook salmon, *O. tshawytscha* (Kirschvink *et al.*, 1985b). Alternating field demagnetization and sIRM data were consistent with magnetically interacting SD magnetite grains arranged in strings within dermethmoid cartilage tissue. Indeed, magnetic particles extracted from tissues were in strings, possibly with attendant organic material as a sheath or envelope. Thus, the magnetic material detected in this salmonid appeared similar in nearly all respects to that from sockeye salmon and yellowfin tuna (and the bacterium *Aquaspirillum magnetotacticum*).

The ability of some fishes to sense experimental fields of geomagnetic character is clearly established. Of the several mechanisms by which diverse species may do so (Faraday effect, permanent magnetism), models incorporating biogenic magnetite have been supported by the bulk of published work. While this does not prove their validity, it does provide a broad database upon which an inferential link between magnetite-based reception and animal geomagnetic responsiveness may eventually be further forged or broken.

3.9 Mammals

Zoeger *et al.* (1981) studied dead, stranded Pacific dolphins (*Delphinus delphis*) in which they identified strongly magnetized tissue (magnetic moment 2×10^{-8} A m^2, 20 times that of the Earth's field). Magnetism was localized to innervated dura mater tissues of the animal's skull (not consistently located from animal to animal). Alternating field demagnetization of the tissue NRM at low field strength indicated that the material contained anisotropic but magnetically "soft" (easily demagnetized or remagnetized) MD magnetite.

Other specimens appeared to lack this but possessed instead what appeared to be superparamagnetic or near-superparamagnetic SD magnetic grains. Zoeger *et al.* (1981) speculated that despite its magnetic "softness" the material might function as a magnetic detector, by deforming in the field, for instance.

After reviewing the U.S. Geological Survey East Coast aeromagnetic data and the location of 212 confirmed cetacean live strandings within the same region, Kirschvink *et al.* (1986) concluded that whales beach themselves at locations where weakly magnetic local anomalies representing minima in intensity and having lower than background gradients intersect the coastline. Their study corroborated observations of Klinowska (1985, 1986), who concluded that live strandings in Great Britain have tended to occur where local minima or "valleys" in the total intensity field cross the coastline or during geomagnetic disturbances, and that whales actively avoid areas of locally higher magnetic intensity.

A report (Baker, 1980) that British college students displaced tens of kilometers were geomagnetically influenced in their choice of selecting the direction toward home was unable to be repeated in the United States (Gould and Able, 1981) or corroborated by numerous others elsewhere (see Baker, 1987a). Baker (1987a) reviewed available relevant data (excluding that of a perpetrated hoax) and concluded that published data conflict with published interpretations of the data—thus keeping alive the controversy concerning whether humans use a nonvisual or magnetic sense in orientation information. Magnetic remanences of 2.3×10^{-6} emu g^{-1} (2.3×10^{3} pA m^{2} g^{-1}) in pineal tissue and approximately 1.6×10^{-5} emu g^{-1} in sphenoid-ethmoid tissue (roughly $10\times$background) have been measured in human bones, and histological staining for ferric iron revealed a continuous iron-rich layer situated 5 μm below the surface of the sphenoid sinus (Baker *et al.*, 1983). Kirschvink earlier (1981b) had reported magnetic remanence associated with human adrenal tissue. Additional papers of interest are found in Kirschvink, Jones, and MacFadden (1985a).

4. WHAT IS THE STATUS OF BIOLOGICAL MAGNETIC SENSING?

The examples cited above are sufficient to illustrate the diverse manner in which organisms may obtain and use geomagnetic information. In addition to its possible use in primary sensing (compasses, maps, clocks) it is possible that geomagnetism may be used by organisms to calibrate clocks or maps based primarily upon celestial, olfactory, or other cues. Biomagnetism appears to occupy a central place in current conjecture regarding such sensing.

4.1 Biological Compasses

Evidence consistent with avian compasses based upon solar, stellar, and magnetic information has been obtained. To show that geomagnetism is used by birds has not, however, been easy. The avian magnetic compass is probably innate and may serve to calibrate celestial compasses through imprinting during the first weeks or months of life; after this it may no longer be a primary reference. Moreover, nocturnally migrating birds appear to use their magnetic compass to choose overall flight direction initially and subsequently switch to stellar compass cues for navigation. Magnetic biocompasses can be sensitive to cardinal direction of the geomagnetic dipolar field (polar compass), to the angle of dip (axial compass), or possibly (Kiepenheuer, 1984) to apparent dip angle (change in dip with respect to a fixed reference such as gravity). The inclination-sensitive types do not allow the animal to discriminate magnetic north from south. At least some animals appear to have both polar and axial magnetic compasses. This could be of particular value to transequatorial migrants (bobolinks) but has also been found in Eastern Red Spotted Salamander newts.

Two postulated biocompass mechanisms have persisted. One is active electroorientation through the Faraday effect (Rommel and McCleave 1972, 1973; Akoev *et al.*, 1976; Kalmijn, 1971, 1981, and references therein, 1984; Jungerman and Rosenblum, 1980), which requires that an animal possess numerous, readily detectable, highly specialized and sensitive electroreceptors. It is a dH/dt type of system in which changes occasioned by the animal's movement with respect to the geomagnetic field are necessary (Kalmijn, 1984). It would work at a required level of sensitivity for geomagnetic compass information only if the return loops had diameters of millimeter scale, and if these paths were in a medium of low electrical resistance such as seawater (Jungerman and Rosenblum, 1980). Thus, it is difficult to conceive of this as a mechanism for birds or even for freshwater fishes, nor would it explain sensitivity to small temporal or spatial geomagnetic field fluctuations that some animals appear to sense.

The second animal biocompass mechanism, as yet unproven but given credibility by the bacterial paradigm (Frankel and Blakemore, 1980, 1989) of SD intracellular ferrimagnetic particles (see also Yorke, 1979, 1981; Bean, 1979; Frankel, 1982, 1984; Kirschvink, 1982, 1983, 1989; Kirschvink and Gould, 1981; Kirschvink, Jones, and MacFadden, 1985a), has been incorporated into diverse animal biocompass models. These include muscle spindle stretch receptors (Presti and Pettigrew, 1980) and proposals by Kirschvink and Gould (1981), which include a "membrane short model," "torque detectors," "superparamagnetic (sympathetic satellite, linear and lattice array) detectors," and "hybrid detectors." A navigational biocompass consisting of stringed or aligned SD particles is proven for magnetotactic bacteria and conceptually valid for animal compass sensing. For organisms other than the bacteria, a conclusive link between the presence of a biogenic mineral phase and geomagnetically influenced compass behavior has not been made.

Consequently, it would be at least premature to focus on ferrimagnetism to explain animal geomagnetic sensitivity to the exclusion of still other fascinating proposals even though the latter are unsupported by experimental data and some seem physical impossibilities given the constraints imposed by conditions within cells or organisms. Such alternatives have included postulated biological (room temperature) superconductors (Cope, 1973), optical pumping (Leask, 1977), Lorentz forces in cytoplasm (Ruhenstroth-Bauer *et al.*, 1987), and biradical chemical reactions induced by anisotropic hyperfine interactions coupled to external magnetic fields (Schulten and Windemuth, 1986). Integration of magnetic detectors with other sensory systems including gravity detectors (Kiepenheuer, 1984; Wiltschko, 1980), the visual system (Semm *et al.*, 1984; Leucht, 1984), or the vestibular organs (Semm *et al.*, 1984) is a distinct possibility. Interesting implications of such mixed sensing are

1. that animals might possess redundant compasses while minimizing structural complexity,
2. that animals might, in effect, "see" or "smell" magnetic stimuli registered as perturbations in these other sensory perceptions, and
3. that disruption of one sense or organ by an experimenter (as has been done in vestibular or olfactory studies with pigeons) might concomitantly prevent magnetic sensing.

4.2 Magnetic Maps

The nature of bird navigational maps (Gould, 1982; Moore, 1980; Ossenkopp and Barbieto, 1978) is incompletely understood and controversial. Olfactory information may comprise the basis for a navigational map outside the local familiar area (Wallraff and Neuman, 1989) whereas nonolfactory, visual information (sun compass, local topography) may be used in pilotage behavior in familiar territory (Wiltschko and Wiltschko, 1989). That the "magnetic topography" can be important to birds is evidenced by the inability of faithful birds to home normally or at all when released for the first time at certain magnetically anomalous locales (Walcott, 1978, 1980; Kiepenheuer, 1984), particularly if they are mature birds not raised there (Lednor and Walcott, 1988). Compass orientation of European robins was unaffected by field intensity differences of 10% (Wiltschko, 1972). Thus, the "map sense," which appears to depend upon minor differences in intensity or field gradients, would appear to involve magnetic reception mechanisms (Yorke, 1981) different from that involved as a compass (see Yorke, 1979). Walker *et al.* (1986) have presented a mathematical model for a compass which would not require a second frame of reference other than the geomagnetic field. Additional experimental studies of the sort conducted by Walcott *et al.* (1988), who studied homing in magnetized and demagnetized pigeons, are needed.

4.3 Magnetism-Based Clocks

There are a number of biological examples in which magnetism appears to play a role in time-keeping. Lunar periodicities have been correlated with the magnetically influenced behavior of invertebrates including snails (Brown, Webb, and Brett, 1960), the sea slug *Tritonia* (Lohmann and Willows, 1987), and a moth (Baker, 1987b). Bees and birds are also sensitive to normal, 30–50 nT, diurnal magnetic fluctuations and to pulses associated with unpredictable magnetic storms (Keeton, Larkin, and Windsor, 1974; Southern 1972b; Martin and Lindauer 1977). The suggestion (Neumann, 1988) that bees might use fluctuating, diurnal, magnetic periodicities directly in time-keeping functions has interest and appears conceptually valid in the light of their extreme geomagnetic sensitivity. No study has revealed just what such a putative magnetic-field-dependent clock might consist of.

5. THE ONGOING STUDY OF BIOLOGICAL GEOMAGNETIC DETECTORS

It is somewhat ironic that 15 years after their discovery, the magnetotactic bacteria remain as the only biological system for which there is a proven mechanism for the geomagnetic response even though the basic feature of their mechanism (intracellular strings of SD biogenic magnetite) figures into most extant models for geomagnetic compass and map sensing by animals. Why this should be so is obvious; animals cannot be "torqued" into position by the geomagnetic field and so would require not only magnetic detector(s) but neuronal amplification and transmission of transduced information prior to its involvement at an appropriate effector organ. A successful hunt would require coordinated behavioral, anatomical, and cell-tissue-organ (electro)physiology studies not representative of the way modern science usually functions (or, at least, is funded). Several lines of experimental evidence could provide direct evidence of a putative magnetic sensor, including

1. surgical removal of suspect tissue from trained animals,
2. analysis of the effect of disrupting an associated sensory (visual, olfactory, vestibular, pineal) system or organ, and
3. electrophysiology in altered magnetic fields.

These will not be trivial pursuits. The reader is reminded that prokaryotes are more equivalent to subcellular organelles than to eukaryotic cells themselves. Thus, the search is for a bacterial-type magnetic apparatus ("magnetic needle") dimensionally equivalent to a few submitochondrial-sized particles possibly within a single animal cell buried in a haystack comprised of an overwhelming mass of tissue! If this is the case, not even magnetometry will disclose the location of such a detector. Frankel (1982) indicated that merely three 50-nm magnetosomes would be needed per cell (e.g., for $\mu H/kT$ to >2) to bring about bacterial rotation in the geomagnetic field within an orientationally meaningful time interval. Models such as the "membrane short model" of Kirschvink and Gould (1981), as presented, require a single, SD magnetite grain of subcellular dimensions. Anatomists, then, may hope that the magnetic sense of animals is so vital that it has been constructed with much redundancy while physiologists would welcome a distinct, localized detector functioning independently of other senses. If animals do indeed use the basic bacterial paradigm for magnetic sensing, then unless it has evolved into a larger, more complex structure than has previously been imagined, locating the detector in the "background" of cell and tissue mass without destroying it may be unlikely. Quite possibly, the use of genetic probes developed from molecular elements of the bacterial compass may prove more effective than tissue disruption in locating the putative animal magnetic detector.

ACKNOWLEDGMENTS

The long-term interest, encouragement, support, and contributions of Dr. Richard Frankel and Nancy Blakemore to studies of magnetogenic bacteria in the author's laboratory are gratefully acknowledged. These studies have been made possible principally by support from the Office of Naval Research and the National Science Foundation. However, funding from the University of New

Hampshire Research Office, the National Geographic Society, and BioMagnetech Corporation is also gratefully acknowledged.

GLOSSARY

Anhysteretic Remanent Magnetization (ARM): Magnetic remanence imparted to a sample by applying an alternating field which is then reduced to zero (ac demagnetization) in the presence of a constant, steady dc field.

Biomineralization: The production of mineral phases within living organisms. Diverse prokaryotic organisms may produce intracellular or extracellular biominerals, including magnetic substances, in which case the organism is said to be *magnetogenic*. Magnetogens producing intracellular biominerals may be *magnetotactic*; that is, they respond in their swimming direction to changes in the ambient geomagnetic field.

Biomagnetism: The property exhibited by cells or organisms of possessing an intrinsic permanent magnetic dipole character due to the presence of an endogenous (in contrast to adventitious) magnetic substance. In all known cases biomagnetism is conferred by the presence of a magnetic biomineral. Two types of these are presently known: magnetic iron oxides (widespread among life forms) and magnetic iron sulfides (confined to certain bacteria).

Curie Temperature: The temperature above which exchange coupling (forces aligning atomic dipoles in a parallel fashion, despite kT) in a ferromagnetic material is lost and the substance becomes paramagnetic (e.g., it loses its permanently magnetized character). For iron the temperature is 1043 K (770 °C) and for magnetite it is 858 K (585 °C).

Dissimilatory Iron Reduction: The process in which organisms oxidize cell energy sources using Fe^{3+} in lieu of, or in addition to, O_2 as a terminal electron acceptor.

emu: "Electromagnetic unit"; $1 \text{ emu} = 1 \text{ erg G}^{-1} = 1\ \mu\text{J T}^{-1} = 10^9 \text{ pA m}^2$.

Eukaryote: An organism belonging to one of the three major, distinct lines of evolutionary descent and consisting of, or having, nucleated cells. Included are traditional groups referred to as fungi, algae, plants, animals, etc., but not prokaryotes (bacteria).

Ferromagnetism: The property shared by iron, cobalt, nickel, gadolinium, dysprosium, and alloys of these, of forming magnetic domains within bulk material as a consequence of exchange coupling. Exchange coupling interactions (a quantum effect) serve to align atomic dipoles in a common direction despite the randomizing tendency of the atoms due to kT. "Hard" ferromagnetic materials have high permeability and retain significant magnetization upon removal of a strong magnetizing field. "Soft" ferromagnetic materials lose permanent magnetism to a considerable degree after removal of a magnetizing field.

Gamma: An older term referring to units of geomagnetism. $1\gamma = 1 \text{ nT} = 10^{-5} \text{ G}$.

Greigite: A magnetic iron biomineral produced by some magnetogenic bacteria and having the empirical formula Fe_3S_4.

Magnetite: A ferrimagnetic mixed-valence iron mineral of the inverse spinel series which can be a biomineral produced either intracellularly or extracellularly by prokaryotic and eukaryotic organisms. It has the empirical formula, $Fe_2O_3{\cdot}FeO$, more commonly expressed Fe_3O_4.

Magnetization (J_s): Magnetic moment (μ) per unit volume (V).

Magnetogen: A microorganism which produces a magnetic (iron) biomineral. Some magnetogenic bacteria produce such minerals intracellularly, others extracellularly. The minerals include magnetic iron oxide (magnetite) or magnetic iron sulfide (greigite). Known magnetogens appear to be dissimilatory iron reducers.

Magnetosome: A biogenic magnetic particle found within an organism or its cells and consisting of a crystalline, magnetic, mineral core, usually within an envelope. In the one case examined to date, the envelope comprises a lipid bilayer-membrane vesicle. Magnetosomes of magnetotactic microbes are commonly arranged in an intracellular string of from several to hundreds of particles per cell.

Magnetotactic: A behavior exhibited by organisms in which their swimming or motion is directed by a magnetic field. The term is conventionally applied to microorganisms and to fields of geomagnetic intensity.

Natural Remanent Magnetization (NRM): The magnetic remanence of a natural substance (rock or cell) in the absence of other magnetizing or demagnetizing fields.

Prokaryotes: Organisms existing as independent cells or cell aggregates but lacking tissue grade of organization. Prokaryotic cells lack true nuclei and differ in other fundamental ways from eukaryotic cells. Prokaryotes include the eubacteria and archaebacteria.

Pyrite: A nonmagnetic iron sulfide biomineral produced by some magnetogenic bacteria and having the empirical formula FeS_2.

Pyrrhotite: A magnetic iron sulfide biomineral which may be produced by some magnetogenic bacteria and which has the empirical formula Fe_xS_{1+x}; e.g., Fe_7S_8.

Saturation Isothermal Remanent Magnetization (sIRM): The magnetic remanence left in a sample of ferromagnetic material after brief exposure to a steady field of up to 10 000 G (800 000 A m^2).

Superconducting Quantum Interference Device (SQUID): A cryogenic (4 K) magnetometer containing one or more loops of superconducting material, each interrupted by a thin insulating barrier to form a "Josephson tunnel junction," and used to detect small amounts of magnetic flux on the order of 2×10^{-15} T m^2 such as in magnetized rocks or cells.

Zeitgeber: An environmental stimulus that serves to "set" a biological clock.

INTRODUCTION

Magnetism of the human body was discovered nearly thirty years ago, when Baule and McFee (1963) detected the weak magnetic field of electrical currents in the heart. Now, with superconducting field sensors, it is possible to monitor fields from many organs of the body. In this way the study of *biomagnetism*—magnetic fields associated with biological activity—has made important contributions in several areas of basic and clinical research. Biomagnetic fields arise from other organisms as well. The smallest are single cells such as macrophages of the lung, which engulf particles that lodge on the alveolar surface. The field produced by these particles provides evidence of the dynamics of the cell's internal cytoskeleton, and the viability of the cells. In studies of other species, such as the homing pigeon and honey bee, there is evidence that magnetic particles biologically produced in the body serve as a "compass" to assist the host in navigation (Kirschvink, 1983). Effects produced by the application of magnetic fields to biological systems are not considered here. (See BIOMAGNETISM AND GEOMAGNETIC FIELD DETECTION BY ORGANISMS.)

1. BIOMAGNETIC FIELDS

Biomagnetic fields arise from three classes of sources: One is *electric current,* associated with the movement of ions within cells and throughout the extracellular space of tissue. Electric currents are responsible for the magnetic field of the heart, brain, muscle, and some other active organs of the body. *Magnetic particles* are a second source. They produce a steady magnetic field because of the type and geometrical arrangement of their constituent atoms. They occur as contaminants in the human body, as well as in other organisms, and their field can be detected when particles are magnetized in a common direction by application of a strong magnetic

field. Examples include airborne particles lodged in the lung as well as ingested pieces of metal in the stomach that come from opening a can of food. The third source is the *magnetic susceptibility* of body tissue. When a magnetic field is applied, the small adjustments of electron orbits in molecules create their own magnetic field. Because the predominant body constituent is water, normal tissue is diamagnetic; however, certain diseases lead to such a large accumulation of iron-bearing ferritin and hemosiderin in the liver that the organ becomes paramagnetic.

The strongest biomagnetic fields are associated with magnetic contaminants in the body, but even near the chests of welders and foundry workers exposed to high levels of magnetic dust they reach only 10^{-5} of the earth's field. The weakest of the biomagnetic fields commonly measured are associated with electrical currents flowing within small populations of active neurons in the brain. They are about 10^{-9} of the earth's field. Figure 1 summarizes typical amplitudes and frequency regions of activity for a variety of biomagnetic fields of interest. Field strengths are commonly given as the magnetic induction *B*, expressed in units of teslas. A typical strength for brain activity near the scalp is about 100 fT (100×10^{-15} T) and for cardiac activity near the chest 10 pT (10×10^{-12} T). An overview of this subject is given by tutorials and research papers of a recent conference (Williamson *et al.*, 1989), and fundamental aspects are covered by an edited textbook (Williamson *et al.*, 1983). The approach taken here is to summarize the methods by which these very weak fields can be detected and then to explain how these measurements provide unique information about physiological processes.

2. INSTRUMENTS AND THEIR USE

Three types of magnetic sensors have proven useful in biomagnetic applications: flux-gate magnetometers, induction coils, and superconducting quantum interference devices (SQUIDS) (see SQUIDS; MAGNETIC INSTRUMENTATION). Examples of how their sensitivity varies with the frequency of a magnetic signal are given in Fig. 2. An induction coil used for biomagnetic measurements (not shown) has achieved an equivalent noise level

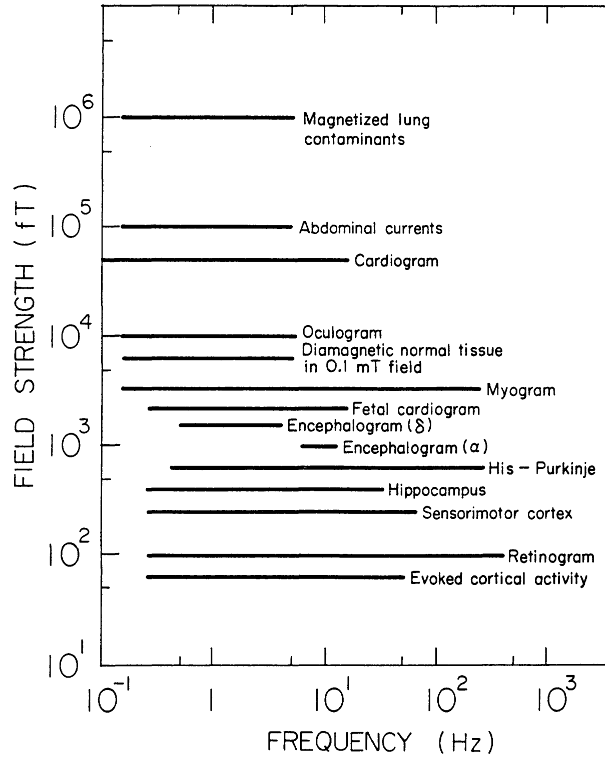

FIG. 1. Typical field strength (in femtotesla) and bandwidth of activity for various biomagnetic phenomena. Lung contaminants refer to exposure in a foundry or welding shop. Abdominal currents may arise after drinking cold water. The cardiogram characterizes the peak strength when ventricular muscle is activated. The oculogram refers to the steady field of the eye. The myogram is the peak strength from stressed skeletal muscle. The fetal magnetocardiogram is measured just outside the mother's abdomen. The encephalogram characterizes low-frequency δ and α rhythms. His–Purkinje signals of the cardiac conduction system are measured directly over the chest. The hippocampal signal is produced when a subject experiences an unexpected sensory stimulus in a train of stimuli. The sensorimotor cortex signal characterizes the peak field when a person voluntarily moves a finger. The retinogram is the change in field near the eye when the level of illumination changes abruptly, and the measure for evoked cortical activity corresponds to the brain's response to a strong visual stimulus.

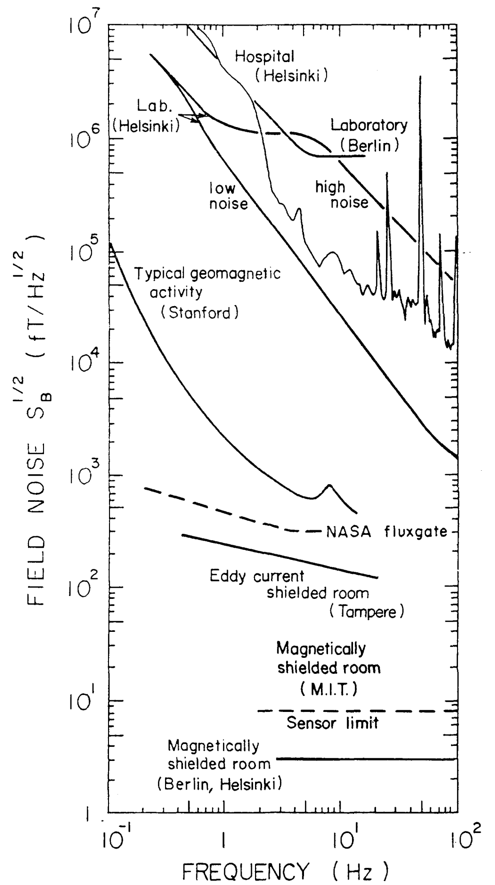

FIG. 2. Magnetic-field noise levels in representative environments compared with sensor noise, each expressed as the rms magnetic field within a 1-Hz bandwidth at each frequency. Representative environmental noise spectra are shown for for a hospital in Helsinki; a laboratory in Berlin; conditions of high and low noise in a laboratory in Helsinki; outdoors at Stanford University, California; within a room shielded from eddy currents by welded aluminum plates in Tampere, Finland; and within a five-layer magnetically shielded room in Berlin. Dashed lines illustrate typical sensor noise for a NASA flux-gate magnetometer measured within a magnetically shielded room (below 5 Hz the room cannot shield all of the environmental noise) and an MIT SQUID sensor (where the shielded room was effective to below 2 Hz).

of 600 fT Hz$^{-1/2}$ at 10 Hz, and this decreases inversely with increasing frequency. By comparison, a special feature of the flux gate and SQUID is their ability to respond to very-low-frequency signals, including dc. The relative advantages of each type of sensor will be considered in turn.

2.1 Flux-Gate Sensors

The heart of a flux-gate sensor is a core of magnetic material with high permeability, so that its magnetization readily responds to the application of a weak field of interest (see MAGNETOSTATICS). Great sensitivity can be achieved with this device, because an ac technique is commonly used which applies an alternating "modulation field" to the core to drive the magnetization periodically around its hysteresis loop. In the presence of a dc field of interest, transitions between the two polarities of magnetization are made slightly earlier when the ac field is in one direction than the opposite direction, and this asymmetry in response can be detected electronically with high sensitivity. The corresponding field sensitivity is limited by inherent magnetic noise in the core.

2.2 Induction Coils

An induction coil was used by Baule and McFee when they first succeeded in detecting a magnetic field of the human body—the heart's field. The coil itself consists of many turns of copper wire, which produces an induced voltage when an ac field passes through the loops. A sensitive, low-noise amplifier enhances the voltage that appears between the ends of the wire. Because this sensor relies on the phenomenon of magnetic induction, it is suitable only for comparatively rapidly varying fields. Its sensitivity can be further enhanced by using a core of high-permeability magnetic material. Sensitivity is limited either by the fluctuating voltage associated with thermal noise of the resistance of the winding (Johnson noise) or by magnetic noise of the core. This instrument was sufficient for Cohen (1968) to detect the α rhythm of the brain, although its sensitivity is comparatively poor at such low frequencies (near 10 Hz).

Quite a different kind of inductive sensor has been developed for magnetic studies of action potentials in isolated neurons having large axons (Wikswo, 1983). Since the field from a single neuron's axon is too weak to detect with a sensor placed several centimeters away, advantage was gained by moving the sensor closer to the source and employing a geometry that maximizes the magnetic flux linking the turns of wire. This is achieved with a small toroidal coil, only millimeters in size (Fig. 3), with the axon threaded through the hole in the toroid. Sensitivity is enhanced if the ring-shaped former is made of a high-permeability ferrite material. The biological current of interest is directed along the length of the axon, and so the corresponding magnetic field threads all of the individual turns of wire of the coil. A SQUID sensor is not required, because the action potential is a rapidly moving excitation, so the frequency content of the signal is many hundreds of hertz, sufficiently high that the voltage induced in the toroidal coil can be detected by a very low-noise amplifier operating at room temperature.

2.3 SQUID Sensors

By comparison with the flux gate and induction coil, the SQUID sensor offers many advantages in addition to greatly enhanced sensitivity (see SUPERCONDUCTING DEVICES). The SQUID wins on several counts: highest sensitivity in the bandwidth of most interest, a usable bandwidth extending down to dc frequencies, and relatively small size for its sensing element. The last-named feature permits many sensors to be mounted close together, with little magnetic coupling, so that details of a field pattern can be obtained simultaneously (see SQUIDS). On the other hand, a SQUID sensor is more expensive than either the induction coil or flux gate. Moreover, aside from a few special cases where specialized refrigeration has been developed (Buchanan, Paulson, and Williamson, 1988), it requires liquid helium to keep the SQUID superconducting.

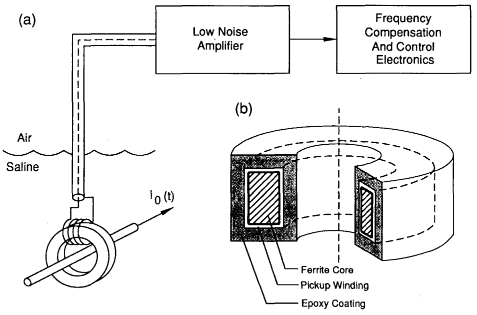

FIG. 3. System for monitoring the magnetic field of an action potential. The specimen is threaded through the hole in the core of the toroidal coil, and the signal following amplification is corrected for the effects of inductance and capacitance in the circuit. (Provided by J. P. Wikswo, Jr.)

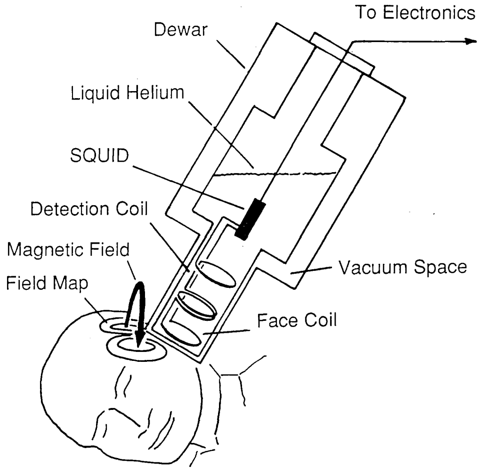

FIG. 4. Typical arrangement for biomagnetic measurements with a SQUID sensor, here for recording the magnetic field of the brain.

2.3.1 Detection Coils. A SQUID is not used directly to detect the field of interest. As illustrated in Fig. 4, there is an advantage to employing a superconducting "detection" coil to do that. One reason is that a large coil couples more signal energy into the SQUID. Another important reason is that the geometry of the detection coil can help to reject unwanted noise from the environment. Most noise sources are relatively distant, so their fields are more uniform than those of interest. Therefore a detection coil formed of two counterwound coils of the same size connected in series, but separated axially by a short distance, discriminates against such sources of uniform field but retains sensitivity to a source that is close by. It is called a *first-order gradiometer.* A uniform field from a distant noise source applies positive magnetic flux in one coil and negative flux of the same magnitude in the other, thus producing net cancellation. By contrast, a source very near the end coil produces a much larger flux in it than in the more distant coil, so its signal is registered with only a small reduction in amplitude. This function of a gradiometer is called *spatial discrimination.* The first-order gradiometer has proved useful in measurements made at sites remote from sources of magnetic noise (Zimmerman and Frederick, 1971).

The detection coil shown in Fig. 4 can be considered two first-order gradiometers arranged back-to-back. It does not respond to a uniform field because neither gradiometer does. Also, it does not respond to an axial field whose strength varies linearly along the axis of the coil. This is because the positive signal in one gradiometer is cancelled by the negative signal in the inverted gradiometer. This provides better discrimination against relatively close noise sources. Therefore the *second-order gradiometer* can be effective in an unshielded laboratory environment, where field gradients are high because of steel in the building or noise sources are simply stronger. With this, even the magnetic field of the human brain can be monitored without shielding (Brenner, Williamson, and Kaufman, 1975).

Spatial discrimination is also achieved with another coil geometry: a planar gradiometer. The simplest is a "figure-8" formed from a single length of wire. In use, it is oriented with the plane of the figure-8 parallel to the surface of the body, so that the component of the field normal to the skin produces the magnetic flux. A uniform field produces no net flux: Only when the field in one loop differs from the field in the other is there net flux. Because the loops are close together, the same subtraction is also carried out with the biomagnetic field of interest. The signal is greatest when the sensor is placed directly over an electric current, oriented with loops on opposite sides of the current. This is because the magnetic field encircling the current passes upward through one loop and downward through the other. The magnetic flux in the circuit has the same sign for each loop, thus producing a maximum output. This feature was exploited in studies of human subjects to deduce the ionic current patterns in the arms and legs of human subjects that produce a steady magnetic field (Cohen *et al.*, 1980). The patterns can be distorted by injury, such as a broken bone. The relative advantages of the figure-8 gradiometer are presently being evaluated for determining the location of electrical activity within the human brain (Kajola *et al.*, 1989). One attractive feature of this planar geometery is that techniques of thin-film deposition could be used to fabricate them with high precision. SQUID sensors made by similar techniques might also be deposited on the same substrate, for simplicity and reliability.

2.4 Measuring a Field Pattern

To determine where a magnetic source lies, its magnetic-field pattern must be measured over the relevant area of the body. If a time-dependent signal is of interest, as for the heart's activity, the sensor is moved from one location to another in succession to record the signal. Brain activity is not so repetitive, but sensory activity can be evoked reproducibly by applying an appropriate stimulus (e.g., appearance of a pattern of light, touch of the skin, or auditory tone) and recording the response with the stimulus as a time reference. Usually the responses are so weak in comparison with ongoing brain activity that measurements at a common location are averaged together to bring the signal-to-noise ratio to an acceptable level. Measuring at a large number of positions is a laborious procedure, so there is great interest in developing multisensor systems to do it at many locations simultaneously. Figure 5 shows an example of an array of detection coils for a 37-sensor system used to monitor brain activity. The diameter of each coil is 2 cm, and their centers are separated by 3.5 cm.

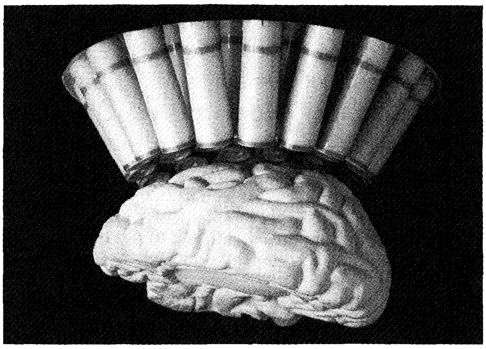

FIG. 5. Array of 37 detection coils positioned for comparison above a representation of the human cortical surface. Each coil is wound as a second-order gradiometer, and only the face coil and middle compensation coil are shown. The axes of the coils are canted so that they point approximately toward the center of the head, and that the dominant signal comes from the radial component of the brain's field. (Provided by Biomagnetic Technologies, Inc.)

Sequential placement of a sensor over the body cannot be employed to measure a steady field pattern, such as that produced by a magnetized lung or by long-lasting currents in the brain. The environmental field has such large gradients that they will likely produce a signal that dominates the one of interest. A common way to avoid this problem is to mount the sensor rigidly in place and move the subject up to the sensor, and then back. By doing this repeatedly and moving different areas of the body up to the sensor, the pattern of steady field can be mapped.

3. ELECTRIC CURRENT SOURCES

An electric current is produced by movement of electric charge. In biological tissue the charge carriers are ions, such as sodium, potassium, and calcium. These are allowed to cross cell membranes by proteins that open channels for specific ions, so that they diffuse to the region of lower concentration. In addition, membranes contain active biological "pumps" that carry specific ions to the region of higher concentration. The pumps for Na^+, K^+, and Ca^{2+} in neurons and cardiac muscle cells are examples. Because of these features, detailed current patterns at the cellular level may be quite complicated. However, it is not essential to take them all into account, because such fine details are not revealed by measurements of a magnetic field made several centimeters away. Indeed, transmembrane currents—while of keen interest to the electrophysiologist—do not produce an appreciable magnetic field. One reason is the symmetry of the radial flow: Current on one side of the cell is opposed by current on the other side, and so their magnetic fields tend to cancel each other. It is the accompanying flow of ions along the axis of the cell that is the principal contributor of magnetic fields outside the body. In tissue where elongated cells are aligned parallel to each other (e.g., muscle of the heart and pyramidal cells of the brain's cortex, called the "gray" matter), there is a net directed flow of current, and this gives rise to a measurable magnetic field.

3.1 Current Dipole Model

The magnetic field of a short length of current can be computed by the law of Biot and Savart (see ELECTRODYNAMICS, CLASSICAL), which says that the magnetic field describes circles centered on the axis of the current, and its strength varies as the inverse square of the distance from the current. For a population of aligned cells, the total field is simply a summation of contributions over the volumes of all cells. This is equivalent to computing the product of current and the path length along which it flows within the cells. The source is therefore characterized by a direction (the average direction of the current) and a strength (the product of the current and length). Therefore the source is a vector. It is known as a *current dipole*, $\mathbf{p}_i$, and its magnitude p_i has the units of ampere–meter. The current dipole is a valid model for a patch of active tissue so long as the spatial extent of the tissue is much smaller than the distance to the field sensor. Typical current dipole moments describing measured activity of the human brain range from 1 to 20 nanoampere–meters (1–20 nA m). This simplified view of a localized biological source plays a central role in biomagnetism, because it provides a means of quantifying the strength of activity. The term "current dipole" describes the fact that this active region of tissue provides current from the head of the dipole to the surrounding conducting volume and receives the returning current at its tail. To the outside world it appears as a source of current I slightly separated by a distance l from an equivalent sink (a "negative" source, $-I$), so the moment is defined as $p_i = Il$. The name was coined by analogy with a charge dipole, where a positive charge Q is slightly separated from a negative charge of equal magnitude $-Q$, and the electric dipole moment is defined as $p_e = Ql$.

It is important to recognize that volume current flowing through a medium of uniform conductivity produces no magnetic field. One way to show this is to integrate the Biot–Savart law over the entire volume when the source is a current dipole. The computation shows that the net field is zero. Therefore, by superposition, any source that can be described by a configuration of current dipoles produces no magnetic field from its volume current in the extracellular medium. The sole sources of field are the current dipoles themselves.

3.2 Primary and Secondary Currents

An active region of tissue that is described by a current dipole, or configuration of current dipoles in different positions and orientations, is called a *primary source.* It is a simplified representation of the more complex configuration of underlying cellular current flow. The primary source sets up a pattern of volume current within the surrounding conducting tissue. In dealing with biological applications, it is essential to take into account the effect of boundaries between tissues of differing conductivity (lung, heart, bones, etc.). They distort the pattern of volume current, and this influence may contribute to the observed magnetic field.

This effect can be taken into account conceptually and mathematically by imagining an equivalent situation: Space is considered to have uniform conductivity, and the effect of each boundary is represented by an appropriate distribution of current sources across the area of the boundary, oriented perpendicular to it so as to reproduce the same volume-current pattern as in the physical situation. These current sources at the boundaries are called *secondary sources* (Geselowitz, 1970). Where the volume current flows into a region of lower conductivity in the physical situation, the secondary source points toward the region of higher conductivity in the equivalent situation, and vice versa. The strength of the secondary source at each point on a boundary is the product of the electric potential and difference in conductivities across the boundary. Therefore if the distribution of electric potential throughout the medium is computed for a given configuration of primary sources, the secondary sources at each boundary can also be computed. The field anywhere outside the primary-source region is predicted by applying the Biot–Savart law to sum contributions from both primary and secondary sources.

3.3 Application to the Human Head

The characteristics of secondary sources have profound implications for the field patterns that are produced by neuronal currents in the human brain. For instance, if the head is considered a spherical core surrounded by a concentric shell of lower conductivity representing the skull, secondary currents at the inner and outer surface of the skull are radially oriented. Therefore, the fields they create outside the head are purely tangential to the scalp underneath. In other words, by measuring the radial component of the field only the primary sources are detected. This greatly simplifies the analysis. On the other hand, for the spherical geometry, the field of a radially oriented primary source is exactly cancelled by the field of the secondary currents.* In other words, a radially oriented primary current is "magnetically silent." Only the tangential component of a primary current can be detected magnetically. Paradoxically, this may be an advantage in brain research, because it means that the field pattern across the scalp has a recognizable symmetry for a localized neuronal source. As illustrated in Fig. 6, the field emerges from one area of the scalp and enters at another area, with the source lying under the midpoint. The span between the locations of these field extrema, in comparison with the radius of the head, indicates the depth of the source (Williamson and Kaufman, 1987). The span increases with depth, reaching half the circumference when the source approaches the center of the sphere. Of course, this limiting case is an example of a radial source, so the field strength at the extrema also goes to zero in this limit.

4. NEUROMAGNETISM

The creation of magnetic fields as a consequence of neural activity is called *neuromagnetism.*

There are three broad areas of investigation that have attracted greatest attention. The first to be considered focuses on the properties of an isolated nerve cell. The second

---

*The easiest way to see this is to recognize that the geometry is cylindrically symmetric about the dipole's axis, so the field lines would be circles centered on this axis. By Ampère's law, the field integrated about a circle outside the sphere is proportional to the net current passing through the area of the circle. But the net current is zero, because the total current, including the dipole's, passing through the area in one direction is the same as that passing through in the other direction.

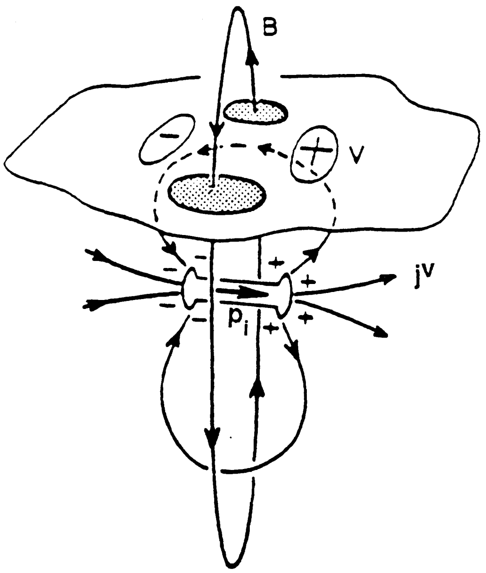

FIG. 6. Current dipole $\mathbf{p}_i$ in the conducting volume of the brain, with the associated volume current density $\mathbf{j}^V$ emerging from the head of the dipole and reentering at the tail. Ovals schematically indicate the positions of the two extrema in the scalp potential (V) and the two extrema of the radial magnetic field (B).

concerns activity of neuronal tissue, such as slices of cerebellum or muscle. The final area comprises processes of the human brain. They include sensory-related activity that is produced in response to a stimulus such as a sound or light pattern; spontaneous activity, with the α rhythm as the best known; and clinical applications, especially for epilepsy.

4.1 Action Potential of an Isolated Neuron

The business of neural tissue is to process information and transmit it from one place in the body to another. Transmission is the simplest process, so it merits initial consideration. To convey information over long distances in the body requires a rapid means, and the *action potential* serves this function. It propagates without distortion along the axon of a nerve cell. Because of its high speed, the entire chain of events as it passes by a particular location on the axon is completed within a few milliseconds. The sequence forming the action potential begins with depolarization of the transmembrane potential, commonly as a result of multiple inputs onto a neuron from neighboring neurons. The standing potential of −80 mV (inside potential relative to outside) rapidly decreases to nearly zero, or even becomes positive. This opens channels in the membrane through which sodium ions enter the cell, where their initial concentration is lower than outside. The electric field produced by the local increase of intracellular positive charge accelerates positive ions within the axon (predominantly potassium) to flow in the direction of propagation, away from the initial site of excitation [Fig. 7(a)]. This is known as the depolarization front. Slower responding potassium channels then open to permit an outflow of these ions, and the decrease in positive charge following the depolarization front causes a backward-directed intracellular current. This is the repolarization front. The action potential is therefore accompanied by two counterdirected intracellular currents. Once the action potential has passed, metabolically-driven "pumps" in the membrane slowly reestablish the original concentration of ions by passing sodium outward and potassium inward.

It is possible with a toroidal coil and low-noise amplifier to measure the magnetic fields accompanying the depolarization and repolarization fronts as they pass by. Comparing the transmembrane potential that can be deduced from this field with the potential directly measured with electrodes is a stringent test of the underlying theory for neuromagnetic fields. Studies of the crayfish axon show that the computed and measured wave forms closely agree with only one adjustable parameter (Roth and Wikswo, 1985). From the fact that the input data were measurements of a current and a corresponding voltage, it can be understood that the parameter corresponds to the intracellular electrical conductivity. Thus this comparison of electric voltage and magnetic field not only provided verification of the underlying theory for neuromagnetic sources but also gave an improved value for the conductivity. These techniques are being extended to characterize the function of a damaged nerve in the extremities of the human body, such as the arm, where a coil can be clamped around the nerve to monitor its response to stimulation.

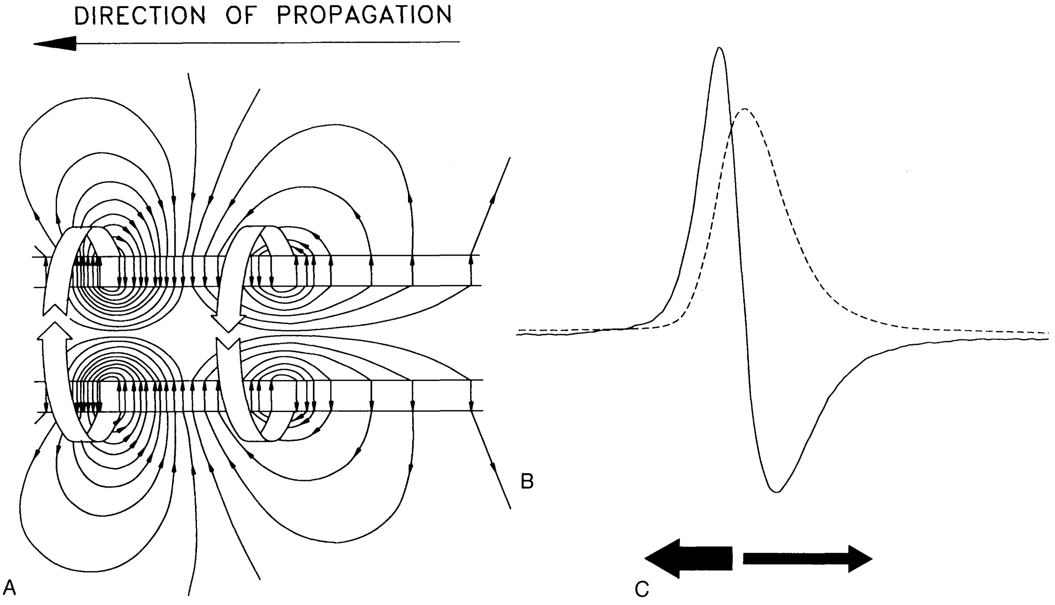

FIG. 7. Currents associated with the action potential of a nerve axon moving toward the left. (a) Curved thin lines indicate current patterns of the intracellular and extracellular space; straight segments show the direction of the transmembrane current (thickness of the membrane is greatly exaggerated compared with the diameter of the axon); and broad arrows encircling the axon show the direction of magnetic field for the depolarization front (left) and repolarization front (right). (b) Corresponding variation of transmembrane potential (dashed) and the axial intracellular currents (solid). (c) Depolarization (broad arrow) and repolarization (thin arrow) current dipoles representing axial currents. (Provided by J. P. Wikswo, Jr.)

4.2 Activity of Neural Tissue

Neurons in the brain are not isolated but establish intimate contact with one another. For this reason there is much merit in studies of tissue removed from the brain of an animal model or invasive studies of animals themselves. The work of Okada, Lauritzen, and Nicholson (1988) shows that it is possible in this way to study phenomena such as spreading cortical depression, where transmembrane potentials in cells become depressed sequentially from one location to another across the tissue. These studies demonstrate that electrode measurements within the tissue are consistent with magnetic measurements outside. This work also illustrates the interrelationship between such basic studies and clinical applications, for there is some evidence that spreading depression may be related to migraine in humans.

4.3 Sensory-Evoked Processes

The greatest effort in neuromagnetism has been devoted to studies of the human sensory systems, which are located in specialized areas of the cerebral cortex, the thin layer of gray tissue covering the brain. This is motivated in part by the notion that electrophysiological studies on animals reveal functional mappings across the sensory cortex, and these mappings suggest underlying strategies that have evolved to most effectively process sensory information. Indeed, the ability of magnetic studies to locate precisely activity evoked in the human auditory cortex has revealed just such maps.

4.3.1 Auditory Cortex. The auditory cortex in humans forms a portion of the horizontal, upper surface of the temporal lobe and is located about 5 cm above the ear canal. One functional sequence across this surface revealed magnetically is a "tonotopic" organization (Romani, Williamson, and Kaufman, 1982) for responses to an amplitude-modulated tone, where tones of higher frequencies evoke neuronal activity deeper beneath the scalp [Fig. 8(a) and 8(b)] (see ACOUSTICS, PHYSIOLOGICAL). The progression can be systematically mapped along a line, where the cumulative distance from one response to the next across the cortex increases as the logarithm of the frequency [Fig. 8(c)]. A similar progression is found for the source of strong neuronal activity following, by 100 ms, the onset of a tone burst. Moreover, tones of greater intensity do not enhance neuronal response strengths, as might be expected. Instead, neuronal activity is shifted to different locations across thecortex with increasing strength. This "amplitopic" organization extends along a line that is approximately at right angles to the tonotopic sequence (Pantev *et al.*, 1988). While neuronal response strength is not affected by tone frequency or intensity (at least for easily heard tones), it is affected by a person's attention. If attention is diverted by a distraction, the neuronal response to a tone decreases in strength. Such applications of neuromagnetic techniques to auditory studies have been particularly fruitful in revealing these as well as many other aspects of functional organizations in humans that had not been known (Hari and Lounasmaa, 1989).

4.3.2 Somatosensory Cortex. Somatic cortical responses can be evoked with electrical or mechanical stimulation of the skin. Neuronal activity appears within the central sulcus, a fissure that begins at a point just anterior to the vertex and runs downward and forward on both sides of the head to meet the upper surface of the temporal lobe. Systematic magnetic studies, in agreement with electrical studies, show the classic somatotopic representation where the location of the cortical response shifts systematically across the cortex with application of stimuli to different areas of the body. The spatial resolution obtained magnetically is sufficient to reveal a slight shift of activity across the central sulcus when a person voluntarily moves a finger. Neuronal activity is first seen in the motor cortex, forming the anterior bank, in preparation for finger movement. As the finger begins to move, the balance of neuronal activity shifts 6 mm posteriorly into the anterior bank as information from the proprioceptors in the joints and muscles is relayed to the somatosensory cortex (Okada, Williamson, and Kaufman, 1982). Therefore it is possible to study activity of this sensory–motor feedback loop noninvasively in humans. Activity in the secondary somatosensory cortex can also be observed (Hari and Kaukoranta, 1985).

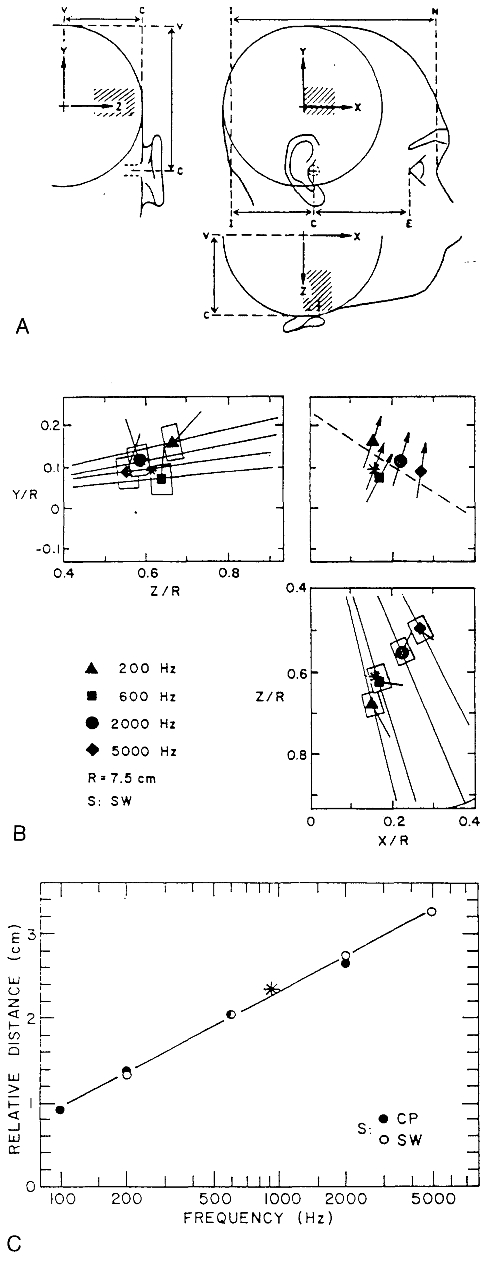

FIG. 8. (a) Three cross sections of the head, depicting the sphere used to model it for auditory studies. (b) Enlarged versions of the shaded sections showing deduced positions of neuronal activity evoked by modulated tones of the indicated frequencies. Boxes indicate the uncertainties for individual source positions. (c) Cumulative distance from one neuronal position to the next, for each of two subjects whose data are indicated by different symbols. The origin is arbitrarily set for 20 Hz. The star indicates a response from SW for rapidly presented click stimuli, where the peak in the power spectrum lies at 900 Hz (Romani, Williamson, and Kaufman, 1982).

4.3.3 Visual Cortex. Although the first sensory evoked response was detected in the visual cortex (Brenner, Williamson, and Kaufman, 1975), this modality has been less studied than the others. One reason, since overcome, was the difficulty of presenting a visual stimulus without also producing a magnetic artifact from the display. An early application provided evidence that a simple reaction time matches a series combination of a sensory response time, which varies with the type of stimulus, and a fixed motor response time of about 115 ms (Williamson *et al.*, 1978). The visual response time can vary from as little as 85 ms to well over 150 ms in response to contrast reversal of a grating pattern when the stimulus is increased in spatial frequency, decreased in contrast, or decreased in luminance. These kinds of studies probe the sequence of timing across various cortical areas. Other studies are beginning to characterize the sequence of subsequent activity in higher visual areas (Lu *et al.*, 1991), some comparing source locations with anatomical features provided by magnetic resonance images.

4.3.4 Cognitive Processes. A subject attracting increasing attention is how higher levels of brain functions are carried out. Memory processes are an example. One structure involved with declarative memory processes is the hippocampus, which is shaped like a pair of ram's horns forming a portion of the innermost surface of the lower right and left temporal lobes. There is considerable interest in finding techniques to elucidate its functions. One such approach, based on many sophisticated investigations of scalp potentials, is a paradigm where a sequence of common stimuli are presented with an occasional stimulus that differs in some physical aspect. Following these "odd" stimuli, one or more long-latency components appear that are not exhibited for the expected stimuli. It was possible magnetically to deduce the location of two of these components, for a visual task, and both were very deep regions within the left and right hemispheres, corresponding to the hippocampal formation (Okada *et al.*, 1983). This suggests that other deep structures may also be accessible to neuromagnetic study.

4.4 Spontaneous Rhythms

It is surprising that the strongest electric and magnetic activity of the brain is in a sense least understood. The well-known α rhythm is generated by a neural circuit involving both the thalamus deep within the brain and the cerebral cortex. This initiates within cortical pyramidal cells a series of bursts of oscillatory activity within the bandwidth of about 8–12 Hz. However, the function of this rhythm is yet to be explained. Magnetic studies are providing the first evidence that α rhythm in humans may be localized, with the strongest features originating within the parieto-occipital fissure. This fissure is the boundary between the classic visual and somatosensory areas of the brain.

Moreover, sources of other spontaneous rhythms may also be localized magnetically by employing a "resonance" technique. Periodic stimulation of an appropriate area of the skin can produce a greatly enhanced somatosensory response if the frequency is properly chosen. When stimulation is abruptly terminated, the response slowly dies away, similar to that of a resonant system. In this way the field pattern can be mapped over the scalp, since the resonant response is quite reproducible. One source of the resonant response is found in the central sulcus at the somatosensory projection area for the portion of the body being stimulated. Other sources are found in the parieto-occipital fissure (Narici *et al.*, 1990). Such investigations are only beginning to shed light on the functions served by these spontaneous rhythms.

Even if the specific function of a spontaneous rhythm is unknown, the signal itself can be used to advantage. One example of research into cognitive functions provides evidence that the visual cortex is involved in mental imagery. When a person is asked to compare an abstract figure with others previously shown in the same portion of the visual field, there is overall suppression of the α rhythm over the back of the head as the person mentally compares the images. However, there is much stronger suppression of the field near the midline at the back of the head, where a field would arise from sources within the visual cortex. Thus, preferential suppression of neuronal activity within the visual cortex implies that it is involved in the mental comparison task (Kaufman *et al.*, 1990). A control experiment in which the person is shown a word and asked to find a rhyme to it does not result in prolonged suppression of the α rhythm over the visual cortex. Instead, there is prolonged suppression over an anterior temporal area, implying that other functions of the brain are involved in this mental task. Thus the source localization provided by neuromagnetic studies is revealing distinct regions of spontaneous activity that are modulated differently by specific cognitive functions. By monitoring the spatial distribution of suppression, it will be possible to identify strategies that individuals employ when dealing with various mental tasks.

4.5 Clinical Applications

The most successful clinical application of neuromagnetism is in locating the site of focal epilepsy preparatory to surgical removal. A large percentage of epileptics who are under drug therapies do not respond appropriately to the therapy, and they become candidates for surgical removal of the epileptic region of tissue. Lesions of the brain, perhaps due to physical injury, may be sources of epilepsy but often focal epilepsy occurs without any manifestation shown in x-ray or magnetic resonance images (Sutherling *et al.*, 1987). Figure 9(a) illustrates one case where two foci alternate in producing epileptic discharges (Barth *et al.*, 1984). Field maps carefully recorded during the discharges reveal two different field patterns from which their respective sources were deduced, using two current dipoles to represent them. The deduced locations on an x-ray image lie at the boundary of a large lesion [Fig. 9(b)].

Other clinical applications of neuromagnetism are on the horizon. There is evidence, for instance, that auditory evoked magnetic fields provide an objective measure of tinnitus. This disease produces "ringing" in the ear, perceived by some patients with tinnitus as wide-band noise and by others as one or more tones of specific frequencies, or as a combination of the two. The ratio of the peak field at about 180 ms following the onset of a tone to the peak field at about 100 ms latency is markedly weaker for patients with tinnitus (Hoke *et al.*, 1989). In the case of a soldier who suffered tinnitus as a result of a nearby explosion, the ratio was seen to increase as the symptoms of tinnitus diminished. In another application, the ability to monitor dc fields from the brain has prompted research into the relationship between slowly varying fields and migraine. Such fields may very well arise from spreading cortical depression, but more research is needed to demonstrate the relationship.

5. MAGNETIC FIELD OF THE EYE

The aligned photoreceptors of the eye's retina produce a steady intracellular current directed toward the front of the eye. When a person changes direction of view, the eyes' rotation markedly alters the pattern of electric potential across the scalp. The corresponding change in magnetic field detected near the eyes is called the *magneto-oculogram.* A particularly interesting feature, magnetically speaking, is that the current dipole source that explains the corresponding magnetic-field pattern for one eye is about 10 000 times greater than expected from the primary source. The reason is that the pigment epithelium containing the photoreceptors has much lower electrical conductivity (by a factor of about 10 000) than the surrounding tissue. To account for current continuity across the epithelial boundaries, secondary sources must be similarly enhanced compared with primary sources. The secondary sources provide the dominant contribution to the measured field (Katila *et al.*, 1981). Changes in the strength of the magneto-oculogram are clearly detected when the eyes adapt to different illumination levels. Changes in the field near the eye are also observed when a person blinks. This is attributed to a change in the pattern of volume current, which introduces a new secondary source at the interface between the eyeball and eyelid.

These are not the only magnetic phenomena that the eye exhibits. Changes in the strength of the magneto-oculogram are produced when the eye responds to a brief flash of light. This is called the *magnetoretinogram,* by analogy with its well-known electrical counterpart, the electroretinogram. Rapid variations in field strength take place over a period of several hundred milliseconds. By comparison with the electroretinogram, individual features can be attributed to activity in photoreceptors and Müller cells of the retina. One advantage of magnetic recordings is that

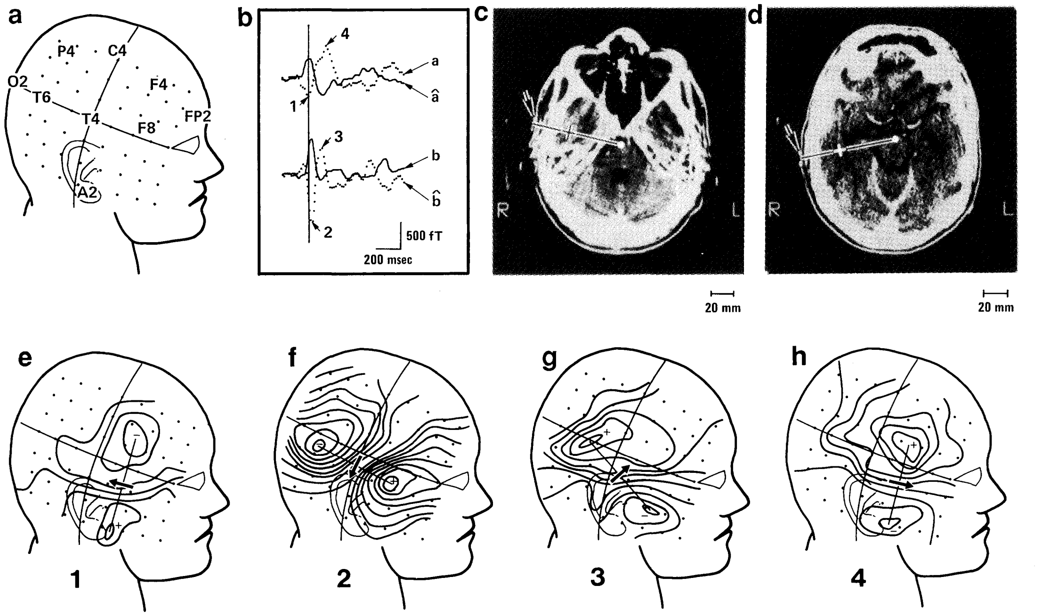

FIG. 9. Sequential activity of an epileptic discharge, obtained from field measurements across the scalp at positions indicated by the dots in (a). Averaged magnetic data (b) and corresponding isofield contours (e)–(h) reveal four alternating spike complexes. Two of them (1 and 3) arise from neuronal activity indicated by the arrows at one location [(e) and (g)] and the other two (2 and 4) from a second location [(f) and (h)]. Computed tomography sections through the head [(c) and (d)] show both sources to be located at the edge of a large area of scar tissue in the right temporal lobe. (Barth *et al.*, 1984; copyright 1984 by the AAAS.)

an electrode need not be placed on the cornea of the eye to register responses, a feature that is particularly beneficial to patients with sensitive eyes.

6. CARDIOMAGNETISM

A biomagnetic application that had attracted the greatest attention during the 1970s was characterizing cardiac activity. Measurements of the magnetocardiogram (MCG) at various positions over the torso revealed different wave forms than did the electrocardiogram (ECG) because the two recordings emphasize different features of the underlying pattern of current. The wave form during one cardiac cycle begins with the *P* wave, which arises from reduction (depolarization) of the transmembrane voltage of muscle forming the walls of the atria. It is followed by a much stronger, spikelike *QRS* wave from depolarization of the ventricles. The sequence concludes with a weaker and slower *T* wave from repolarization of the ventricles.

However, visual inspection of the wave forms has shown few obvious advantages for the MCG compared with the ECG in revealing cardiac abnormalities. Since the ECG is a well-established procedure involving much less expensive apparatus, medical interest in cardiomagnetism has not developed much for this specific application. More elaborate statistical studies have revealed, however, that signatures of the MCG provide information on certain disorders that are not as well revealed by the ECG, and vice versa (Nakaya, Mori, and Nomura, 1989). There may well be clinical benefits to be derived from the MCG in such applications.

6.1 Conduction System

More attention has been focused recently on exploiting the capability of magnetic measurements to locate disorders by applying the current dipole model to describe sources ofabnormal signals. While some attention has been directed to infarcts of cardiac muscle, primary emphasis has been placed on evaluations of the conduction system. This system

(Fig. 10) provides signals to coordinate activity of the atria and ventricles. The pacemaker at the sinus node establishes the basic cardiac rhythm. Its output initiates the depolarization of membranes of working cells in the walls of the right and left atria, as expressed by the *P* wave. In response, the muscle begins to contract. A delay of about 40 ms in the timing signal is provided by slow conduction through the atrial–ventricle node (A-V node) to allow the atrial muscles sufficient time to force blood into the ventricles. Then the signal quickly passes through a conduction path known as the His bundle, which bifurcates to form the left and right bundle branches. These in turn convey the excitation to Purkinje fibers that form a spreading network across the working muscles of the ventricles. There the excitation propagates as a wave front, moving upward through left and right ventricles, producing the *QRS* wave of the cardiogram as the muscles begin to contract to force blood out of the heart. This is followed by a period of repolarization of the working muscles, as indicated by the *T* wave.

Several types of disorders may occur in the conduction system. A delay or "block" may form at any level in the pathway; an "accessory" conducting path may be formed that bypasses the A-V node and directly connects one of the atria and the corresponding ventricle; and "reentry" may occur in muscle, where a pathway feeds the excitation back to another location. Any of these may disrupt the normal excitation cycle and cause an arrhythmia or increased frequency (tachycardia).

The conventional treatment for such disorders is surgery to bypass a block or disrupt an accessory pathway. To minimize the time needed to locate the site of disfunction during surgery, it is important to deduce where it may be as accurately as possible beforehand. The standard procedure consists of inserting a catheter through a vein into the heart and monitoring electrical activity at various positions, as the catheter is followed by x-ray images. In special cases, the catheter may even be used to affect treatment, by passing a strong current to ablate the portion of tissue.

Recent studies indicate that many of these disorders of the conduction system may be localized magnetically. A "high-resolution" procedure is carried out by measuring the cardiac signal at closely spaced intervals of 3–4 cm across the chest while recording within a wide bandwidth extending up to 300 Hz or more. In this way, excitation of the His bundle can be monitored, and localization of various types of arrhythmogenic tissue is possible by fitting a current dipole's field pattern to the measured pattern at select moments of time (Fenici *et al.*, 1989). Validation of this interpretation comes from comparisons with invasive electrophysiological studies, endocardial catheter mapping, and in some cases the results of surgical operations. For instance, Fig. 10 illustrates a possible site for preexcitation of the left ventricle via a conducting path from the left atrium (denoted as ECP). Certain atrioventricular accessory pathways may be localized magnetically with an accuracy of about 2 cm if the source is modeled as a current dipole (Nenonen *et al.*, 1990). But to achieve such accuracy it appears essential to employ a realistic model of the torso, as illustrated in Fig. 11, to account for the secondary sources associated with its surface. Infarcts within cardiac muscle may also be identified by using a current dipole model to represent the disruption of electrical activity.

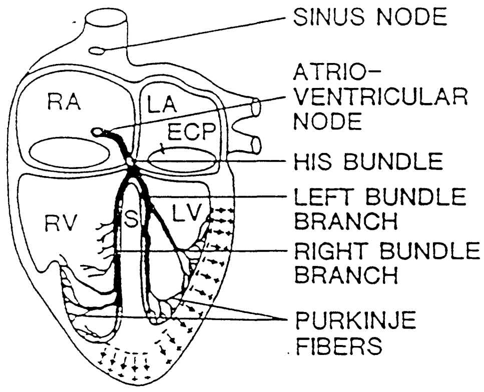

FIG. 10. Conduction system of the human heart. An accessory pathway between left atrium and ventricle is denoted by ECP. (Provided by T. Katila.)

7. REMANENT MAGNETISM

Normal human body tissue is nonmagnetic, in the sense that it has no remanent moment in the absence of an applied magnetic field. However, a remanent moment may be

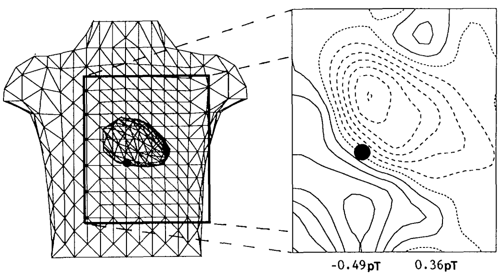

FIG. 11. Localization of the accessory pathway (dark circle) between atrium and ventricle in a patient (Nenonen *et al.*, 1990). Isofield contours in the right panel illustrate where the field emerges from the chest (solid contours) and reenters (dotted contours). The wire frame figure depicts the realistic torso and heart models employed in the computer calculation. (Provided by G. Stroink.)

detected when magnetic materials are ingested with food or are introduced by other means. Indeed, with a SQUID sensor it has been possible to locate a small portion of a magnetized acupuncture needle that had been broken off in a patient's back (Ilmoniemi *et al.*, 1988). It is also possible to detect biologically produced magnetic materials such as magnetite in the pigeon's head by using a SQUID magnetometer (Walcott, Gould, and Kirschvink, 1979). Nevertheless, the phenomena that have attracted greatest interest in studies of humans are associated with magnetic particles that become lodged within the lung.

7.1 Pneumomagnetism

Magnetic particles in sufficient quantity in the lung can be magnetized to produce a field that is detectable outside the body (Cohen, 1973). This is a pronounced effect in workers who have been engaged in specific occupations where they were exposed to magnetic dust, as in foundries, welding shops, and shipyards. If a strong magnetic field, of a fraction of a tesla or so, is applied to the volume of the lung for a few minutes and then terminated, a remanent field can be detected outside the chest. Flux-gate sensors are often sufficient for this purpose. Researchers originally hoped that the field pattern measured across the chest would provide information about the distribution of material within the lung. However, the inherent ambiguities in the solution for this inverse problem have discouraged subsequent development in this approach. Nevertheless, two other characteristics of the magnetic field continue to attract attention: clearance and relaxation.

7.1.1 Clearance. If the process of magnetizing the lung is repeated over many days, and the remanent field is measured shortly after the field is turned off, the remanent field is found to decrease from one week to the next. This has been interpreted as indicating that particles are being cleared from the lung, and the rate of decrease may be a measure of the effectiveness of clearance processes. The phenomenon can also be applied for research purposes if a small amount of magnetite dust (considered harmless in small quantities) is breathed by a volunteer subject. Figure 12 indicates that clearance is much slower in longterm smokers than in nonsmokers. This implies that other foreign materials are also likely to remain longer in smokers' lungs, thus putting smokers at greater risk to physi-

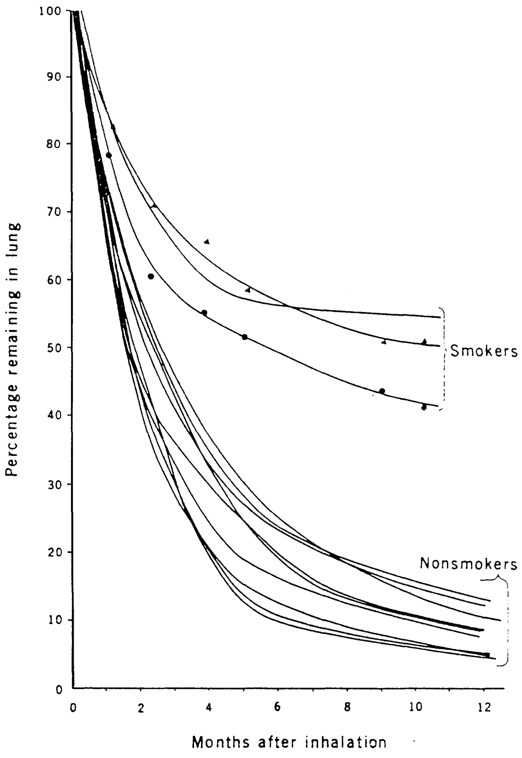

FIG. 12. Decrease of the remanent moment near the chest of smokers and nonsmokers who had inhaled fine magnetite dust. (From Cohen, Arai, and Brain, 1979; used with permission of the American Association for the Advancement of Science.)

ological insults of air pollutants in addition to the cigarette smoke itself.

7.1.2 Relaxation. The second feature of interest is *relaxation*, a steady reduction in the lung's field once the original magnetizing field is reduced to zero. It is now recognized that relaxation is signaled by particles that have been captured by macrophages (Brain *et al.*, 1984), specialized cells released on the alveolar surface that serve as the lung's garbage trucks. Macrophages engulf foreign material, thereby keeping it separate from normal body tissue, and the cells with their burdens are ultimately carried up the ciliary escalator of the bronchi to be swallowed, or taken into the body by other mechanisms. Relaxation occurs because the internal cytoskeleton of a macrophage is in continual motion, and this rotates magnetic particles so that their magnetic moments no longer point in a common direction (Valberg and Feldman, 1987). *In vitro* studies show that application of a material that is toxic to macrophages eliminates relaxation. This has encouraged a wide variety of magnetic studies to investigate the influence of diverse substances on relaxation rates.

8. BIOSUSCEPTIBILITY

One additional biomagnetic effect is proving beneficial in the clinic: measurement of the magnetic susceptibility of the liver in patients with iron overloads. Water, the major constituent of the body, responds to an applied magnetic field by producing a much weaker magnetic field in the opposite direction (diamagnetism). Deoxygenated hemoglobin in blood is paramagnetic; its responding field lies in the same direction as the applied one. As a consequence, the magnetic susceptibility of blood in the veins is 7% less than the diamagnetic susceptibility of pure water. Patients with the diseases hemochromatosis or thalassemia major are unable to recycle iron from dead red blood cells into the formation of new cells. Instead, iron is stored as components of the magnetic proteins ferritin and hemosiderin, which accumulate in the spleen, liver, and eventually other organs. Accumulation within the heart leads to disease that proves fatal. One method to combat this accumulation is administration of iron chelation drugs into the blood, so that iron is captured and eliminated in the stool. However, to follow the progress of treatment, it is important to monitor the changing iron concentration in the liver. This can be done with chemical analysis of biopsy tissue removed by insertion of a needle; however, many patients refuse this because of the pain involved.

Farrell *et al.* (1980) developed a magnetic technique to measure the susceptibility of liver tissue *in vivo*. A Dewar flask containing a SQUID sensor is placed a few centimeters above the patient, who is reclined on a special bed (Fig. 13). The Dewar also contains a superconducting magnet that produces a strong field in the region within a few centimeters below the SQUID's detection coil. Between the Dewar and the patient is a flexible bag containing water, with a connection to a water reservoir. The patient is raised by the bed, displacing some of the water, and the SQUID output is a measure of the difference between the magnetic susceptibilities of water and tissue. To obtain a quantitative value for liver susceptibility, the geometry of liver and intervening tissue must be taken into account. This geometry can be obtained from an ultrasonic scan *in situ*.

Normal liver tissue is diamagnetic, but patients with large iron overloads will exhibit a strongly paramagnetic susceptibility. Figure 14 shows the good correlation between iron

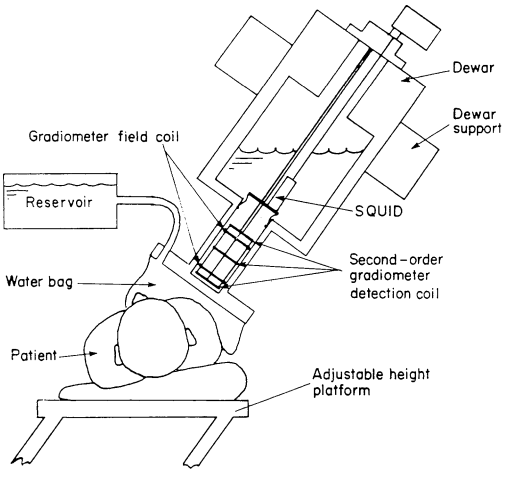

FIG. 13. Arrangement for recording the magnetic field produced by the susceptibility of a nearby region of the body when the person is moved toward the detection coil.

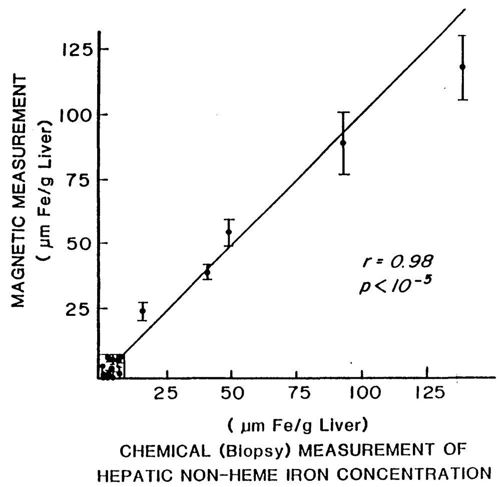

FIG. 14. Correlation of liver iron concentration obtained from magnetic measurements (vertical axis) and from chemical analysis of tissue provided by biopsy (horizontal axis) (Brittenham *et al.*, 1982).

concentrations determined magnetically and by chemical biopsy. There is reason to believe that the former is more representative of liver iron concentrations, because the volume assayed is several cubic centimeters, whereas the volume of tissue obtained with a needle extraction is orders of magnitude less. There is optimistic hope that with modest improvements in sensitivity and control over the measurements, iron deficiency may also be detected. This would prove a major benefit for the differential diagnosis of several diseases.

9. SUMMARY

Advances in biomagnetic studies during the past twenty years have been made possible by the continued development of the superconducting sensor (SQUID) and in some cases by the commercial appearance of large arrays of SQUID sensors. Basic research in understanding how to interpret magnetic-field patterns of the brain, heart, lung, and liver has provided a framework for ongoing clinical and occupational health studies. There are three sources of biomagnetic fields: ionic electric current, which is important in the brain, nerve, and heart; materials with permanent magnetic moments that are taken up from the environment, as in respiration; and the magnetic susceptibility of tissue whose atomic electrons respond to an applied field by producing their own, much weaker, field. The latter is an important signal indicating the progress of diseases that produce iron overload in the liver.

A diverse range of biological topics are within reach of biomagnetic techniques. In some cases, as for neuromagnetism and pneumomagnetism, the applications are making fundamental contributions to our understanding of physiology, with corresponding benefits for clinical applications. In others, such as cardiomagnetism, the technique is a complement to existing procedures, and ultimate acceptance rests on the balance between benefit and relative costs of competing technologies. New applications of magnetic measurements continue to be found, and the ever-increasing sensitivity of SQUID detectors ensures that this will continue to be true for many years.

GLOSSARY

Action Potential: Propagating excitation along a neuronal axon.

Current Dipole: Short element of current, representing intracellular current flow within a single cell or population of cells. Serves as the simplest model for a source of magnetic field.

Detection Coil: Superconducting coil connected as the input to a SQUID magnetic field sensor.

Flux Gate: A magnetic-field-measuring instrument that relies on an ac system to detect the response of its magnetic core.

Induction Coil: A coil of wire used to indicate the strength of an ac field by the strength of the voltage induced in it.

Macrophage: Mobile cell on the lung's alveolar surface that scavenges foreign materials.

Neuron: Nerve cell.

Primary Source: Current distribution representing active tissue, often modeled as a current dipole or arrangement of current dipoles.

Secondary Source: Current distribution along the locations of boundaries between media of differing electrical conductivity, to represent their effect on the extracellular current when the body is represented as a medium of uniform conductivity.

SQUID: Superconducting quantum interference device, an extremely sensitive device for measuring magnetic fields.

INTRODUCTION

Biomass converted to fuel (biofuels) has had a significant role in the supply of energy throughout history. Until the middle of the 19th century, it was the predominant source of energy providing heat, cooking, and light. During the late 19th century, the industrial revolution demanded more energy-dense fuels to produce steam. Coal filled that need until it was supplanted by petroleum, particularly as the demand for liquid transportation fuel arose in the early 1900s. During the 1930s and 40s, natural gas, then considered a waste product from oil wells, entered the marketplace as a source of fuel and chemical feedstock. With the increase in environmental awareness in the 1960s, biomass began a resurgence and today provides about 4% of the United States' energy needs. In addition, it supplies as much as 30% of some lesser developed countries' energy needs. With further utilization of existing and development of the resource and/or new improved conversion technologies, it can be a major energy supply source that has positive impact on domestic energy supply, the environment, the forest products industry, farm crops, and local job markets.

1. ENERGY CONSUMPTION

Today the United States has three principal sources of primary energy: coal, petroleum,

and gas. Other sources are nuclear energy, hydropower, biomass, geothermal, and other renewables such as wind and photovoltaics. Table 1 lists the consumption of energy by source. Further reading on energy consumption in the United States can be found in Energy Information Administration (1988, 1989) and National Wood Energy Association (1988).

2. THE RESOURCE

There is a broad range of materials which make up the biomass resource. Table 2 lists biomass resources by resource measurement category and current consumption.

2.1 Conventional Wood and Wood Wastes

This resource includes the standing forests of the United States and the wastes from various forestry and wood product operations. It has a moisture content of 50% when green and physical characteristics dependent on the source. Examples of wood waste include the limbs and slash left in the forest during logging, sawdust from woodworking and sawmill operations, and bark and sludge from paper making. The principal energy use today is to cogenerate steam and electricity for the paper and lumber industries. The second largest use is for home heat in the form of logs, wood waste, and pellets. Wood averages about 19.5 MJ/kg on a moisture- and ash-free basis.

2.2 Agricultural Crops, Wastes, and Residues

This is a diverse resource including residues from food crops, wastes from food processing, and manures. They are more moist than wood and are more diverse physically.

2.2.1 Crops. Crops such as plant oils from seeds (sunflower, rapeseed, safflower, etc.) can be used as diesel fuel, particularly for on-farm vehicles. Engine trials indicate severe coking of diesel injectors unless the oils are modified by transesterification with methanol or ethanol. Then they become suitable diesel substitutes. Certain species such as guayule and euphorbia produce latexes that can be converted to liquid fuels.

2.2.2 Wastes. Wastes such as corn cobs and stover, wheat straw, and rice husks are used to generate heat for drying, steam for industry, and electricity for the grid. Manures and food-processing wastes are used to produce biogas for boiler and engine fuel.

2.2.3 Excess Corn. Excess corn and other grains, molasses, and food-processing wastes are used to produce fuel ethanol.

2.3 Municipal Wastes

These are the wastes of residential, commercial, and institutional activities and the mixed industrial wastes that are discarded in

Table 2. Biomass resources (in quads).

Resource	Total	Accessible	Reserves	Current
Forests & wood wastes	442	20	12.5	2.5
Agricultural wastes & manures	10.5	5.2	1.1	0.2
Municipal & industrial wastes	2.4	1.8	1.6	0.2
Recycling	0.8	0.4	0.4	0.2
Energy crops	55	28.0	9.2	0.0
Aquatic crops	5	1	0	0

sanitary landfills. Municipal wastes are burned directly for heat and/or electricity, used to produce refuse-derived fuel (RDF), or recycled. Municipal waste, as are most wastes, is a unique fuel. Typically, it is delivered free. Further, a disposal or tipping fee is paid to the owner or operator of the energy plant. This fee is based on the cost of disposing of the waste by other means. For example, the cost of disposing of waste in a specific Long Island community is $150 per ton (1988) whether sent to the local waste-to-energy plant or hauled off the island. The negative cost of waste as a fuel is increasing as the environmental costs of landfill as an alternative disposal system are recognized and internalized.

2.3.1 Residential Wastes. Residential wastes are heterogeneous with roughly 55% organic matter (mixed paper, food and yard wastes, plastic, textiles, and urban wood), 25% moisture, and 20% inorganics (iron, glass, aluminum, other metals, dirt, and grit). They average about 21.8 MJ/kg on a moisture- and ash-free basis.

2.3.2 Commercial, Institutional, and Industrial Wastes. Commercial, institutional, and industrial wastes tend to be more uniform, drier, and of high combustible content. However, they are closer to wood and average about 19.5 MJ/kg on a moisture- and ash-free basis.

2.3.3 Sludge. Sludge from sewage treatment plants is included in the municipal wastes. Sewage sludge is 92%–95% moisture as produced, and depending on the source may be dewatered mechanically to 20%–40% solids. The energy content is about 25.5 MJ/kg on a moisture- and ash-free basis.

2.3.4 Recycling. There are several components of municipal solid waste that are recyclable, including paper and plastics, aluminum and iron, and glass. The best recyclable component is aluminum beverage containers. They have a positive market value in part because each kilogram conserves 220 MJ when compared to production from ore. For the last few years, aggressive recovery activities by aluminum companies and a purchase price of $600–$1000 per ton have resulted in 55%–60% of all aluminum beverage containers being source separated and recycled. By tonnage, waste paper has been the principal recycled material. Manufacturing waste newsprint conserves about 4.6 MJ/kg. However, because of oversupply, collectors have had to pay to dispose of separated newsprint on the East Coast for the year 1989. Other paper such as corrugated boxes requires as much energy to recycle as to produce from virgin material. Further reading on the energy aspects of several recyclable materials can be found from United States Department of Energy (1982).

2.3.5 Biogas. Biogas is recovered from landfills and sewage treatment plants. It is used as a boiler fuel, as a fuel for engine generator sets, as natural gas after the carbon dioxide is scrubbed, and in a few instances compressed as an automotive fuel.

2.4 Energy Crops

A significant increase in the availability of biomass resources will require the development of new and improved crops. These crops can be suited for terrestrial or aquatic environments. Energy crops are at varying stages of development.

2.4.1 Terrestrial Crops. Terrestrial energy crops can be either trees or grasses depending on the conversion process and the land to be utilized.

There are two broad categories of trees, coniferous or softwood and deciduous or hardwood. Softwoods are used commercially for pulp and dimension lumber. Research has improved their growth from 2.5 to 7.5 metric tons per hectare and their fiber yield. Hardwoods have been used for high value specialty purposes such as furniture and veneers. The natural supply has been sufficient to meet demand and no improvement was undertaken until their value as energy crops was recognized. Hardwoods are preferred as an energy crop since certain species grow faster than softwoods and they coppice when cut. Further, second and third growth cycles are proving to be more productive than the first cycle. Because of the broad diversity of land forms, soils, and climate, several species are required. Six species have been selected for development from 140 surveyed based on growth rate, survivability in adverse conditions, nutrient requirements, and ability to coppice. The principal genus in development is *Populus* (poplar, cottonwood, etc.). The *Populus* species are candidates for growth in every region of the United States. The other species are more limited in range. Black locust is a nitrogen-fixing tree with range limited to the midwest and southeast. Silver maple has been selected for the midwest, great plains, and northeast; American sycamore for the southeast, sweet gum for the southeast, and eucalyptus for subtropical regions. In nature, these trees produce up to 7.5 dry metric tons per hectare per year (DT/H). However, by selection of fast-growing clones, hybridization, and biotechnological manipulation, growth rates of over 30 DT/H have been reached and an average United States growth of 25 DT/H is reasonably achievable. Since the nutrients concentrate in the leaves and energy wood is harvested in the winter while dormant, fertilizer requirements are minimal. Since the trees are closely spaced (2 m or less), the leaves and branches shade the ground and weeds are controlled.

As with wood species, there are two broad categories of agricultural crops, the annuals which die and require replanting each year, and the perennial crops which retain viable root mass each year. The perennials are preferred as energy crops since annual reestablishment is not required and the living root system reduces erosion. Selection of target species is still ongoing in the United States; however, the thick-stemmed perennial grasses (e.g., napier grass) are favored. The annuals such as sorghum are being considered because of their fast growth rates. Energy cane (a variety of sugar cane) has produced 150 DT/H in Puerto Rico.

The availability of land and the potential for competition between food and fiber and energy and chemical uses are of concern. However, world economies are learning to grow food. Two major importers of food in the past, India and China, now export food. Exports of large United States surpluses are decreasing. The federal government is subsidizing farmers to keep land out of production. Twelve million hectares of land are in the Conservation Reserve Program which removes highly erodible land from agriculture practice. Trees are approved for planting on these lands to stabilize the soil. The federal government pays to keep 20 to 30 million hectares of land fallow to reduce surplus crops. The Agricultural Research Service has identified a need for alternative crops for 60 million hectares of current farm land by 2010. Further, the Department of Agriculture has identified 62 million hectares of land, now in pasture and range, that are suited for farmland. This total acreage at an average of 25 DT/H could provide 58 EJ (55 quads) of energy per year.

2.4.2 Aquatic Crops. There are three potential aquatic biomass resources: the emergents or marsh crops such as cattails, macroalgae such as giant kelp grown in the open sea, and microalgae.

Emergents have a resource base limited primarily to the marsh land of the upper midwest. They are difficult to harvest and to match to a conversion process which must have a year-round supply of feedstock. Macroalgae are difficult to grow and harvest although they have some valuable energy-crop characteristics such as the 45% sugar content of kelp.

Microalgae are single-cell organisms that live in either fresh or saline water, grow rapidly, and under stress fix large quantities of lipid (plant oil). These oils are typically hydrocarbons in the C_{18} to C_{22} range and are similar to the plant oils from seeds. The same transesterification will be needed to convert them to suitable diesel fuels.

2.5 International Considerations

Worldwide, there is broad interest in the use of biomass as an energy resource. Many of the developing countries generate as much as 30% of their primary energy from biomass. In many cases the resource is overused and actions are necessary to reverse the trend through improved efficiency and replanting. For example, inefficient stoves in the sub-Saharan Desert region are being replaced and new trees planted to halt desertification of the area.

The major food-raising countries all have an interest in the improved use of agricultural and wood wastes. Under the auspices of both internal and international agencies there is increasing use of bagasse from sugar cane and rice husks for the cogeneration of steam and electricity for refinery operation. Many countries are considering the infrastructure and legal changes necessary to supply electricity from wastes to the nations' electric grid. The Brazilians have embarked on a major program to use ethanol from cane sugar as a gasoline replacement.

The industrialized nations are more advanced than the United States in the productive use of municipal solid waste. While we use perhaps 20% for energy and recycling other countries make use of up to 75% of their waste.

Worldwide there is increasing interest in the growth of energy crops. As noted, Brazil produces ethanol from cane sugar. In addition, they have a great deal of expertise in fast-growing eucalyptus trees. Now they are engaging in research to produce ethanol from those trees. England, Sweden, Canada, Finland, and the United States cooperate under the auspices of the International Energy Agency. Belgium maintains a bank of over 3000 *Populus* species clones. In fact, several of the United States commercial plots have been planted with clones from that bank. India and the United States have a bilateral agreement in part to develop energy crops. The Indians are the preeminent researchers in species of *Populus* for alkaline soil conditions. However, statistics are not readily available for the worldwide potential for energy crops.

3. CONVERSION TECHNOLOGIES

There are two broad categories for the conversion of biomass to a fuel form, thermochemical and biochemical. The former uses heat and is typified by fast reaction times (seconds to minutes) and harsh conditions (high temperatures from 300 °C to over 1000 °C and pressures of up to 200 atm). The products tend to be variable. The biochemical systems use enzymes (natural catalysts) and are typically slow (reaction times of hours to days) and mild (temperatures from room to the boiling point of water, and atmospheric pressure). The products are specific.

3.1 Preparation

The design and operation of any biofuels system depends on the form of the feedstock. In general, smaller and more uniform particles favor conversion. However, obtaining such fuel can be expensive. The simplest form of preparation is drying, and the most complex is the separation of municipal solid waste (MSW) into various components. A recent innovation is a combustion system that can burn whole trees.

The preparation of biomass has two aims: provision of a more uniform fuel and separation of the fuel into components. Wood generally is used as chunk wood (5- to 15-cm pieces), hog fuel (2.5 to 5 cm), and sawdust. Finer particles may be compressed into pellets or briquettes. Screens are used to remove rocks and other inerts, and magnets to remove tramp metal such as saw teeth, barbed wire, etc. MSW is used as received or processed to produce refuse-derived fuel (RDF), materials for recycling, and inerts. MSW is prepared by screens of various designs for size separation, hammermills, and flail mills for size reduction and a series of technologies to separate specific components, such as magnets to recover ferrous metals. Refuse-derived fuel and magnetic metals have been recovered successfully. The technology to recover glass and aluminum has been developed. MSW separation is an art unto itself. Further reading can be found in Diaz *et al.* (1982) and Hasselriis (1984).

3.2 Thermochemical Conversion

As biomass is heated, the long chains of molecules that comprise cellulose, hemicellulose, and lignin begin to break into simpler molecules and become modified. The final form of those molecules depends on the rate at which heat is applied, on the length of heat application, on the final temperature, on the external oxygen available, and to a lesser extent on the pressure. High heat rates, short residence times, and limited oxygen can favor the retention of long-chain molecules that are liquid at standard temperature and pressure. As reaction time increases, heat rate decreases, final temperature increases, and oxygen levels increase, the molecules become shorter until with sufficient time and oxygen, the fuel is completely oxidized.

3.2.1 Combustion. The most common technology for the use of biomass as a fuel today is combustion. There are thousands of facilities that burn biomass and MSW to provide industrial steam and heat, electricity, and district heating. In addition, over 2 million homes use wood stoves as a principal means of heat.

During combustion, fuel is first dried to drive off free water, then the long chains of molecules are broken until essentially the carbon reacts with oxygen to form carbon dioxide. The general chemical equation is

$$C_x(H_2O)_y + xO_2 \rightarrow xCO_2 + yH_2O. \qquad (1)$$

In an ideal combustion process only the stoichiometric amount of oxygen is added. In practice, excess air (oxygen) must be added to maximize the oxidation of the carbon and minimize the formation of carbon monoxide. Figure 1 is a typical graph of carbon monoxide versus oxygen. Since these graphs are a function of the specific fuel and conditions of combustion, no units of measurement have been added. As the amount of excess air is increased, the combustion process is cooled, carbon monoxide production increased, and overall efficiency reduced. A modern biofuels combustion system can reduce carbon monoxide emissions to 30 parts per million (ppm) and achieve efficiencies in the 65%–75% range. Here, efficiency is defined as the steam produced per unit of total-energy input. For comparison a modern natural gas plant is 80% efficient, fuel oil 85%, and coal 90%. The differences are principally related to the amount of water produced per joule of fuel burned both from the conversion of fuel hydrogen to water and from free and fuel-bound water.

The success of the combustion of biomass is a function of the design of the system. The majority of biomass combustion facilities have a grate to retain fuel for complete combustion and to distribute part of the combustion (underfire) air. Grates vary from a simple slab of metal with small air distribution holes (pinhole grate) for sawdust to complex reciprocating grates for raw MSW. The Energy Research and Development Administration (1977) provided sketches of a series of MSW grate systems. In addition to the primary air delivered through the grate, secondary air is delivered above the grate to promote turbulence and to ensure complete combustion.

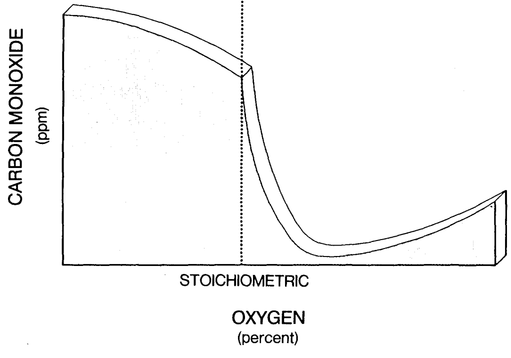

FIG. 1. Carbon monoxide vs oxygen.

The grate is contained in a firebox which may have walls constructed from either refractory fire brick or a membrane of welded tubes (waterwall). In the latter case the tubes are filled with water which removes both radiant and sensible heat. Waterwall systems have integrated superheaters, economizers, and feedwater heaters to recover steam. Refractory systems have a separate waste heat boiler. Because radiant heat of the fire is captured, waterwalled systems tend to be more efficient than refractory systems; however, the refractory systems tend to have lower maintenance and repair costs. Further reading on design and a more complete description of boilers can be found in Robinson (1986), Chap. 13.

The quality (temperature and pressure) of the steam recovered depends on its end use and the overall system function. For example, industrial processes frequently require 1 MPa, saturated steam while electric generation is most efficient at high steam pressures and degrees of superheat. Particularly in MSW fired units, steam temperature is technically limited by the wall temperature of the superheater tubes. As the tubes are heated, they are subjected to two distinct corrosion patterns. First, there is a low-temperature peak of corrosion at about 150 °C followed by a high-temperature peak at around 450 °C. Corrosion at high temperatures is not well understood although it is most likely caused by a complex sulfur, iron, and chlorine reaction. Overall pressure is not a limiting factor. See Plumley (1977) for diagrams and further discussion on corrosion regimes.

An emerging thermal technology is the fluid bed combustor. The biomass fuel is combusted in a chamber that is partially full of sand. Air is injected below the bed and the sand acts as a fluid. The large mass of turbulent hot sand ensures very rapid heat transfer and complete combustion of the fuel. Heat is recovered by in-bed and above-bed tubes, waterwall tubes, and integrated boiler banks. If limestone is substituted for sand, the bed also captures chlorides and sulfur oxides. Fluid bed combustion units require less excess air than other biomass combustion designs and are more efficient in the production of steam. There are two variants of the fluid bed combustor. The atmospheric fluid bed uses low air velocities to retain sand in the combustion chamber. The circulating fluid bed uses high enough air velocities to elutriate sand. Hot sand and char are removed in a hot cyclone and recycled to the main bed. There are a significant number of fluid bed combustion units operating in the wood products industry, most providing hot air for drying and curing products.

Pollution-control systems for combustion systems include particulate and acid-gas controls. Table 3 has proximate and ultimate analyses for wood, MSW waste, and coal. Because of low-acid gas-forming components, wood-burning systems require only particulate control. Modern MSW combustion facilities generally are required to have sophisticated acid-gas controls. The acid-gas controls available include wet scrubbers, dry scrubbers, and direct lime injection into the combustion chamber. Wet scrubbers condense acid gases with a water spray. They leave an acid solution that is difficult to manage. Dry scrubbers spray a slurry of lime into the combustion gas stream and collect dry reagent in a bag house or electrostatic precipitator. They reduce chlorine emissions by 90% and sulfur by 70%. Direct injection of lime into the combustion chamber costs 10% that of dry scrubbing with 10% degradation of efficiency of removal. The control of acid gases in fluid beds is achieved by the selection of lime or limestone as the bed material.

Table 3. Proximate and ultimate analysis (percentage by weight). From Domalski *et al.* (1987).

	Wood	MSW	Coal
Proximate analysis (as received)			
Moisture	50.0	25.1	13.1
Volatile	40.3	43.8	27.9
Fixed	9.7	6.1	51.1
Ash	0.02	25.0	7.9
Ultimate analysis (dry)			
Carbon	48.9	39.5	74.3
Hydrogen	5.9	5.0	4.9
Oxygen	43.3	29.5	7.8
Nitrogen	0.03	0.5	1.4
Chlorine	0.01	0.4	NA
Sulfur	0.01	0.1	3.7
Ash	0.02	25.0	7.9

There are several particulate control systems including cyclones, baghouses, and electrostatic precipitators. Cyclones act as a centrifuge. They are relatively inefficient and not used in modern pollution-control systems. Baghouses pass combustion gas through finely woven bags that capture particulates. As a layer of particulate builds, efficiency of capture increases. When the pressure drop across the bag exceeds a set limit the bag is taken off line and cleaned with a reverse flow of clean air. They are favored in modern plants since they are more efficient in the removal of fine respirable particulate. Electrostatic precipitators generate an electric charge on particulates before passing the combustion gas between plates with the opposite charge to attract and hold the particulate until the unit is taken off line and the plates are cleaned. Both baghouses and electrostatic precipitators are more than 99% efficient.

3.2.2 Gasification. As the available oxygen is reduced in a combustion system, the carbon is no longer completely oxidized and combustible gases containing carbon monoxide, hydrogen, and other higher hydrocarbons are produced. Continued decrease of oxygen finally results in unreacted char that is mostly carbon and ash. The gasification reaction is endothermic; therefore, an external source of heat is required. The source of heat may be the combustion of char with air or oxygen, or an external heat source. When char is burned with air in the reactor, the product gas is diluted with nitrogen and has a heating value of 1.8–7.2 MJ per standard cubic meter (MJ/SCM) (low-energy gas). If pure oxygen is used, the diluting nitrogen is removed and a product gas with a heating value of 10.9–14.5 MJ/SCM (medium-energy gas) is produced. Finally, if the reactor is heated externally, the production of hydrocarbons such as methane is favored over carbon dioxide. The gas produced has a heating value of 12.7–19.9 MJ/SCM (medium-energy gas). The chemical reaction is

$$C_x(H_2O)_y + \text{heat} \rightarrow yCO + yH_2 + (x-y)C. \quad (2)$$

Since there is no way to exclude oxygen and free water from the reactor completely, a series of other reactions occur, and Eq. (2) is modified. At least part of the CO is shifted to hydrogen via the water-gas shift reaction [Eq. (3)], and if partial combustion is the entire source of heat, the carbon char is burned to carbon dioxide [Eq. (4)]. Other reactions and incomplete reactions combine to produce higher hydrocarbons such as methane and long-chain molecules that are solid or liquid at atmospheric conditions:

$$CO + H_2O \leftrightarrow CO_2 + H_2 \text{ (water-gas shift)}, \quad (3)$$

$$C + O_2 \rightarrow CO_2. \quad (4)$$

3.2.2.1 Reactors. There are a series of types of gasification reactors. In the updraft gasifier, a descending bed of feedstock is first dried, then gasified, and the char is burned (either in air or oxygen) to produce a rising stream of hot gas to drive the reactions. The downdraft gasifier partially combusts the surface of a bed of feedstock. An induced draft pulls the hot product gas down through the glowing bed of coals. As a result the majority of the long-chain molecules are cracked and tars are reduced to produce gas. This product gas is cleaner and more adaptable to the internal combustion and gas turbine engines. Also, the fluid bed reactor has been adapted to gasification. The high thermal mass of the bed with its rapid heat transfer and relatively long residence time is well adapted to gasification. Fluid bed reactors can operate with the source of external heat from partial combustion of the char in the bed, from fire tubes in the bed, or by external heating of the bed material. Further reading on gasification can be found in Reed and Das (1988).

3.2.2.2 Utilization. Low-energy gas cannot be transported economically over distances of more than a kilometer. Therefore, its use is mostly viewed as a fuel for a boiler or, where tar and ash are low, as an engine fuel. Most of the 40 or so applications to date have been as a boiler fuel although at least one gasifier–engine-generator system has been permitted. In addition to fuel uses, medium-energy gas is a suitable chemical feedstock. Again, low tars and ash are desirable characteristics. In addition, the CO/H_2 ratio may be adjusted by the water-gas shift reaction [Eq. (3)]. For example, if methanol (CH_3OH) is the end product, then the CO/H_2 ratio must be adjusted to 1/2.

3.2.3 Liquefaction. As reaction time and final temperature are decreased, more long-chain molecules survive when compared to gasification. These molecules condense at standard conditions to a viscous, oxygenated fuel called biocrude. Biocrude might be considered as a substitute for fuel oil but because of instability and corrosiveness, will more likely be upgraded to other liquids such as gasoline. One of the early, large-scale attempts to produce a liquid biofuel used MSW refined to a fine (less than 30 mesh) powder which was pyrolyzed while entrained in a hot gas stream. The unreacted char was removed and burned to provide the reaction gas stream. The liquid product was condensed to a viscous, relatively unstable, corrosive oil that was to be used as a partial replacement for fuel oil in a utility boiler. The combustible gas produced was used for drying the feedstock and for reactor heat. The risk of the technology and the lack of government funds to support further testing led the industrial partner to abandon the technology when there was a major refractory failure in the reactor. The high level of processing and the limited use of the product oil were contributing factors. A second system was constructed based on the high-pressure liquefaction of wood in a carrier of hot wood oil. This system successfully produced many barrels of biocrude, but was uneconomic.

Any of the reactors discussed under gasification could be adapted to liquefaction. However, only two systems are in active research. The first is based on fine wood in a carrier of product oil at high temperature and pressure. The biocrude oil produced is relatively low in oxygen and can be hydrotreated to produce first run (i.e., 72 octane) gasoline. The chemistry of the technology is complex and varies with the feedstock. The second technology uses a vortex reactor that transfers heat rapidly from a hot wall to fine biomass. Unreacted wood and char are removed by a cyclone and recycled. The product gas is passed through a zeolite catalyst to produce gasoline. More development is necessary before either technology can be fully assessed for commercial viability. Current models indicate that when fully developed the technology could produce gasoline for a wholesale cost of $1.00 per gallon.

3.3 Biochemical Conversion

Biochemical conversion takes advantage of enzymes to convert biomass to other more useful products. The two processes in use which are significant to energy are fermentation to produce ethanol and anaerobic digestion to produce methane. In the fundamental operation of life processes, genes, which are segments of DNA, produce enzymes which convert organic molecules to useful products. Enzyme production is self-regulated. A specific promoter initiates the production of enzyme. When either enough product is available or no more feedstock is present a repressor gene turns off the production of enzyme. For example, in human nutrition, organisms in the mouth produce alpha-amylase, an enzyme which reduces starch to sugar. Food more difficult to digest is reduced to sugar in the stomach by dilute acid. The sugar is absorbed in the bloodstream. Further reading on biotechnology and enzyme production can be found in Watson *et al.* (1983).

3.3.1 Fermentation. Fermentation processes have been used for thousands of years to produce beverage alcohol. More recently with the oil crises of 1973 and 1978, ethanol has been produced as a transportation fuel. Starch is reduced to glucose by commercial alpha-amylase enzymes [Eq. (5)]. The glucose is then fermented by a yeast such as *Saccharomyces cerevisiae* to ethanol and carbon dioxide [Eq. (6)]:

$$(C_6H_{10}O_5)_n + nH_2O + \text{yeast} \rightarrow nC_6H_{12}O_6, \quad (5)$$

$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2 + \text{heat}. \quad (6)$$

The conversion of glucose to ethanol is not a simple rupturing of appropriate atomic bonds in the glucose atom. The pathway was first described by Embden and Meyerhoff (Solar Energy Research Institute, 1981). There are 12 distinct steps that are catalyzed by different enzymes. First, a phosphate group is added, then that compound is changed to fructose and another phosphate group is added. This compound is cleaved into two different isomers of three carbon compounds, each with a phosphate group. One of the isomers (dihydroxyacetone phosphate) is modified by another enzyme into the second (glyceraldhyde 3-phosphate). A second phosphate group is added and a hydrogen ion removed. Next, one of the phosphate groups is replaced by a hydroxyl (OH) radical. Then the phosphate group is moved to a new location in the atom and a hydroxyl radical and a hydrogen ion are removed from different locations in the molecule. The second phosphate group is removed to produce pyruvate, which is reduced to carbon dioxide and acetaldehyde. Finally, a hydrogen ion is added to acetaldehyde to produce ethanol. Further information on this reaction and microbiology, chemistry, and ethanol production is provided in Solar Energy Research Institute (1981).

A beer with 8%–10% alcohol is produced. Any remaining unconverted organic material is filtered and the water removed by distillation to the azeotrope of a mixture of 93% ethanol and 7% water. The remainder of the water is separated by chemical alteration of the combined boiling points or by selective absorption.

The current fuel ethanol market uses starch or sugar as its feedstock. In the United States over 85% of the fuel-grade ethanol is made from corn starch. In 1988, about 330 bushels of excess corn were converted to 850 million gallons of fuel-grade ethanol. The remainder is made from other grains, molasses, and industrial waste. In Brazil the majority is made from sugar. However, the United States and Brazilian industries require subsidies to survive. The United States industry is supported by a rebate of 6¢ of the 9¢ federal gasoline excise tax if 10% ethanol is blended with the gasoline (equivalent to a 60¢ per gallon of ethanol rebate) or a 60¢ per gallon of ethanol income tax credit (rarely used). In addition, there are state tax incentives equivalent to 10¢–20¢ per gallon of ethanol in 20 states. In Brazil, where all gasoline is a blend with 20% ethanol and a significant number of new cars are designed for pure ethanol, the industry is supported by a tax on gasoline.

3.3.1.1 Future Ethanol Production. Sugar and starch prices are based on food and feed value. They are unlikely to produce economic ethanol until the current price of gasoline doubles. Cellulosic crops such as wood or grasses could provide an economic feedstock. These might be wastes or specific energy crops (see earlier section on terrestrial crops).

3.3.1.2 Pretreatment. To use crops, their three major components (cellulose, hemicellulose, and lignin) must be separated and the former two hydrolyzed to sugar. The paper industry hydrolyzes lignin with a strong alkaline solution to leave the cellulose and hemicellulose fibers intact. For ethanol production, the hydrolysis of the hemicellulose into five-carbon sugars (primarily xylose) is preferable. A number of technologies including weak acid, organosolv, ammonia–freeze-dry explosion, and steam explosion are used to hydrolyze the hemicellulose.

3.3.1.3 Hydrolysis. Cellulose is crystalline and difficult to hydrolyze. Acid digestion will reduce the cellulose molecule to glucose; however, control is difficult and the acid will degrade glucose to furfural. Acid hydrolysis was used in the United States and Canada to produce industrial ethanol in World War II. That practice stopped as soon as ethylene became available from oil after the war. The Russians still operate over 40 acid hydrolysis plants to convert wood to ethanol.

Also, cellulose can be hydrolyzed enzymatically. Certain yeasts produce a consortium of enzymes that degrade cellulose specifically to glucose. The enzyme endoglucosidase breaks the long- chain cellulose molecule at interior bonds. Exoglucosidase removes a disaccharide from the end of the cellulose chain. The third, beta-glucosidase, completes the reduction of the disaccharide to hexose which may then be fermented to ethanol. Betaglucosidase is the rate-limiting enzyme. Finally, hexose is fermented to ethanol via Eq. (6).

3.3.1.4 Xylose Fermentation. The hemicellulose that was hydrolyzed to xylose in the pretreatment step represents 25%–35% of the total feedstock. Its use is essential if the overall ethanol production system is to be economic. There is no known organism or enzyme that economically will ferment xylose at efficiencies comparable to glucose. However, an enzyme, xylose isomerase, produced by *E. Coli* naturally converts xylose to a different five-carbon sugar isomer, xylulose. Xylulose is fermented to ethanol by commercial enzymes. Normally, *E. Coli* does not produce large quantities of xylose isomerase. Biotechnology has been used to modify the appropriate repressor gene of *E. Coli* to increase xylose isomerase production. Today 70% of the hemicellulose can be fermented to ethanol. Incremental improvements are expected to increase that to 90%:

$$(C_5H_8O_4)_n + nH_2O \rightarrow nC_5H_{10}O_5, \qquad (7)$$

$$3C_5H_{10}O_5 + \text{enzymes} = 5C_2H_5OH + 5CO_2. \qquad (8)$$

The actual conversion path is from 3 xylulose to 1 fructose and 1 glyceraldhyde 3-phosphate. These then follow the pathway briefly described above for glucose fermentation.

3.3.1.5 Lignin. Lignin, the third component of plant matter, is not readily biodegradable, and therefore cannot be readily converted to ethanol at this time. However, it is a useful fuel that can be used to produce steam and electricity to power the overall plant. Today, lignin that is hydrolyzed in paper making is burned for energy, to recover chemicals, and for disposal. In addition, lignin can be converted to an aryl ether thermochemically. The process is one of hydrogenation and then reaction with either methanol or ethanol to produce methyl (MAE) or ethyl aryl ether (EAE). MAE and EAE are high-octane liquids that can be used in transportation fuel blends.

3.3.2 Anaerobic Digestion. Anaerobic digestion is a common occurrence in nature. It is likely to have been the source of today's natural gas. As biomass died in swamps and was submerged 50 to 250 million years ago, it was digested into methane and carbon dioxide. Some of the gas was trapped and, as time passed, water dissolved the carbon dioxide, leaving natural gas.

Like ethanol fermentation, anaerobic digestion is a complex process that relies on a host of organisms. First, carbohydrates are hydrolyzed to simple organic acids. These are converted to acetic acid by acetogenic bacteria:

$$(C_6H_{10}O_5)_n + 7nH_2O + \text{enzymes} \rightarrow 6nCH_3OOH. \qquad (9)$$

Then the strict anaerobic methanogens reduce acetic acid to methane and carbon dioxide:

$$CH_3OOH + \text{enzymes} \rightarrow CH_4 \text{ and } CO_2. \qquad (10)$$

Also in the methane production pathway is the reduction of carbon dioxide with hydrogen via

$$CO_2+4H_2 \rightarrow CH_4+2H_2O. \qquad (11)$$

A description of these pathways was given in National Research Council (1977). Chapter 19 of Robinson (1986) contains design parameters.

4. BIOMASS ENERGY AND THE ENVIRONMENT

Biofuels impact on many environmental sectors including the agricultural, forestry, greenhouse, energy conversion, and energy use sectors. The overall impact is a function of the specific fuel pathway; for example, the impact of an energy crop is different from the impact of a corn crop. Similarly, the impact of a combustion system is different from that of a fermentation process.

4.1 Agricultural Sector

The principal concerns of the agricultural sector are erosion and chemical releases to the environment. Erosion is caused by the lack of a stabilizing vegetation layer on the land. In general, it is associated with an annual row crop such as corn. Energy crops such as fast growing trees or perennial grasses leave viable root systems to hold soil in place. Currently, trees are approved for the purpose of controlling erosion on United States land which has been taken out of service under the Soil Conservation Reserve program. Chemical pollution results in surface runoff and ground-water contamination. Excess fertilizer causes algae blooms which cause oxygen depletion in receiving waters. Herbicides and pesticides may be poisonous to aquatic life. Energy crops require smaller applications of fertilizer and chemicals. For example, while an annual farm crop requires annual fertilizer applications of 260 kg/hectare, energy trees require 225 kg/hectare in the first year, and 110 kg/hectare in the second year, and no further applications until harvest. In addition, some fast-growing trees (e.g., black locust) are nitrogen-fixing species that might be intermingled to provide fertilizer to a plot. Bacteria living symbiotically in root structures actually provide for nitrogen fixation. Biotechnology may be able to transfer these characteristics to other fast-growing energy species. Herbicide application is required annually for agricultural crops but only in the first and second years after establishment for an energy crop. Then the crown closes and shade provides weed control. Pesticide applications are not well understood but the first energy tree clone biotechnologically altered for disease control has been planted in test plots. Overall, energy crops are expected to improve the agricultural environment.

4.2 Forestry Sector

The principal concern in the conventional forestry sector is the air pollution caused by the open burning of slash and waste developed in the harvesting of a timber stand. The development of uses and collection systems for these materials plus environmental regulation will lead to their recovery and use as energy feedstocks. In addition, the sawdust and wastes of the forest product industry increasingly are being used as energy sources rather than being landfilled or incinerated with poor combustion control. Today, the forest products industry is over 50% self-sufficient in energy production. Within 20 years, it expects to be 100% self-sufficient.

4.3 Greenhouse Gases

Incoming short-wave solar radiation is absorbed by the earth, clouds, and the atmosphere and reflected from the earth and clouds, and backscattered by air. Long-wave surface and atmospheric radiations are emitted to space. Some of this radiation is absorbed by CO_2, ozone, and water vapor from which it is reflected back to earth. Several gases are increasing in concentration in the atmosphere and may upset the normal balance of radiation so as to cause the earth's temperature to rise. The greenhouse gases of concern are CO_2, CH_4, NO_x, ozone, and CFC's (chlorofluorocarbons such as Freon). Biofuels can affect the release of the first three and generally are not involved in the generation of the last two. Figure 2, adapted from Green (1989), displays the global average earth energy balance. The buildup of CO_2 and NO_x is directly related to the combustion of fossil fuels while the increase in CH_4 is related to food production and waste disposal (see AIR POLLUTION: COMPONENTS, CAUSES, AND CURES).

FIG. 2. Earth's energy balance.

Carbon dioxide is produced during the combustion of any fuel. Two important fuel characteristics are the heating value per pound and the hydrogen-carbon ratio. Figure 3 is adapted from Green (1989) and gives these values for several common fossil and biofuels. The higher the hydrogen-carbon ratio, the less carbon dioxide produced per unit of energy. Thus the best fuel is pure hydrogen and the worst, anthracite coal. The quantity of carbon dioxide in the atmosphere has been increasing since the beginning of the industrial revolution and currently is about 350 ppm (up from 280 ppm in 1850). The uncontrolled burning of biomass fuel releases both carbon dioxide and methane. However, when a biomass waste is burned, no new net carbon dioxide is added to the atmosphere since the biomass will decay in a relatively short period. Further, when an energy crop is grown for energy, the carbon dioxide absorbed in the growth is released in the utilization process. Thus the carbon dioxide is recycled.

Methane is present in significantly lesser

FIG. 3. Fuel characteristics.

amounts than CO_2; however, methane is a much more reactive gas than CO_2 in the upper atmosphere. While expert opinion varies, recently the EPA has published the relative reactivity of methane as being 30 times that of carbon dioxide as a greenhouse gas. Further reading on greenhouse gas issues can be found in Walter *et al.* (1989). The specific impact of greenhouse methane is particularly important in the utilization of wastes. Municipal waste decays anaerobically in landfills and in certain circumstances biomass may also decay anaerobically. The equations of this decay are the same as Eqs. (9) and (10), that is, for every molecule of CO_2, a molecule of CH_4 is produced. Each molecule of methane is estimated to have 30 times [United States Environmental Protection Agency (1990)] the greenhouse effect of a molecule of carbon dioxide. Therefore, productively using organic waste not only reduces the relative CO_2 effect from 31 to 2, but also displaces CO_2 that would have been produced from fossil fuel.

4.4 Acid Gases

Another environmental issue is the release of acid gases and more specifically sulfur oxides into the atmosphere. The conversion processes generally collect much of the acid-gas component of the primary feedstock, e.g., refining crude oil to motor fuel collects the majority of sulfur that is naturally present in oil. Despite this, gasoline still contains about 0.4% sulfur and diesel fuel up to 3% sulfur. In contrast, bioalcohols are sulfur free.

The direct combustion processes oxidize the available sulfur compounds to SO_x. This produces acid rain which, in certain locations, is believed to be the cause of damage to forests and lakes. The amount of acid rain produced by any combustion process is proportional to the amount of fuel-bound sulfur. Table 3 lists the fuel-bound sulfur for biomass, municipal waste, oil, and coal. For comparison, the chlorine contents of biomass and municipal waste are also listed since it produces HCl when burned. Both sulfur and chlorine emissions are being controlled by wet or dry scrubbers, particularly in the case of municipal waste combustion.

Nitrogen oxides are produced both from fuel nitrogen and from the oxidation of nitrogen in the air during combustion. The amount of NO_x produced by the fuel is proportional to the nitrogen in the fuel. Table 3 lists the fuel nitrogen for biomass, municipal solid waste, oil, and coal. Nitrogen oxidized from the air is a function of the temperature of combustion. It is lower for biomass and municipal solid waste which tend to burn at lower temperatures because of relatively high moisture contents.

4.5 Other Emissions

The principal products of combustion are carbon dioxide and water. Sulfur oxides, nitrogen oxides, and hydrogen chloride are discussed above. Carbon monoxide and other trace gases also are produced. These are controlled to meet current emission standards and are no higher than the similar emissions from coal and oil plants. In addition, particulates are discharged from the stack. Compared to the combustion of coal and No. 6 oil, particulates are controlled to the same or more stringent standards, particularly for municipal waste.

GLOSSARY

Accessible Resource: A subset of the total resource base that can be acquired by current technology or technology that will be available in the near future.

Anaerobic Digestion: A biological reaction that occurs in the absence of air.

Azeotrope: A mixture of two liquids such that the vapor at the boiling point has the same composition as the liquid, and thus the boiling point does not change as the evaporation proceeds.

Biogas: The gas produced by anaerobic digestion. Stoichiometrically it is 50% methane and 50% carbon dioxide.

Biomass: Any natural organic material or waste of recent origin excluding fossil fuels.

Carbohydrate: A compound made up of carbon, hydrogen, and oxygen with the hydrogen and oxygen in the atomic ratio of 2 to 1.

Cellulose: One of the four main components of plant matter. It is a long, crystalline, straight-chain carbohydrate primarily made up of glucose. The chemical formula of cellulose is complex but may be simplified to $(C_6(H_2O)_5)_n$.

Coppice: The regrowth of a tree from the stump.

Disaccharide: Two monosaccharides bound together with an OH^- radical removed from one and a H^+ radical from the other. The most common is sucrose which has one glucose and one fructose molecule combined. The chemical formula is $C_{12}H_{22}O_{11}$.

Enzyme: A natural biochemical catalyst. They are responsible for specific chemical reactions and are not consumed during the reactions.

Extractive: One of the four main components of plant matter. They are various chemicals and components such as sap. They carry nutrients throughout the tree, and provide disease and pest resistance. Of the extractives, sugar and starch are the main components of interest for biochemical conversion processes and resin is the main component of interest for thermal conversion processes.

Hemicellulose: One of the four main components of plant matter. It is a long, straight chain polysaccharide primarily composed of xylose (a five-carbon sugar). The chemical formula of hemicellulose is complex but may be simplified to $(C_5(H_2O)_4)_n$.

Hexose: A monosaccharide with six carbon atoms.

Hydrolysis: The process of splitting an atom by the addition of water with one hydrogen molecule incorporated into one fragment and the hydroxyl radical into the other.

Lignin: One of the four principal components of plant matter. It is an amorphous polymer primarily composed of phenol molecules.

Monosaccharide: A simple carbohydrate. The two most common are glucose and fructose, both of which have the formula $C_6H_{12}O_6$; however, the atoms are organized in different ways and they have different chemical characteristics. The corresponding pentose is xylose with the formula $C_5H_{10}O_5$.

Pentose: A monosaccharide with five carbon atoms.

Photosynthesis: The system by which plants use sunlight to convert CO_2 and water to plant matter and oxygen. Although the actual chemical composition of plant matter is very complex, frequently it is simplified as $C_x(H_2O)_y$. The values of x and y vary, although typical values are $x=1$, $y=0.72$ to 1. The general formula for photosynthesis is $nCO_2+xH_2O+\text{sunlight} \rightarrow C_n(H_2O)_x+nO_2$.

Polysaccharide: More than two linked monosaccharide molecules.

Quad: A measure of energy equal to 1 quadrillion Btu or 1.054 EJ.

Reserve: That subset of the accessible resource that can be economically and legally used to yield useful energy.

Resource Measurement Categories: Standardized definitions from the mineral industry to describe a resource. Further reading on the categories and quantities of renewable resources can be found from the Meridian Corporation (1989).

Short Rotation Hardwood: A fast-growing wood species that coppices and is grown on excess agricultural land. Short rotation wood was developed for energy but is being commercialized as a fiber and energy resource.

Starch: A folded chain of monosaccharides with the general formula of $(C_x(H_2O)_{(x-1)})_n$.

Sugar: A simple carbohydrate. There are three basic classes: monosaccharide, disaccharide, and polysaccharide.

Total Resource Base: The combination of undiscovered and identified, subeconomic and economic concentrations of a resource.

INTRODUCTION

Biomechanics is defined as the application of mechanics to problems in biology and physiology. The mechanics implied in this definition are the classical fields of rigid-body dynamics, solid mechanics, and fluid mechanics. In the applications of each of these fields to biological problems, nonlinear as well as linear theories are often required. In representing body motions not only rigid-body dynamics may be required but also dynamics of jointed, hinged, and flexible structures. In the applications of solid mechanics to soft tissues, the strains are often large and the constitutive equations are nonlinear. Biological fluids, particularly blood, are non-Newtonian and thixotropic. Both biological fluids and solids are generally viscoelastic. Thus, while linear theories of elasticity and Newtonian fluids are often useful as a first approximation, nonlinear field theories are often required.

If the definition of mechanics is expanded to include statistical mechanics, thermodynamics, heat, and mass transfer, then the area of application of biomechanics can be correspondingly expanded. However, for the purposes of this article the more classical definition will be assumed and only a limited

number of areas of application will be mentioned, mostly in relation to the human body. In biological tissues, temperature is often an important variable. Further, many mechanical properties are modulated by biochemical changes. These important aspects, however, will not be generally covered in this article since there are special articles on various biophysical topics in this Encyclopedia. They include CELLULAR BIOMECHANICS, BIOMEDICAL ENGINEERING, BIORHEOLOGY, MEMBRANE BIOPHYSICS, PROSTHETICS AND ARTIFICIAL ORGANS, AEROSPACE MEDICAL PHYSICS, and BIOLOGICAL EFFECTS OF SOUND AND ULTRASOUND. The reader is referred to these articles.

The term *biomechanics* and research specifically directed to this field have become widespread only in the last two or three decades. Looking back in history one can identify investigations and ideas that can be classified as biomechanics although they may not have been called by this name at the time. Such early efforts tended to be sporadic and due to a few outstanding individuals who were often physicists as well as physicians. One can find instances of application of ideas of mechanics to biology which paralleled or even preceded the development of new principles in mechanics. For example, it could be said that Leonardo da Vinci (1452–1519) as an engineer and artist appreciated the mechanical aspects of the muscle and skeletal systems of the human body and to some extent the mechanics of the heart, heart valves, and blood flow. Galileo (1564–1642) was a student of medicine before he became a physicist. He discovered and used the pendulum to measure the pulse rate. The discovery of circulation of blood is attributed to William Harvey(1578–1658). Harvey studied at Padua while Galileo was a professor there. During this period Santorio (1561–1636), also a professor of medicine at Padua, made careful measurements of human body weight and showed it decreased even in periods of no obvious intake or efflux. René Descartes (1596–1650) wrote a theory of physiology based on mechanical principles. However, it was not very realistic. A classical treatment of muscular and skeletal dynamics was given by Giovanni Borelli (1608–1679). He also considered the mechanics of swimming, flying, and the contractions of the heart. Robert Hooke (1635–1703), after whom Hooke's law is named, also worked on biomechanics. Leonhard Euler (1707–1783) wrote one paper on wave propagation in the arteries among his many works on fluid mechanics. Thomas Young, after whom Young's modulus is named, also discussed the theory of blood flow. In fact, the concept of Young's modulus came from the study of elasticity of artery walls. Young was a physician concerned with astigmatism and color vision as well. The French physician Jean-Louis-Marie Poiseuille (1779–1869) established Poiseuille's law of viscous flow in a circular tube out of his interests in blood flow. In this case the experimental law (1841) preceded the solution of the Navier–Stokes equations. The theoretical formula was derived some years later by Hagenbach (1859).

Another physician who contributed to many aspects of the mechanics of physiology was Hermann Von Helmholtz (1821–1894). In biomechanics he is best known for his studies of hearing. Helmholtz represents a kind of scientist who was equally at home in physiology and in the latest physics of the times. Such comprehensive individuals seem to be more rare after 1900 as scientific knowledge rapidly expanded on many fronts. In the period from 1900 to about 1960 applications of mechanics to the development of such engineering products as aircraft and automobiles greatly advanced in theory and practice. But the development of applications of mechanics within medicine and physiology did not share equally in this development.

Beginning about 1960 there developed a widespread interest in applications of mechanics to biology. At the present time there is again a close integration of these diverse fields most often by a cooperation of individuals trained in different disciplines, e.g., biology and physics, or medicine and engineering. The symposium on biomechanics held in 1970 (Fung *et al.*, 1972) indicates the status of the field at that time. Since 1973 the American Society of Mechanical Engineers has held annual symposia on biomechanics. There is also a Journal of Biomechanics at this time and many additional meetings and societies concerned with applications in bioengineering which include biomechanics discussions. One area in which applications have become highly developed is orthopedics. A new Journal of Orthopedic Research has been recently instituted. A series of books by Fung (1981, 1984, 1990) and the *Handbook of Bioengineer-*

ing (Skalak and Chien, 1987) indicate the scope of current work in biomechanics.

1. WHOLE-BODY DYNAMICS

In considering the motion of an entire human being, an adequate model can be obtained for many purposes by considering each major segment as a rigid body connected by appropriate joints and hinges. Each segment must obey the laws of motion of a rigid body which may be expressed in any convenient coordinate system. At each of the hinges or joints of the body the reactions on the two segments connected must be equal and opposite and the transmitted moments along hinge axes are set equal to zero or they may depend on a spring and/or dashpot behavior (see Fig. 1).

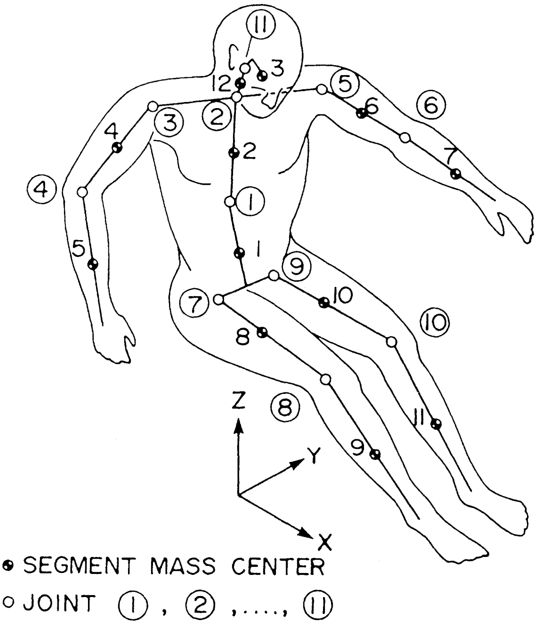

FIG. 1. Three-dimensional model of aircraft occupant consisting of 12 rigid segments. The model has 29 degrees of freedom. Resistances at each of the body joints are modeled using both a nonlinear torsional spring and a viscous damping element. (From Laananen, 1986, by permission.)

1.1 Applications of Whole-Body Dynamics

Models of the human body consisting of linkages of rigid subunits are useful in studying crashworthiness, gait analysis, and stresses developed during automatic ejection from aircraft.

1.1.1 Crashworthiness. In the case of crashworthiness, the motions of the various parts of the body are well represented and computer models predict such things as head contact with a front windshield or sliding under a seat belt during severe deceleration. The analysis of the injury or trauma to be expected from such crash forces requires a more detailed model and analysis including an appropriate representation of the skeletal system and the soft tissues (see Nahum and Melvin, 1985). In the problem of head injury, for example, the skull may be represented as an elastic shell. The brain and other soft tissues are much less rigid than the skull and may be represented as a viscoelastic solid of low modulus as a first approximation. Detailed studies indicate that injury to the brain is most easily caused by sudden angular accelerations which induce shear stresses that in turn may rupture blood vessels. The combination of such studies with neurophysiological function is a current area of research (Viano, 1988).

1.1.2 Aerospace Biomechanics. The behavior and performance of the human body in aerospace environments offers a variety of interesting problems. The rigid-body linkage model is useful in estimating forces produced by emergency ejection for aircraft. Models for this purpose have been highly developed and analyzed in detail. In space the absence of gravity limits the motions which a freely floating person can perform. The linkage model is also useful in this case.

1.1.3 Gait Analysis. Whole-body models are also useful in studying gait analysis. The details of the motion of each part of the body during walking and running have been analyzed from cinematographic records and by measurement of forces by devices flush with the walking surface. This equipment is similar to the devices used in measuring forces on model aircraft in wind tunnels. Gait analyses are useful in diagnosing pathologies of the joints and skeletal system. They are also useful in evaluating the functioning and efficiency of prostheses.

2. MECHANICAL PROPERTIES OF BIOLOGICAL TISSUES

2.1 Mechanical Properties of Bone

Bone is a composite material, made up of a matrix and a mineral crystal phase, principally hydroxyapatite, which is hard, dense, strong, and brittle. These fibers are surrounded by the softer collagenous matrix. Mammalian bones have a specific gravity of about 2.0 and have roughly equal parts of one-third mineral, one-third collagenous matrix, and one-third water. These proportions vary with species, age, and location. A typical long bone is a hollow structure with a dense bone shell made up of compact or cortical bone. The cavity is usually partly filled with a less-dense form of bone called cancellous or trabecular bone. Cancellous bone is made up of a meshwork of small plates with many spaces between them like a sponge. The individual plates are of similar strength and composition to cortical bone.

In vivo bone is a living tissue made up of highly organized cells and a blood supply which permeates the entire structure. Bone may remodel itself under stress by adding material at its outer surface or by changes in its compositon and density throughout its volume. These functions are carried out by special cells called osteoblasts which build up new bone and osteoclasts which cause its degradation. The cells and fibers in bone are mainly oriented along principal stress trajectories which makes the mechanical properties of bone anisotropic. Among the tissues of the body, bone is relatively solid, rigid, elastic, and brittle. In tension, bone fractures at an extension of about 2%. The ultimate strength of bone depends on the direction of stress with respect to the axis of the bone. Bone is stronger in the direction of its longitudinal axis. It is generally taken to be transversely isotropic, meaning that properties are the same for all directions perpendicular to the long axis. The ultimate strength of cortical bone has been determined for samples from various animals tested in different directions. Mean values for the ultimate strength of human bone are given by Reilly and Burstein (1975). In the direction of the long axis the ultimate strengths of human bone in tension and compression are 133 and 193 MPa, respectively. Perpendicular to the long axis the ultimate strengths in tension and compression are found to be 51 and 133 MPa, respectively. Shear strengths of bone are reported as derived from torsion tests on circular specimens whose long axis coincides with that of the bone. For such tests the mean shear ultimate strength is 68 MPa. A more comprehensive discussion of the elasticity and strengths of bone may be found in the chapter by Cowin *et al.* (1987).

Testing of bone has been carried out in standard procedures of tension, compression, bending, and shear testing statically and at various strain rates. Data by Carter and Hayes (1977) show that both elastic modulus and ultimate strength increase with the strain rate but only to a power of about 0.06. Viscoelastic and fatigue properties of bone are also discussed by Cowin *et al.* (1987). Fatigue data indicate that *in vitro*, bone accumulates fatigue damage so that the stress amplitude for failure decreases sharply at the order of 10^6 cycles. However, *in vivo* it is expected that bone repairs and remodels continuously so that the *in vitro* fatigue testing does not fully reflect the performance of bone *in vivo*.

In the range of most physiological stresses, bone acts as an anisotropic (transversely isotropic) elastic material. Cowin *et al.* (1987) showed that linear stress-strain relations for the elastic range require 12 nonzero material constants of which 9 are independent. In terms of the usual Young's modulus in tension or compression, shear modulus, and Poisson's ratio, the 12 elastic parameters can be summarized as 3 Young's moduli in the principal directions, 3 shear moduli, and 6 Poisson's ratios. The Young's modulus for human bone in the longitudinal direction is about 17 000 MPa. In the transverse directions, the Young's modulus is about 11 500 MPa. The shear moduli are of the order of 3300 MPa. The Poisson's ratio varies widely in different experiments but generally lies within the range of 0.3–0.5. The properties of bone vary widely with the particular bones, age, sex, species, and conditions of stress. Astronauts in space and patients who are for some reason immobilized lose mineral content of the bone over a period of days or weeks (see AEROSPACE MEDICAL PHYSICS). The influence of stress on bone remodeling has been discussed by Cowin (1988) and the modulation of formation of bone during growth by the stress field has been discussed by Carter (1988).

Additional discussion of the structural function of bone has been given by Fung (1984). In a macroscopic sense the form of bones can often be identified as tending toward an optimal structural arrangement. The trabeculi in cancellous bone tend to be oriented along lines of principal stress. Further, the hollow form of bone is a very efficient structural shape for stiffness and bending rigidity. Computer programs utilizing remodeling laws based on strain energy density show realistic developments comparable to observed forms (Huiskes, 1988).

In the testing of bone, it is important that it be kept wet at all times. Otherwise the properties begin to change rapidly. The properties of bone may be determined by standard tension and compression tests but also by ultrasonic testing (Cowin *et al.*, 1987).

Bone also exhibits interesting electromechanical effects. It is piezoelectric and it has been suggested that there may be an electrochemical effect as an important part of bone remodeling under stress. Bending of a bone may produce an internal fluid flow which in turn may produce a streaming potential. These electromechanical effects are not discussed here in detail but more information may be found in a chapter by Johnson and Katz (1987).

2.2 Mechanical Properties of Soft Tissues

Most soft tissues of the body have characteristically a highly nonlinear stress-strain curve. At low stresses the tension modulus is usually quite small. After an extension of 20%–50%, the stress-strain curve turns upward and the tension modulus is much larger just prior to failure. Figure 2 shows some test results for skin which exhibit this typical nonlinear behavior. Many tissues of the body are anisotropic. For example, the arterial walls are stiffer in a circumferential direction as compared to the longitudinal elasticity.

For most applications, it is sufficiently accurate to assume that soft tissues are incompressible. The bulk or volumetric elastic modulus of most soft tissues is several orders of magnitude greater than the shear or Young's modulus. An exception to the assumption of incompressibility is in the lung which undergoes large volume changes during breathing. However, these changes occur in the air space, and the soft tissues which make up the walls of the alveoli are themselves relatively incompressible. Another exception is in the analysis of ultrasound or shock waves. In these phenomena the compressibility of the

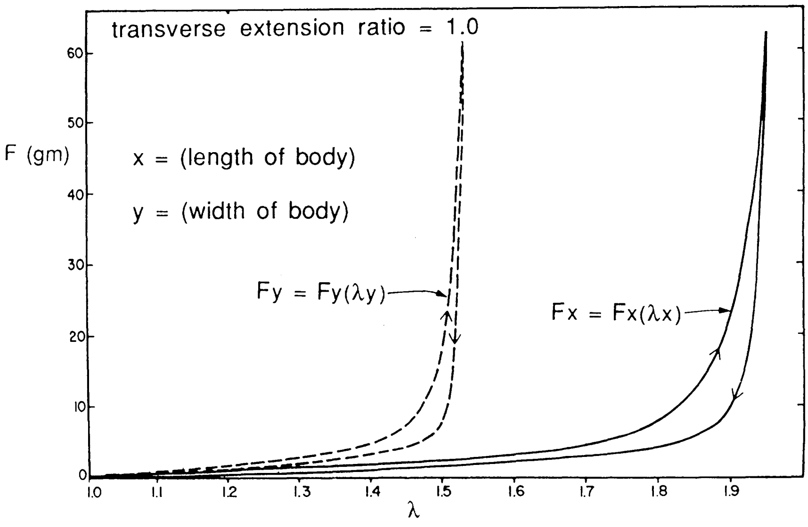

FIG. 2. Load-strain relations of a square (13.5×13.5 cm) specimen of rabbit abdominal skin. The tissue is stretched in one direction while the transverse dimension is kept constant. Solid line: stretch along the body length. Dashed line: stretch along the body width. (Adapted from Lanir and Fung, 1974, by permission.)

tissue, although high, is essential to understanding the physics of the stress propagation.

Most soft tissues also exhibit some degree of history dependence and viscoelasticity, but these are relatively secondary effects. If a tissue is removed from the body and tested in a cyclical manner it is generally found that the first few cycles do not repeat each other exactly, but there is a gradual increase of strain. After several cycles the stress strain curve becomes repeatable but not exactly the same on loading or unloading. The unloading curve generally shows a smaller stress at a given strain resulting in a closed loop in the stress-strain diagram as shown in Fig. 2. The area within this loop represents energy lost by hysteresis. Fung (1984) suggests that this behavior be called pseudoelasticity. The loading limb of the curve may be described as nonlinear elastic and the unloading curve is also nonlinear elastic but with a somewhat different stress-strain relation. Each of the loading and unloading curves may be described in terms of a strain energy function W per unit initial volume. A convenient set of stresses and strains for this description are the Green's strain tensor E_{ij}, and the corresponding Kirchhoff stress components (see Fung, 1984). The strain energy function W for an elastic material is assumed to be a function only of the strain components E_{ij}. Then, the Kirchhoff stresses S_{ij} are given by the derivatives of W with respect to E_{ij}, as is usual in finite deformation theory of elasticity.

If the tissue is considered as incompressible, then isotropic pressure p must be added to the stress components. This pressure p is not determined by the strains but can be found from the equations of motion and boundary conditions in solving a particular problem.

The form of strain energy function which gives the characteristic steepening nonlinearity of soft tissues is usually an exponential function of the strain components as suggested by Fung (1984). In general, it will not be sufficient to do only uniaxial tension or compression tests to define the strain energy function, but tests with more than one stress component different from zero are required.

For tissues which are naturally a thin sheet such as skin or arterial wall, it is convenient to test and describe the stress-strain relations in terms of tensions per unit length of a cut edge (dyn/cm). Such tensions may be regarded as the integral of the Cauchy stress through the thickness of the material. In testing of a plane sheet of tissue such as skin, the anisotropy is revealed by applying loads in different directions, as illustrated in Fig. 2. Lanir (1987) lists about 25 different stress-strain relations which have been used to describe tests on skin.

Soft tissues also show some viscoelastic behavior in the sense that the stress-strain curves do depend to some extent on strain rates. However, this is a very weak dependence and as a result hysteresis curves such as shown in Fig. 2 are relatively independent of frequency over a large range of frequencies of the order of 0.1–100 Hz.

The viscoelastic behavior of soft tissues may be described in terms of relaxation functions as suggested by Fung (1984). Typical forms for the relaxation functions are found by assuming simple models such as a Kelvin, Voigt, or standard solid model. For large deformations, describing nonlinear stress-strain relations, the variables in the relaxation functions are taken to be the Kirchhoff stress tensor and Green's strain tensor. Complete tensor descriptions have not been fully developed and validated for any particular tissues. However, one- and two-dimensional experiments using reduced relaxation functions fit the experimental data well. The relaxation functions of biological tissues are relatively independent of frequency over a wide range of frequencies which may be interpreted physically as indicating that the appropriate model is a large number of Kelvin bodies in series, each element having a slightly different time constant (Fung, 1984).

The typical steepening of the soft-tissue stress-strain curve at high strains is physically due to the presence of collagen fibers which are in a coiled form in most soft tissues. When these fibers are stretched so they uncoil and orient in the direction of principal tension, they become very stiff and account for the stiffening indicated in Fig. 2 and most other tissues. One tissue in which collagen is arranged in a parallel straight fiber arrangement is tendon, which consists primarily of collagen only. This produces a much stiffer and stronger material than soft tissues in which less collagen is present and is woven in a loose and random manner. The ultimate strength of tendon is about 60 MPa, while that of skin is about 15 MPa. Further, the strain at failure is at about 10% elongation of tendon and 110% for skin. The stress-strain for tendon is much closer to that of an elastic brittle material than the highly nonlinear form for skin (Fig. 2).

All of the above discussion and most reports in the literature of the properties of soft tissues are, of course, on excised specimens which no longer have their blood supply, innervation, or metabolism. It is clear that since a normal person does not change dimensions or elastic properties radically day to day, the normal body function restores properties to a hemostatic condition after most stresses below a point of tissue damage or trauma. This regenerative capacity is not represented in physical testing and it should be kept in mind in interpreting tests that there may be differences between excised specimens and the behavior tissue *in vivo*.

Another interesting aspect, closely related to the above, is the recently explored question of residual stress in soft tissues *in vivo* (Fung, 1984). For purposes of this discussion the residual stresses are defined as those remaining in a tissue or organ after removal from the body and placed in a state of no external loading. For example, if a section of artery or the entire heart is excised from an animal and placed in an open container of saline then essentially there is no pressure difference between the inside and outside surfaces so these tissues are said to be unloaded. However, there still may be some residual stresses present. This is most dramatically revealed in the case of the artery by cutting a small ring off the artery which remains circular as long as the ring is intact. But if the ring is cut through at one point, it opens out. The angle drawn between the cut ends and a point midway between them on the far side of the artery is called the opening angle. It may be anywhere from a negative angle (closing up) to over 180° (bending backwards) so that the curvature is actually reversed. The residual stresses implied by this experiment are probably functioning *in vivo* to produce a much more uniform stress distribution in the arterial wall than would occur if the wall were purely elastic with zero residual stress when unloaded (Fung, 1984).

It should also be appreciated that many tissues are normally under some stress *in vivo*. This may be partially residual stress but may also be the normal state with or without residual stress. For example, if a section of artery is excised, it shrinks in length by 10%–20%. This indicates that it is stretched and under stress longitudinally *in vivo* but this is not a residual stress. (The same is true of nerves.) In the circumferential direction, arteries are normally under tension due to the pressure which rarely if ever drops to zero. The circumferential stress due to pressure is in addition to the residual stress.

The human skin is under some tension *in vivo*. This, however, is not due to residual stress but is a result of the growth and metabolism of the skin itself. Scar tissue tends to shrink abnormally and produce locally high tensions. This is more of the nature of a local residual stress.

Lung tissue normally operates in a state of isotropic tension but this is in the nature of *in vivo* stress rather than a residual stress. The heart wall undergoes large fluctuations of stress due to the active contraction of the tissue. However, when excised and unloaded, a ring cut transversely from the ventricle shows residual stresses when the ring is cut open similar to that of the arterial wall. In any stress analysis, the *in vivo* and residual stress levels should be taken into account to have a realistic modeling of the stress distribution *in vivo*.

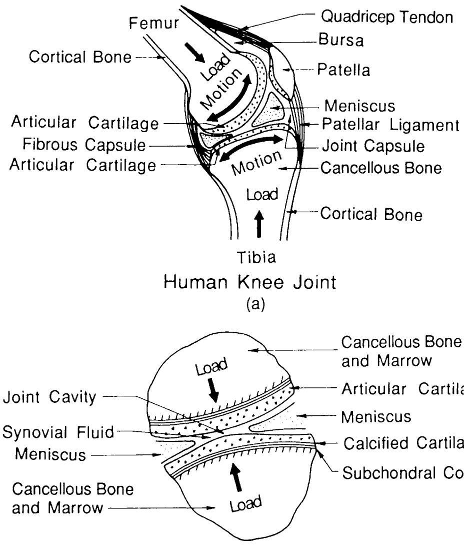
3. BIOMECHANICS OF JOINTS

3.1. Anatomy of Diarthroidal Joints

The skeletal joints which allow relative motion of the bones they connect are called diarthroidal or synovial joints. This includes the hip, knee, elbow, shoulder, ankle, wrist, and finger joints. In such joints the bones themselves are not in contact, but are covered at their contact ends by a thin layer of a special tissue, namely, articular cartilage. This is a fibrous, porous tissue which is usually between 0.5 and 2 mm in thickness. The cartilage is bathed in a special fluid called synovial fluid, and the joint is enclosed in a fibrous capsule which retains this fluid. The combination of cartilage and synovial fluid results in an extremely low coefficient of friction in joints, of the order of 0.05 to 0.003. This is much lower than is typically achieved in machine designs.

A schematic of the human knee joint anatomy is shown in Fig. 3. The contact surfaces are generally curved so that the contact area is much less than the cartilage surface area at a given position, and it changes as the joint moves. Tendons and ligaments connecting the two bones at a joint aid in its stabilization and give it a tensile strength. The capacity of the cartilage and synovial fluid to carry any tension is negligible. The meniscus of the knee is a softer tissue than cartilage and plays a role in stabilization of the knee movement.

Cartilage consists of about 25% solid material and 75% fluid. The principal solid phase is collagen fibers (65%) and proteoglycans (25%). The pores of this matrix are extremely fine, of the order of the 2–6.5 nm. For this reason the fluid in cartilage is not easily squeezed out. The cartilage is a porous medium but with quite low permeability. There are some living cells distributed in cartilage called chondrocytes. These cells can repair and reproduce cartilage, but do so at a very slow rate, and wear or damage to cartilage is often, in effect, irreparable.



Human Knee Joint

FIG. 3. (a) Schematic representation of the human knee joint, showing salient features which are important to its mechanical function. (b) Enlargement of the region of load bearing, showing the articular cartilage, calcified cartilage, subchondrial cortex, and cancellous bone. The calcified cartilage and subchondrial cortex function as a shell, providing backing to the articular cartilage, and are supported by cancellous bone. The cancellous bone–bone marrow system provides the shock-absorbing mechanism for the diarthroidal joint. (Adapted from Mow and Mak, 1987, by permission.)

Synovial fluid is a special clear fluid which is generated by a special tissue called the synovium. Synovial fluid is derived in part from blood plasma but with an important addition of hyaluronic acid protein added. This is a very large macromolecule which results in a non-Newtonian behavior of the synovial fluid. It is viscoelastic and exhibits shear thinning and a normal stress effect. Synovial fluid is important to the production of a low coefficient of friction in joints. If it is replaced by saline, the coefficient of friction may rise by several orders of magnitude. Further details and references can be found in the chapter by Mow and Mak (1987).

3.2 Mechanical Properties of Cartilage

The importance of cartilage to the performance of joints has led to extensive experimental and theoretical work concerning its properties and behavior. It is possible to cut disks or elongated tension specimens of the cartilage from the surfaces of large joints. Such specimens can be tested as if they consisted of a single, solid material. However, to have reproducible results, the tests need to be conducted while the sample is submerged in fluid. It is found that cartilage behaves macroscopically as a viscoelastic solid. In a simple tension test there is just one stress component, in the direction of tension, and one corresponding relaxation function. In this case, the Green's strain for the direction of extension is

$$E_{11}=\tfrac{1}{2}\,(\lambda_1^2-1), \tag{1}$$

where λ_1 is the stretch ratio, i.e., the final length divided by the initial length of the specimen. The Kirchhoff stress is

$$S_{11}=F/A\lambda_1, \tag{2}$$

where F is the tensile force, A is the initial cross-sectional area, and λ_1 is the extension ratio. By applying a sudden stretch and measuring the relaxation of force with time, the relaxation function for a cartilage specimen can be measured directly, as shown in Fig. 4.

In order to evaluate the possible exudation of fluid from cartilage under stress and the effect of fluid movement on the properties of

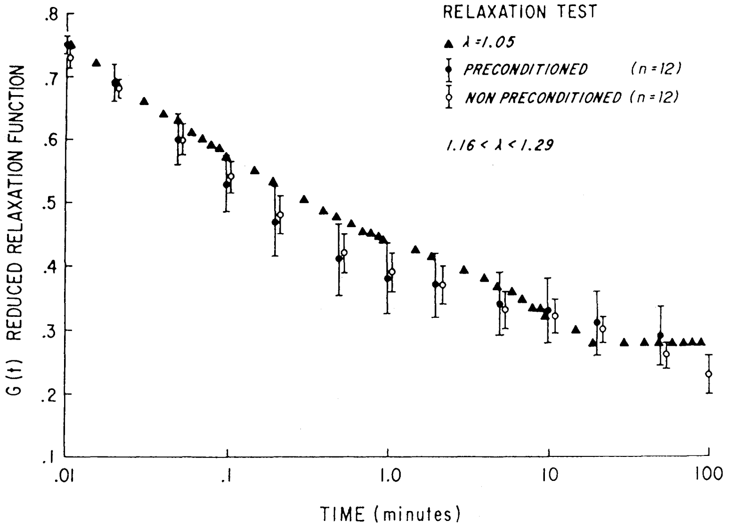

FIG. 4. The reduced relaxation function of articular cartilage at a lower stretch ($\lambda = 1.05$) and at higher stretches, $\lambda = 1.16$–1.29. Preconditioning refers to performing a number of cycles of stress and strain before a test, until the initial response is stabilized; *n* is the number of specimens tested. (From Woo *et al.*, 1979, by permission.)

cartilage it is necessary to establish experimentally the permeability of the cartilage as a porous matrix. The apparent permeability k_a of porous medium is defined by Darcy's law,

$$V = k_a \nabla p, \qquad (3)$$

where the V is the velocity of fluid flow computed as the discharge divided by the gross area, k_a is the apparent permeability, and ∇p is the spatial pressure gradient. An average value of permeability of cartilage is 0.58×10^{-15} m^4/N s (McCutchen, 1962). When sufficiently high pressure gradients are applied to cartilage, the pressure causing the flow may also cause appreciable compression of the solid structure of the cartilage, which then, in turn, modifies the permeability. Cartilage permeability may also be decreased by compression not associated with pressure, for example, by squeezing a specimen between porous plates. The two effects have been expressed in an empirical formula by Mow and Lai (1980),

$$k_a = A \exp(-\alpha \epsilon), \qquad (4)$$

where A is a parameter dependent on the pressure drop across the specimen, α is a second constant also dependent on pressure drop, and ϵ is the strain which is imposed on the cartilage in advance of testing the fluid flow through it; ϵ is called the clamping strain. The permeability decreases with increasing clamping strain and with increasing pressure drop.

For a complete treatment of the mechanics of cartilage a biphasic model is assumed (Mow and Lai, 1980). In this theory both the fluid and the solid matrix of the cartilage are assumed to be individually incompressible. The relative motion of the fluid and solid gives rise to a drag force on the fluid, which in turn is applied also to the solid with reverse sign. The constituent equation for the solid is assumed to be that of a viscoelastic material, and the fluid is taken to be a viscous incompressible fluid, but on a macroscopic basis, a stress associated with the change of volume per unit of cartilage volume is incorporated. The possibility of volume change arises from the possible relative motion of the solid and fluid. The biphasic theory has been applied to compression and relaxation tests and shown to reproduce the deformation and stress data quite accurately. Thus, the properties of cartilage are fairly well defined, but the mechanics of joint lubrication are not entirely clear because the roles played by various possible lubrication mechanisms are not definitively known.

3.3 Lubrication Mechanisms in Joints

Several different mechanisms of lubrication of joints have been proposed theoretically and demonstrated to some extent experimentally. It appears that no one mechanism is operative in all cases and that a variety of lubricating effects may take place under different conditions of movement and loading.

The mechanism of lubrication of the knee or hip joints may be quite different after a period of standing still as opposed to a repetitive sequence of steady running or walking. Various mechanisms of joint lubrication that have been proposed in the literature are outlined below and some of the experimental results are indicated.

A logical suggestion for the mechanism of joint lubrication is the kind of viscous hydrodynamic action which is achieved by the use of lubricating oil in machine bearings of either rotating or sliding type. This mechanism is known as hydrodynamic lubrication. This kind of lubrication requires the presence of a continuous film of fluid between the parts of the joint, which is tapered to some extent. It also requires a continuous relative sliding motion and a continuous supply of fluid. It is estimated that during level walking the fluid film thickness which would be required in the knee would be of the order of 10^{-3} mm. This is less than the surface roughness of the cartilage surface so hydrodynamic lubrication seems unlikely under these conditions. For faster motions it remains a possibility.

A second kind of mechanism is the direct sliding of one cartilage surface on the other. This is known as boundary lubrication. Among artificial surfaces, Teflon on Teflon is an example of fairly low boundary lubrication capacity. The frictional coefficient for Teflon-coated surfaces is of the order of 0.05–0.1. For cartilage it is suggested that there is a lubricating glycoprotein fraction (LGF) which provides a low boundary friction. This component is not the hyaluronic acid, but a single polypeptide chain of about 250 000 molecular weight. This molecule adheres strongly to the cartilage surface. It appears that *in vivo* after a long period of standing still some such boundary lubricating mechanism would be required.

Basically, the two mechanisms available for joint lubrication are boundary lubrication and hydrodynamic lubrication. However, the fact that cartilage is porous, elastic, and fluid filled leaves open some possibilities of exchange of fluid between the lubricating gap and the cartilage and also for a role for the deformability of the cartilage itself. Even in the case of materials which are not porous, such as rubber, there can be an effect of the deformability of the surface on lubrication phenomena. The pressures generated by hydrodynamic lubrication can deform a soft boundary such as a rubber sheet, which in turn influences the distribution of pressures and eventually the friction coefficient. This mechanism of deformation of the cartilage may also play a role in joint lubrication. A related idea is called weeping lubrication in which the normal load applied to a joint is assumed to compress the cartilage and thereby cause exudation of a fluid film which then can act as a lubricant. This is similar to a bearing which is pressure fed oil continuously. Another possible mechanism is called squeeze film lubrication. In its pure form, squeeze film lubrication occurs when two rigid surfaces with a viscous fluid between them are pressed together. A transient fluid motion ensues in which the viscous liquid is forced out of the space between the approaching rigid surfaces. This viscous flow can generate large pressures and reduce the normal velocity of the plates to very small values. A tangential force applied at the same time will then experience a very low friction coefficient. Nonlinear and viscoelastic fluids will have enhanced squeeze film lubrication. This mechanism may be operative when a person lands after jumping off some small height. During the sudden load, squeeze film action is likely.

Another suggestion is called boosted lubrication. In this mechanism it is suggested that as two cartilage surfaces approach each other, water is squeezed out from the contact region into the cartilage. This would leave a gel layer, which could support greater loads than the normal synovial fluid. A more complete discussion of these suggestions and references may be found in the chapter by Mow and Mak (1987).

In summary, there is no single mechanism of joint lubrication which is known to be operative in all conditions *in vivo*. Both boundary and hydrodynamic lubrication appear to be involved in different situations. The involvement of the flow through the porous media of the cartilage and its deformation may play roles that are not yet fully or accurately identified. A possibility of both exudation and absorption of lubricating fluid has been discussed by Lai and Mow (1979). A theoretical analysis of a porous indent sliding along a layer of cartilage shows that the approaching compression may force fluid out of the cartilage, and on passing a given area a fluid may be reabsorbed by the cartilage. This kind of action indicates some of the weeping-type action and some reabsorption. This has been termed a self-generating mechanism of joint lubrication.

4. MUSCLE MECHANICS AND PHYSICS OF BODY MOVEMENTS

Throughout the animal kingdom, almost all active force generation is provided by muscles whose basic capacity is to generate tensile force or contraction, rather than thrust or compression. Body movements are usually the result of muscle contraction coupled to skeletal elements or softer tissues via tendons. Many different geometric arrangements of muscle, tendons, and bones give the large variety of resultant motions that animals can perform. The entire system is under neural control, both for stimulation of muscle and for the return of sensory signals indicating position. Visual, balance, and touch information supplied to the brain serves to generate exquisite control in time and space.

Mammalian muscles are grouped into three types: skeletal muscle, heart muscle, and smooth muscle. Skeletal muscles are those that produce voluntary body motions. Heart muscle has some unique characteristics and is controlled by its own pacemaker. Smooth muscles are generally not under conscious control. They occur in the intestines, arteries, ureter, and many other organs. They are called smooth muscles because under the microscope, they appear to be homogenous, as opposed to skeletal muscles which show characteristic striations at the microscopic level (see Fig. 5).

4.1 Skeletal Muscle

The basic force-generating elements of all mammalian muscles are myosin and actin fibers whose interaction produces a sliding motion of these interdigitating filaments as shown in Fig. 5. Groups of actin-myosin fibers are organized into myofibrils with a very regular spacing along the length called the sarcomere length and a regular hexagonal pattern in cross section. Groups of muscle fibers form larger units called fascicles which have distinct connective tissue sheaths. A number of fascicles form a muscle (Fig. 5) which has a thicker sheath and is connected by tendons at each end to bones or other tissues.

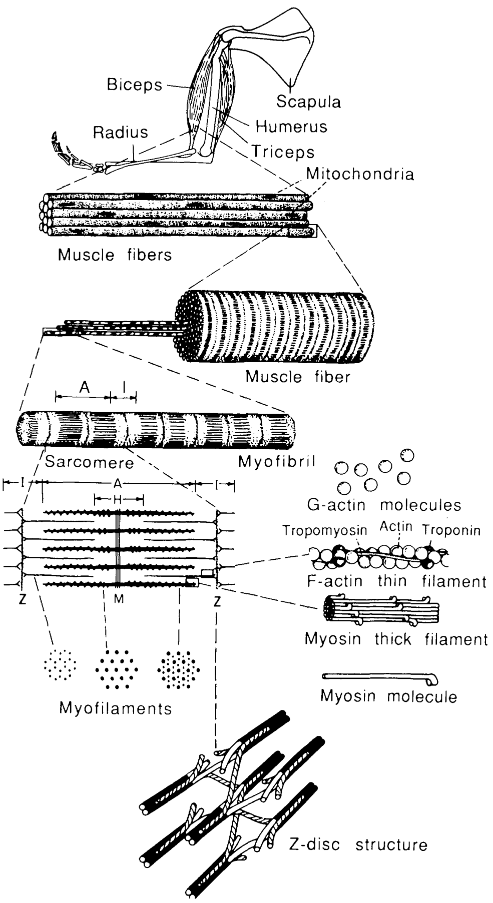

FIG. 5. Structure of skeletal muscle and arrangement of agonist (biceps) and antagonist (triceps) muscles of the arm. (Adapted from McMahon, 1984, by permission.)

There is an extensive literature on the anatomy, physiology, and biophysics of muscles (e.g., *Handbook of Physiology,* 1979, Sec. 10). The details of the interaction of myosin heads which rock back and forth to move along the actin filaments is still an area of active research. This is the level at which the consumption of biochemical energy in the form of ATP (adenosine triphosphate) takes place and is transduced to mechanical work and motion. The resulting macroscopic behavior has been described by various phenomenological theories, of which the most famous and most widely used is Hill's equation (1938). Improvements and more detailed models have made Hill's equation obsolete to a certain extent, but it captures some basic aspects of muscle behavior.

Hill's equation may be written as

$$(v+b)(T+a)=b(T_0+a), \tag{5}$$

where T is the tension force in the muscle, v is the velocity of contraction, and a and b are constants. This equation relates the velocity v to the tension T when the tension is suddenly reduced from an isometric, tetanized state, characterized by an initial length L_0 and tension T_0. The tetanized state means the frequency of electrical pulse stimulation is greater than a critical value (about 100 Hz), which produces the maximum tension at the fixed length L_0. The main effect contained in Hill's equation is that the velocity of contraction increases as the tension T decreases. The main physiological result is that the useful power generated tends to be approximately constant in the middle range of velocities. For more comprehensive theories, see the *Handbook of Physiology* (1979), Sec. 10; Fung (1981); and McMahon (1984).

4.2 Heart Muscle

Heart muscle has sarcomeres made up of actin and myosin filaments interdigitating as in skeletal muscle. The main differences between heart and skeletal muscle are in the organization of the fibers and in the manner in which they are excited and supplied with nutrients. The muscle fibers of the heart have more branching of their structures and capillaries and mitochondria are more abundant. The capillaries deliver oxygen and nutrients to the tissue which must be supplied continuously. The mitochondria are intracellular units which manufacture ATP, which is the molecule used as fuel in the actin-myosin contraction.

Another difference between heart and skeletal muscle is in the excitation control. Heart muscle is excited by a wave of electrical polarization which causes all fibers of the heart to contract nearly synchronously. In skeletal muscle, the response may be graded by having a limited number of fibers activated depending on the frequency and degree of stimulation.

The mechanical properties of a single heart muscle fiber in the activated state (during systole) is similar to skeletal muscle in that Hill's equation (10) is a good first approximation to its behavior. In the resting state, a significant difference is found. In the heart, for the resting state (during diastole) the remaining stress is appreciable and is important to appropriate refilling of the heart with blood. In skeletal muscle, the tension in the relaxed state is very small and the degree to which it may be extended by small tensions is larger than in the heart. Further details on stress-strain behavior of heart muscle may be found in Fung (1981).

The macroscopic arrangement of heart muscle fibers is also very different from skeletal muscle. In skeletal muscle usually all fibers of a muscle have more or less the same orientation in space to produce a contractile force in a particular direction. Heart muscle is wound in approximately helical layers around the chambers of the heart. Along a line normal to surface of the heart, the orientation of the muscle fibers varies continuously through the thickness of the heart wall by 90° to 120°. The anatomy of the heart muscle is extensively illustrated by Streeter (1979) and models incorporating this geometry are developed in Glass and Hunter (1990).

4.3 Smooth Muscle

Smooth muscles differ from skeletal and heart muscles in that the smooth muscles do not have the regular arrangement of actin and myosin which form the sarcomere striations. The contractile elements in smooth muscle are also actin and myosin, but these fibers are arranged in a more random manner. The actin filaments are attached to centers called dense bodies and form a network more or less aligned in the principal length direction of the fiber. The myosin filaments have a concentration in smooth muscle which is less than 10% of that in skeletal muscle. The contraction of smooth muscle is comparatively slow (1–3 s) but may maintain some contractile force continuously.

Two types of smooth muscle are distinguished as multi-unit smooth muscle and visceral smooth muscle. Multi-unit smooth muscle consists of fibers that act independently and are stimulated by the sympathetic nervous system. Multi-unit smooth muscles are found, for example, in arterial walls. Visceral smooth muscle fibers are more organized and form a network or connected sheets which contract as a unit. This type of smooth muscle is found in the intestinal walls, the ureters, uterus, bile ducts, and vas deferens. Visceral smooth muscles may undergo spontaneous rhythmic contractions with a period of the order of 1 min. Further details of smooth muscle properties may be found in the *Handbook of Physiology* (1980), Sec. 2, Vol. 2, and Fung (1981).

4.4 Coupling of Muscles and Skeleton

Muscles are generally connected to skeletal elements via tendons which are comprised of stiff fibers of collagen. Tendons insert directly into the bones and operate effectively only in tension. Thrusting and retracting movements are produced by having two sets of muscles and tendons operating on opposite sides of a joint which acts as a fulcrum. An example, the elbow, is shown in Fig. 5. The biceps muscle (agonist) acts to close the angle of the elbow; the triceps (antagonist) acts to straighten out the arm.

In most muscles, the tendon and muscle fibers have more or less parallel directions and the tendons are similar at the two ends [Fig. 6(a)]. However, other arrangements occur in which muscle fibers connect at distinct angles to the tendon. These pennate arrangements are illustrated in Fig. 6(b). A bipennate arrangement occurs inside the claw of the crab (Alexander, 1983).

The leverages and linkages of muscles, bones, and tendons in various animals are extensive and varied. A famous and remarkable early (1681) work "On the Movements of Animals" by G. A. Borrelli has recently been translated into English (Maquet, 1989). Modern works, which clarify and update much of the speculation of Borelli, are books by Alexander (1983) and McMahon (1984).

5. MECHANICS OF THE LUNG

The mechanics of the lung is a particularly interesting subject as it involves the flow of blood on one side and/or air on the other side of membranes only about 1 μm thick arranged in a complex and remarkably efficient manner. Several subtopics may be defined in the mechanics of the lung, each of which is an extensive subject. These may be broadly indicated as blood flow mechanics, air flow and diffusion, gas exchange, elasticity and surface tension, control of breathing, lymph flow, and oedema formation. For discussions of blood flow and air flow, the reader is referred to the article BIORHEOLOGY. The present article will cover some mechanical effects of elasticity and surface tension. Other topics may be found in the books by Fung (1984), West (1977), and Guyton (1986); in the *Handbook of Physiology* (1981), Sec. 4; and in the *Handbook of Bioengineering* (1987).

5.1 Structure of the Lung

Most of the volume of the lung is made of small terminal air sacs called alveoli which are polyhedral in shape and have one wall open, the mouth through which gases enter and leave, mostly by diffusion at this level. The dimensions of alveoli are about 150 μm and there are about 300 million of them in the human lung.

The walls of each alveolus may be described in an idealized manner as consisting of two parallel membranes connected by a regular array of posts. The blood flow takes place between the membranes and the air is on the outside. An increase in blood pressure can expand the space between membranes and reduce the resistance to blood flow (see Fung, 1984). An increase in the alveolar air pressure reduces the blood flow space, and if the alveolar air pressure exceeds that of the blood, the blood flow is cut off. This leads to a variety of interesting possibilities which will be discussed in the next section.

Each alveolus faces onto an air passageway or bronchiole which is in turn joined to a larger bronchial airway and so on until the main bronchus is reached. Alveoli are like expandable leaves on a tree whose twigs and branches are the hollow bronchi. The blood flow system has two more trees in it: one of arterial blood vessels and one of venous blood vessels which tend to run close to the arterial tree until the finest level supplying and draining the alveolar walls.

Lungs are divided into several lobes, each of which is something like a balloon filled with alveoli. The exterior of each lobe carries a thin pleural membrane which is separated from the chest wall by a very thin fluid layer. This allows the lobes of lung to slide relative to the chest wall.

5.2 Zones of the Lung

In a person in an upright position, gravity produces an appreciable pressure difference in blood pressure from the apex to the base of the lung. The variation in the air pressure throughout the lung is much less because of the much lower density of air. The result is that three different zones can be distinguished:

zone 1, $p_A > p_a > p_v$;
zone 2, $p_a > p_A > p_v$;
zone 3, $p_a > p_v > p_A$;

where p_a and p_v stand for the arterial and venous blood pressures and p_A is the alveolar air pressure. In zone 1, which may occur at the apex of the lung, the blood flow is cut off. In zone 3, the capillary bed of the alveolar walls will be fully open to blood flow. In zone 2, there will be some blood flow, but there will be a narrowing of the blood vessels. In this condition it is found that the flow is independent of venous pressure, but depends only on the difference $p_a - p_A$. This condition is sometimes likened to a waterfall because the flow over a waterfall depends only on the level of the water upstream (arterial pressure) and the height of the lip (alveolar air pressure) but not on the tailwater elevation to which it falls (venous pressure).

5.3 Elasticity and Surface Tension in the Lung

The alveolar walls of the lung, together with the airways, blood vessels, and connecting septa, form a continuous three-dimensional structure somewhat like a foam. Also like a foam, each alveolar wall is normally under some tension. The lung is in fact inflated like a balloon. But since the air pressure in the lung is, on the average, only equal to atmospheric pressure, the inflation pressure difference required from inside to outside must be provided by having the pleural space (thin fluid layer) around the lung at subatmospheric pressure. Remarkably, this is provided by nature by appropriate osmotic and lymph flow effects. This negative pressure is of the order of 6 cm H_2O below atmospheric pressure.

The elastic recoil of the lung is due in part to the stretching of the alveolar walls, but an even larger part of the elasticity observed is attributable to surface tension. The interface between the solid tissue of the alveolar wall and the air in an alveolus is coated with a thin layer of fluid containing a surfactant manufactured by the cells of the lung. This surfactant reduces the surface tension to a level of about 5–40 dyn/cm, well below that of an air-water interface (70 dyn/cm). This reduction of surface tension reduces the work of breathing and makes the lung less susceptible to collapse of alveoli by surface tension. Alveoli do not collapse by emptying one alveolus into the other because the surface tension and alveolar air pressure act on both sides of each alveolar membrane. The free edges of the mouths of the alveoli are kept from collapsing by a ring of elastic fibers which circle each opening and are connected to nets of similar connective tissue fibers in the alveolar walls.

6. COCHLEAR AND VESTIBULAR MECHANICS

The inner ear contains two systems which transduce mechanical events into neural signals. The cochlear apparatus (Fig. 7) responds to sound waves impinging on the ear drum while the vestibular apparatus senses linear acceleration, angular motion, and orientation with respect to the direction of gravity. Each of these systems has complex mechanical responses which aid in coding the neural signals sent to the brain.

6.1 Structure of the Inner Ear

In humans, the pressure fluctuations of sound reaching the ear drum set the small bones of the middle ear [malleus, incus and stapes (Fig. 7)] into vibration which in turn generates a mechanical wave motion through the spiral of the cochlea. Frequency discrimination is established primarily in the cochlea. The extreme range of human hearing is about 20 Hz to 20 kHz. Certain animals such as the elephant can respond to lower frequencies which propagate well through a jungle. Some species, such as bats, whales, and dolphins, which use echo ranging for prey and obstacle detection, regularly use frequencies in the range of 100–200 kHz.

The main components of the vestibular system are the semicircular canals, which sense angular motion, and the utricle and saccule, which sense linear acceleration and gravity. The three rings of the circular canals are at right angles to each other which allows for three-dimensional sensing. While these structures are located in the inner ear in close proximity to the cochlea, they are mechanically distinct and transduce neural signals to separate sets of nerve fibers.

6.2 Frequency Discrimination

Acoustic signals are transduced in the cochlea by so-called hair cells attached to the basilar membrane which runs the length of the spiral of the cochlea. The basilar membrane tapers along the spiral channel and its amplitude of vibration varies along its length, depending on the frequency of excitation (see ACOUSTICS, PHYSIOLOGICAL). On both sides of the basilar membrane there is a fluid-filled space and the motion of this tapered membrane-fluid system has been extensively analyzed (see Steele, 1987). The fluid motion bends the fine "hairs," thus stretching the cell membrane and initiating the mechanoelectrical transduction. There is also a contribution to the tuning (localization of frequency response) by an active process which utilizes electrical potential differences to amplify selected frequencies.

The details of the structure of the inner ear vary greatly in different animal species. In bats, whales, and dolphins, who use very high (100–200 kHz) echo-ranging signals, the cochlea is a heavier, bony structure with very stiff elements throughout. In lizards, snakes, and turtles, the cochlea has a simpler structure, but the tuning due to the transducing cells (hair cells) is still present to a large extent. The mechanism of this tuning is a subject of continuing current research.

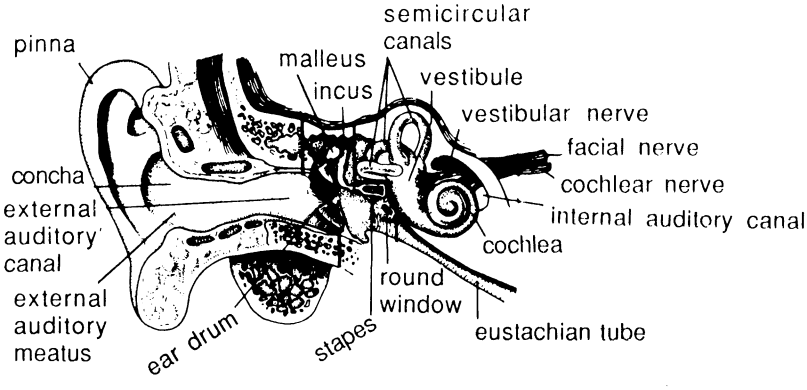

FIG. 7. Cross section of human ear showing outer, middle, and inner ear. (Adapted from Yost and Nielson, 1977, by permission.)

6.3 Vestibular System Mechanics

The three semicircular canals of the inner ear each have an enlarged portion called the ampulla which contains a gelatinous partition called the cupula. Mechanical deformation of the cupula is transduced by neural cells into electrical signals which are sent via axons to the brain. During angular acceleration, the fluid (endolymph) lags behind the motion of the bony walls which results in a relative motion of the fluid and its bony housing. This relative motion produces deformation of the cupula which is then transduced to neural impulses (see AEROSPACE MEDICAL PHYSICS). The fluid mechanics and frequency response of this system are discussed by Van Buskirk and Grant (1987). They also developed a theory for the otolith organs, which are linear acceleration sensors. These units contain a thin layer of calcium carbonate crystals (otoconial membrane) which rests on a soft gelatinous membrane (cupular membrane). The calcium carbonate crystals have a specific gravity of 2.71 and their inertia causes a shear deformation of the cupular membrane during linear acceleration parallel to the membrane plane. Two such units (the utricular and saccular maculae) in different planes allow sensing of linear acceleration in any direction. These deformations of the cupula membranes are transduced to neural impulses by cellular structures of the nerve endings.

7. SWIMMING AND FLYING

Observations and theories of swimming and flying of fish, birds, and insects have become analytical and quantitative only in the last 30 to 40 years. The aerodynamic theories and fluid mechanics developed to design airplanes and ships had little impact on the theory of biological counterparts until about 1950. Since then, many papers and books have reflected considerable progress (see Lighthill, 1975; Pedley, 1977; Alexander, 1983).

Different mechanisms of swimming naturally divide according to the type of motion involved and the size of the animal, or more accurately the Reynolds number range in which the motion takes place. The usual Reynolds number, R, used is

$$R = UL/\nu, \tag{6}$$

where U and L are the velocity and characteristic length of the animal, and ν is the kinematic viscosity of the external fluid (usually air or water). Because of their small size, the Reynolds numbers of sperm and microorganisms are generally in the range of 10^{-3}. In this range all inertial effects are negligible and analyses of swimming modes are problems in viscous flow (Stokes flow). Birds and fish generally operate at much higher Reynolds numbers (10^2–10^6). Here inertial effects are important and, in fact, usually essential, as in the production of lift by a wing. Some of the corresponding theories for low and high Reynolds numbers and various types of propulsion (cilia, flagellate, undulatory, flapping, clapping) are outlined in the following sections. A pictorial summary of swimming modes from Lighthill (1975) is shown in Fig. 8.

7.1 Swimming of Microorganisms

Some protozoa and sperm cells swim by creating an undulatory motion of a long thin tail or flagellum. A two-dimensional theory of such motion at low Reynolds number was first developed by Taylor (1952). Later theories (e.g., Blake, 1974) treat the three-dimensional flow field by considering the flagellum to be replaced by a distribution of stokeslets (point forces). Flagella produce propulsion by actively propagating waves of lateral (or rotatory) displacement rearwards along their length. The resistive viscous (stokeslet) force developed has a useful, propulsive component in the direction of motion.

Another type of microorganism motion utilizes a large number of cilia, which are like fine, short hairs covering a surface. Cilia beat in a rhythmic, coordinated fashion so that waves of displacements are propagated rearwards as envelopes of the outer tips of the cilia. Models of such motions are also based on use of stokeslet distributions, but in this case, taking the boundary into account by the use of appropriate images in the boundary surface (Blake, 1974). Ciliary propulsion is limited to small organisms because it is comparatively slow and because the structural requirements for a large cilium would be severe. By contrast, undulatory propulsion can be effective over the full range of Reynolds

numbers, although the source of propulsive force changes from viscous to inertial as Reynolds numbers increase.

7.2 Modes of Swimming of Fish

The range of Reynolds numbers for a small fish swimming slowly to a blue whale at top speed may vary from 10^3 to 10^9. The propulsive mechanisms in this range are various, but all depend on unsteady inertial forces. Viscous effects are limited to a thin boundary layer which produces the predominant component of drag. The drag is overcome by propulsive forces which may be computed by inviscid flow theory.

For long thin fish, like the eel, the common form of propulsion is by creation of an undulatory wave which is propagated rearward along the length of the body. This is called anguilliform propulsion. The amplitude of the motion typically increases rearward and the tail makes much wider lateral excursions than the head. Lighthill (1975) gives a qualitative explanation of the propulsive force generated based on the relation

$$w = W(V-U)/V, \tag{7}$$

where U is the mean forward velocity of the fish, V is the velocity of propagation of the wave rearward, W is the lateral velocity of the fish, and w is the effective transverse velocity of the tail. The thrust arises due to the inertial reaction of the water being set in motion primarily as a two-dimensional flow in planes normal to the undulating axis. U is typically about $0.6V$, for efficient forward propulsion. The lateral momentum of the fluid generated when the tail passes a given point is proportional to w and the force reaction on the fish is equal to the rate of change of momentum proportional to Uw. The rate of work done is then proportional to UwW. Part of this work goes into vortex wake production and is lost in the fluid. The remainder is useful work of propulsion (which is also lost to the fluid through viscous drag).

Anguilliform propulsion does not require that the entire length of the fish participates in the lateral undulatory motion, but does require that the amplitude increase to a maximum value at the tail. In many fish, the lateral undulatory motion is restricted to the latter half or third of the fish's length. This is called the carangiform mode of propulsion. The effective part of the fish in producing force is then the tail which may be extended (vertically) and shortened (lengthwise) for efficiency. However, the basic rearward propagating wave motion is preserved even if the undulating region is less than a full wavelength. For high speed and efficiency, the ultimate form of the tail of a fish evolves to a crescent moon shape called the lunate tail typical of sharks, marlin, and tuna. Aquatic mammals such as dolphins, whales, and mermaids also have lunate tails, but these are flukes in the horizontal plane which undergo undulatory motion vertically. A lunate tail generates a vortex at each point that it reverses its transverse velocity, W. This leaves a Kármán vortex street in the fluid behind the fish which represents lost energy, but is necessary to produce forward thrust.

There are a variety of other mechanisms for swimming which are used by smaller classes of fish. Some so-called armored fish, like the sea horse, swim by dorsal and pectoral fin motions. Jellyfish and squid use an intermittent jet propulsion. Rays and skates use a large horizontal area with a flapping motion resembling the flight of a bird. Sea turtles have limbs grown into flippers which also swim by flapping like a bird's wings.

7.3 Flight of Birds

Most birds fly by a flapping motion of their wings which produces both lift and forward thrust. The up and down strokes are not symmetric either in time or in inclination of the wings. The down stroke is longer and takes place with the plane of wing more nearly horizontal. The combined downward motion of the wing and forward motion of the bird gives lift and some thrust. During the upward stroke, the wing is also tilted upwards and typically the wing tip is drawn in and back relative to the body. Both lift and thrust are smaller in the upstroke. Many birds are able to separate the primary feathers of their wing tips during the downstroke which enhances lift as in leading-edge slots of high-lift airplane wings. The tails of most birds are used primarily for control, but may also be used for braking on landing and for more efficient soaring. Most soaring birds glide at a low angle within a rising column or bubble of thermal currents. During soaring, no active lift is generated, but altitude may be gained or maintained by the upward motion of the air.

Hovering flight of the humming bird may be regarded as an adaptation of flapping forward flight in which the motion of the wings is more or less in a horizontal plane. The body of the bird is nearly vertical to allow the movement to and fro in a horizontal plane, and the wings are rotated rapidly at the end of each stroke so that the same edge is leading and the angle of attack is positive during both forward and backward strokes. Many larger birds which do not hover because the power requirements would be excessive nevertheless use a more nearly hovering mode during

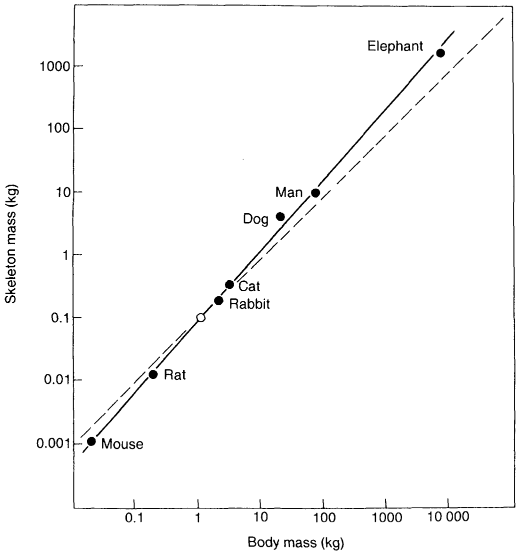

FIG. 9. Log-log plot of mass of mammalian skeletons vs body mass. The solid regression line has a slope of 1.13. The dashed line has a slope of 1.0. (From Schmidt-Nielsen, 1977, by permission.)

landing and briefly at steep takeoff. The wings beat more nearly horizontally and twist to maintain lift.

7.4 Modes of Insect Flight

Insect flight preceded that of birds in an evolutionary sense, dating back 3×10^8 years whereas birds evolved about 1.6×10^8 years ago. Evolution of flight mechanisms is summarized by Lighthill (1975) and studied in detail by Smart and Hughes (1972).

Many insects use a flapping motion for forward flight that resembles that described above for birds. The wings are rotated to maintain a positive angle of attack during both down and up strokes. Insects hovering may use a wing motion similar to that of humming birds, but other systems have also evolved. The dragon fly uses a complex coordinated motion of four wings. Another remarkable system involves clapping; the wings are brought together at the end of each cycle. This is the clap. The wings then separate by rotation about a line along the common trailing edge, like opening a closed book. Air sucked into the space between the unfolding wings generates a circulation and hence lift on the rest of the downstroke. This motion was first analyzed by Weis-Fogh (1973) studying the hovering of a small wasp. It is fundamentally different from other motions producing lift described above.

8. SCALING AND LIMITATIONS IN BIOMECHANICS

Although the size of animals measured in terms of total body mass ranges from approximately 10^{-16} kg for some bacteria to 10^5 kg for a whale, the range of size of a particular kind of animal is limited by constraints of material strength, energy generation capabilities, and physical laws, including geometric factors strongly. Moreover, within broad categories of animals, parameters such as metabolic rates and top speed vary in systematic ways with size and for discernible reasons (see McMahon and Bonner, 1983). Scaling laws are extensively discussed in the Symposium volume edited by Pedley (1977) and the book by McMahon (1984). Some of the salient results are outlined below.

8.1 Size and Power Limitations

One of the apparently simplest scalings is the estimation of skeletal dimensions versus body weight. But the realities are not so simple as the theory and illustrate the kind of pitfalls possible. If different sized animals were simply scaled up equally in all dimensions, the mass of the skeleton M_s would be a constant fraction of the total body mass M_0. But, in fact, a larger fraction of the body mass is occupied by skeleton in larger animals. This is a consequence of the fact that the strength of bone per unit area is approximately constant in all mammals. Then to support an increased mass, the cross-sectional area A of supporting bones should be in proportion to total mass M_0. The length of any bone L is roughly proportional to ${M_0}^{1/3}$. Hence the skeletal mass should be proportional to ${M_0}^{1.33}$. But the reality is (Schmidt-Nielsen, 1977) (see Fig. 9)

$$M_s=0.1{M_0}^{1.13}. \tag{8}$$

This shows that static load of total mass is not the controlling factor. Impact loading controls, and even then the accelerations that different animals invoke vary greatly. As Schmidt-Nielsen (1977) remarks, if an elephant were to jump like a mouse, he might break his bones on take-off and totally collapse on impact. Nevertheless, the strength of bone limits the total size (mass) of terrestrial animals by virtue of the strength of bone being relatively a constant. The heaviest terrestrial animal was the dinosaur baluchitherium weighing about 30 tons. If evolution had developed stronger materials than bone and higher power capabilities per unit weight than muscle, then much bigger, faster, and more powerful mobile entities could evolve. The huge open-mine steam shovels, ocean liners, nuclear submarines, jet planes, and spacecraft are existing examples, although they are not yet self-reproducing.

The limitations of power generation spring from two sources. One is metabolic rate which is a measure of power-generating capacity. The other is muscle properties; most muscles have similar maximum stress and maximum strain-rate capabilities.

Resting or basic metabolism rates in warm-blooded animals appear to be a function of heat loss to surroundings. Hence, basic metabolism w_0 (in watts) might be expected to vary in proportion to surface area, which in turn varies approximately as $M_0^{2/3}$. But data from many animals show that

$$w_0 = KM_0^{0.75}, \qquad (9)$$

where K is a constant. The difference between $\frac{2}{3}$ and 0.75 has been attributed to the fact that animals are not strictly geometrically similar (McMahon, 1973).

8.2 Scaling in Terrestrial Locomotion

In higher vertebrates the maximum stress that muscle can develop is about 300–400 kN m^{-2}, independent of the size of the animal. The maximum strain (shortening) is about 0.3, also relatively constant. Hence the work performed per contraction per unit volume of muscle is relatively constant independent of body size. By contrast, the frequency of contraction generally increases with decreasing body size so that the power (watts) delivered by a unit volume of muscle is higher in small animals and their peak metabolism is greater per unit volume. Incidentally, the volume of a muscle is very nearly constant during any contraction.

Data on various four-legged animals show that the metabolic cost (as measured by O_2 consumption) of moving a unit mass of the animal a unit distance increases dramatically as the size of the animal decreases. This specific metabolic cost varies as $M_0^{-0.4}$. An interesting aspect of muscle behavior is that metabolic energy is consumed both when muscles perform positive work and when they perform negative work, as in braking an impact. In level running, there is no change in kinetic energy, potential energy, or elastic strain energy over a complete stride. But metabolic work is done in accelerating and decelerating limbs relative to the body. Energy is also consumed in the imperfect elasticity of the system. In running, the body bounces like a mass on a spring, but the legs are imperfect springs and energy is lost in each rebound.

The quantitative relations of maximum speed and power consumption as a function of size are complicated by variations of geometry, skeletal mass, stride frequency, and gait. A theory based on geometric similarity and the muscle properties mentioned above was given by Hill (1950). The maximum running speed was found to be independent of size and the metabolic power at top speed varied as $M_0^{2/3}$. Within certain limits, these predictions are approximately correct. A greyhound and a horse have nearly the same top speed, around 18 m/s, but extrapolations to larger and much smaller animals fails.

A more elaborate analysis has been given by McMahon (1984) based on elastic similarity. The basic idea of elastic similarity is that the elastic deflection of a structure under its own weight should be proportional to its length. This leads to a law of transverse dimensions (say diameter d) being proportional to $L^{3/2}$. This in turn leads to realistic predictions of the variations of galloping frequencies, rise of center of mass during a stride, joint angle excursions, and power consumption. However, a coherent theory for prediction of top speeds for the full range of existing animal sizes is not yet assured.

8.3 Scaling in Aquatic Locomotion

The main determinant of similarity of fluid motion in swimming is the Reynolds number, Eq. (11). At low Reynolds numbers the flagellate type of swimming has been analyzed by Lighthill (1975) to show that there is a maximum efficiency which is achieved when the ratio of forward speed U to the rearward wave speed V is about 0.3. The peak efficiency, however, is low, around 0.1. In all flagellate microorganisms the cross section and molecular structure is similar. Since the propulsive power per unit length is then more or less constant, the swimming velocity U is relatively constant, independent of total length.

In high–Reynolds-number fish swimming, the maximum speed increases with length or size of the fish because of the nature of the drag and power available. The drag D is proportional to $\frac{1}{2}\rho U^2$ times surface area, A, and a drag coefficient, C_D. The metabolic power available is increased with body mass M_0 to some power b between about 0.8 and 1.0. Assuming M_0 is proportional to L^3 and surface area S is proportional to L^2, where L is the length of the fish, equating P to UD yields

$$U = kL^{\beta}, \qquad (10)$$

where k is a constant and β varies from about 0.11 to 0.60 depending on the variation of the drag coefficient C_D with Reynolds number. Wu (1977) shows that Eq. (10) can be fitted to a variety of sizes of fish under maximum or lower states of effort. In all cases, the speed of swimming increases with size.

One consequence of the above scaling law is that the specific energy cost S (energy expended per unit of mass moved a unit distance) decreases with size. The theory and data show that (Wu, 1977)

$$S = S_0 M_0^{-\gamma} \tag{11}$$

where S_0 is a constant and γ varies from 0.11 to 0.34 for different cases.

Another aspect of scaling concerns the frequency ω (rad/s) of beating of the tail motion. In carangiform propulsion, Bainbridge (1958) states that the reduced frequency ($\omega L/U$) is approximately constant and equal to 10 independent of length L. Wu (1977) interprets this as an implication that the hydrodynamical efficiency is independent of size. Due to the variation of U with L, ω itself is proportional to $L^{-\alpha}$, where α is of the order of 0.88. The beat frequency of birds' wings also decreases as size increases.

8.4 Scaling in Flight

Scaling in flight mechanisms is more complex than in swimming because in addition to propulsion to overcome drag, a lift must be provided simultaneously. The scaling of lift and power limits the maximum wing span of birds. Either more power or strength of structure per unit weight would allow larger birds.

The fact that large birds fly faster than small ones may be understood in terms of wing loading w defined as total weight gM_0 divided by wing area S. S increases proportionately to $M_0^{2/3}$ so wing loading w increases as $M_0^{1/3}$. To maintain higher wing loadings, higher speeds are required to operate at the best lift/drag ratio. The trend (of scattered data for many birds) is that the flight speed U varies as $M_0^{1/6}$.

The mass of the pectoralis major muscle of birds is about 15% of total body mass M_0. This enters into considerations of power and maximum size of birds. Available power is proportional to muscle mass times contraction (flapping) frequency. As the wing span of a bird increases, the relative wing mass increases since the wings act as cantilever beams for which the stress increases rapidly with span; in fact, to keep peak bending stress constant, wings must thicken and total mass rises more quickly than available power which suffers as size increases because larger size means lower flapping frequency. Tucker (1977) estimates all these factors in a quantitative formula and concludes that a wing span of about 15 m is a realistic upper limit. For flapping flight, the maximum climb angle goes down with increasing wing span until it becomes completely impractical.

8.5 Scaling in the Cardiovascular and Respiratory Systems

The mean arterial blood pressure of mammals from the size of a mouse to a horse is very nearly the same. Further, the muscle stress during contraction is also relatively constant. It follows that hearts of different sizes are more or less geometrically similar. Measurements of many animals show that the volumes associated with the heart and lungs vary directly with the total body mass. West (1977) has also shown that alveolar surface area varies directly with body mass.

The heart rate of small animals is much faster than for large ones. This may be understood in terms of the metabolic rate variation given in Eq. (9) and the linear variation of heart size with body mass M_0. The stroke volume (blood volume ejected per stroke) is proportional to heart size and hence to M_0. The mean blood flow required is proportional to metabolic rate and hence to $M_0^{0.75}$. Hence the heart rate (beats per minute) must vary as $M_0^{-0.25}$. Measurements on various animals confirm this prediction. For similar reasons, the respiratory frequency (breathing cycles per minute) also varies as $M_0^{-0.25}$ (see McMahon, 1984).

The variation of heart rate with body size has another interesting result concerning wave propagation in the arterial system. The speed of a pressure wave in an artery is given approximately by the Korteweg-Moens formula

$$C = (Eh/2\rho R)^{1/2}, \tag{12}$$

where E and h are the Young's modulus and thickness of the arterial wall, R is the artery radius, and ρ is the density of the blood. It is found that C is relatively constant at about 4 m/s in mammals. The increasing heart rate with decreasing body size indicated above results in a constant ratio of wavelength of pressure waves at the fundamental heart rate to the length of the main arteries. The mean distance from the heart to capillaries is approximately 1/4 of a wavelength in all animals. This is a favorable value from the standpoint of the mechanical impedance that the arterial system presents to the heart (McMahon, 1984).

Another interesting aspect of heart rate concerns life span. In terrestrial mammals, life span has been shown to vary approximately as $M_0^{0.25}$. The variation of heart rate as $M_0^{-0.25}$ then results in the conclusion that all mammals live for the same total number of heart beats per lifetime. No particular reason for this result is known.

In conclusion, it may be said that scaling laws have some validity and many broad trends of size variations follow roughly their predictions. But individual variations of form and functional adaptation make scaling only an approximate guide in specific cases.

GLOSSARY

Actin: A type of fiber found in most cells; a principal component in muscle.

Alveolus: The smallest subdivision in a lung; a small air sac.

Anguilliform Propulsion: The mode of swimming by causing a lateral wave motion, like an eel.

ATP: adenosine triphosphate.

Carangiform Propulsion: A mode of swimming in which only the tail and hinder part of the fish is oscillated.

Chondrocytes: Cells which produce cartilage.

Cochlea: The spiral apparatus in the inner ear which transduces sound to neural impulses.

Collagen: A fibrous material found in tendons and many other connective tissues.

Cortical Bone: The part of a bone that is more dense and usually at the surface.

Diarthroidal Joints: Flexible joints such as the elbow or knee.

Diastole: The portion of the heart cycle during which the heart muscle is relaxed.

Elastic Similarity: The proportions which arise if the elastic deflection of a structure is a constant fraction of its size.

Fascicles: Subdivisions of a muscle.

Flagella: Long thin structures of microorganisms that are actively oscillated to produce propulsion.

Hydroxyapatite: A hard, brittle component of bone.

Lunate: Shaped like a crescent moon.

Myosin: A fiber that produces contractile force in muscle by its interaction with actin.

Pectoralis Major: The main muscle used by birds on the downstroke of wing flapping.

Pennate: A shape of a muscle resembling a pennant.

Pleural Space: A very thin, fluid layer surrounding the lung.

Sarcomere: A microscopic unit of sliding filaments of a muscle.

Smooth Muscles: Muscles which have a homogeneous microscopic appearance and contract slowly.

Squeeze Film: Lubrication that derives from squeezing out a fluid from between two surfaces.

Synovial Fluid: The lubricating fluid found in joints.

Systole: The portion of the heart cycle during which the heart is actively contracting.

Tetanized: The state of a muscle stimulated to its maximum contraction.

Trabecular Bone: A porous form of bone composed of a network of bony struts and plates.

Vestibular System: The semicircular canals and organs which provide rotational sense and balance.
